1. Evaluate nature of patient's pain, its location and intensity using pain rating scale. 2. Avoid activities that aggravate or worsen pain. 3. Because pain is usually related to bone metastasis, ensure that patient's bed has a bed board on a firm mattress. Also, protect the patient from falls/injuries. 4. Provide support for affected extremities. 5. Prepare patient for radiation therapy if prescribed.	1. Determining nature and causes of pain and its intensity helps to select proper pain-relief modality and provide baseline for later comparison. 2. Bumping the bed is an example of an action that can intensify the patient's pain. 3. This will provide added support and is more comfortable. Protecting the patient from injury protects him from additional pain. 4. More support, coupled with reduced movement of the part, helps in pain control. 5. Radiation therapy may be effective in controlling pain.	<ul style="list-style-type: none"> • Reports relief of pain • Expects exacerbations, reports their quality and intensity, and obtains relief • Uses pain relief strategies appropriately and effectively • Identifies strategies to avoid complications of analgesic use (eg, constipation)

Continued

CHART
49-3

PLAN OF NURSING CARE
The Patient With Prostate Cancer (Continued)

Nursing Interventions	Rationale	Expected Outcomes
6. Administer analgesics or opioids at regularly scheduled intervals as prescribed. 7. Initiate bowel program to prevent constipation.	6. Analgesics alter perception of pain and provide comfort. Regularly scheduled analgesics around the clock rather than PRN provide more consistent pain relief. 7. Opioid analgesics and inactivity contribute to constipation.	

NURSING DIAGNOSIS: Impaired physical mobility and activity intolerance related to tissue hypoxia, malnutrition, and exhaustion and to spinal cord or nerve compression from metastases
GOAL: Improved physical mobility

Nursing Interventions	Rationale	Expected Outcomes
1. Assess for factors causing limited mobility (eg, pain, hypercalcemia, limited exercise tolerance). 2. Provide pain relief by administering prescribed medications. 3. Encourage use of assistive devices: cane, walker. 4. Involve significant others in helping patient with range-of-motion exercises, positioning, and walking. 5. Provide positive reinforcement for achievement of small gains. 6. Assess nutritional status.	1. This information offers clues to the cause; if possible, cause is treated. 2. Analgesics/opioids allow the patient to increase his activity more comfortably. 3. Support may offer the security needed to become mobile. 4. Assistance from partner or others encourages patient to repeat activities and achieve goals. 5. Encouragement stimulates improvement of performance. 6. See Nursing Diagnosis: Imbalanced nutrition: less than body requirements.	<ul style="list-style-type: none"> • Achieves improved physical mobility • Relates that short-term goals are encouraging him because they are attainable

COLLABORATIVE PROBLEMS: Hemorrhage, infection, bladder neck obstruction
GOAL: Absence of complications

Nursing Interventions	Rationale	Expected Outcomes
1. Alert the patient to changes that may occur (after discharge) and that need to be reported: <ol style="list-style-type: none"> a. Continued bloody urine; passing blood clots. b. Pain; burning around the catheter. c. Frequency of urination. d. Diminished urinary output. e. Increasing loss of bladder control. 	1. Certain changes signal beginning complications, which call for nursing and medical interventions. <ol style="list-style-type: none"> a. Hematuria with or without blood clot formation may occur postoperatively. b. Indwelling urinary catheters may be a source of infections. c. Urinary frequency may be caused by urinary tract infections or by bladder neck obstruction, resulting in incomplete voiding. d. Bladder neck obstruction decreases the amount of urine that is voided. e. Urinary incontinence may be a result of urinary retention. 	<ul style="list-style-type: none"> • Experiences no bleeding or passage of blood clots • Reports no pain around the catheter • Experiences normal frequency of urination • Reports normal urinary output • Maintains bladder control

blood vessels. Laparoscopic radical prostatectomy and robotic-assisted laparoscopic radical prostatectomy have become the standard surgical approaches for localized cancer of the prostate. Although sexual impotence is a common side effect, these laparoscopic radical prostatectomy approaches result in low morbidity and more favorable postoperative outcomes, including improved quality of life and less sexual dysfunction if the nerves are spared. (Surgical approaches are discussed in detail later in this chapter.)

Radiation Therapy

Two major forms of radiation therapy are used to treat cancer of the prostate: teletherapy (external) and brachytherapy (internal). Teletherapy (external beam radiation therapy [EBRT]) may be given for 5 days per week for 7 to 8 weeks. It is a treatment option for patients with low-risk prostate cancer; progression-free survival is similar to that of low-risk patients treated with radical prostatectomy.

Patients with intermediate-risk and high-risk cancers receive higher doses of EBRT and may be candidates for both pelvic lymph node irradiation and androgen deprivation therapy (NCCN, 2008). Intensity modulated radiation therapy (IMRT) is one method of delivery of EBRT. IMRT sets a dose for the target volume and restricts the dose to surrounding tissue. A new approach to delivery of radiation uses a computer-controlled robotic arm to deliver a course of radiotherapy (ie, stereotactic radiosurgery) to localized prostate cancer. This method, referred to as the CyberKnife, is being evaluated in clinical trials and compared with other methods of delivering radiation to treat prostate cancer.

Brachytherapy (internal implants) involves the implantation of interstitial radioactive seeds under anesthesia. It has become a commonly used monotherapy treatment option for early, clinically organ-confined prostate cancer. The surgeon uses ultrasound guidance to place 80 to 100 seeds (depending on the prostate volume), and the patient returns home after the procedure. Exposure of others to radiation is minimal, but the patient should avoid close contact with pregnant women and infants for up to 2 months. Radiation safety guidelines include straining urine for seeds and using a condom during sexual intercourse for 2 weeks after implantation to catch any seeds that pass through the urethra. This approach can be completed in one day, with little lost time from normal activities. Brachytherapy may be combined with EBRT with or without neoadjuvant androgen deprivation therapy for patients considered at intermediate risk. High-risk patients are considered poor candidates for permanent brachytherapy (NCCN, 2008).

Although cure rates with radiation are comparable to those of radical prostatectomy, radiation therapy possesses its own unique set of side effects, which differ depending on the method of radiation administration. Patients receiving EBRT or brachytherapy may experience inflammation of the rectum, bowel, and bladder (proctitis, enteritis, and cystitis) because of the proximity of these structures to the prostate and the radiation doses. Inflammation and mucosal loss at the bladder neck, prostate, and urethra can cause acute urinary dysfunction. Both irritative and obstructive urinary symptoms can cause pain with urination and ejaculation until the irritation subsides. Rectal urgency, diarrhea, and tenesmus may occur as a result of radiation of the anterior rectal wall. Late side effects include rectal proctitis, bleeding, and rectal fistula, painless hematuria, chronic interstitial cystitis, urethral stricture, erectile dysfunction, and, rarely, secondary cancers of the rectum and bladder (Michaelson, Cotter, Gargollo, et al., 2008).

Hormonal Strategies

The number of survivors of prostate cancer in the United States is estimated at 2 million; approximately one third of these men currently receive **androgen deprivation therapy (ADT)** (Michaelson, et al., 2008). ADT is commonly used to suppress androgenic stimuli to the prostate by decreasing the level of circulating plasma testosterone or interrupting the conversion to or binding of DHT. As a result, the prostatic epithelium atrophies (decreases in size). This effect is accomplished either by surgical castration (bilateral **orchiectomy**, removal of the testes), which has traditionally been the mainstay of hormonal treatment, or by medical

castration with the administration of medications, such as luteinizing hormone–releasing hormone (LHRH) agonists. Bilateral orchiectomy decreases plasma testosterone levels significantly because approximately 93% of circulating testosterone is of testicular origin (7% is from the adrenal glands). Thus, the testicular stimulus required for continued prostatic growth is removed, resulting in prostatic atrophy.

However, orchiectomy often results in significant morbidity. Although the procedure does not cause the side effects associated with other hormonal therapies (described later), it is associated with considerable emotional impact. Because patients who have prostate cancer are living longer with the disease, health care providers have now begun to focus their attention on effective therapeutic modalities that promote an acceptable quality of life. Patients may be given the option for testicular prostheses to be placed during surgery.

LHRH agonists include leuprolide (Lupron) and goserelin (Zoladex). Additional hormonal manipulation with antiandrogens may be prescribed for patients who do not show adequate serum testosterone suppression (less than 50 ng/mL) with medical or surgical castration. Antiandrogen receptor antagonists include flutamide (Eulexin), bicalutamide (Casodex), and nilutamide (Nilandron). LHRH agonists suppress testicular androgen, whereas antiandrogen receptor antagonists cause adrenal androgen suppression. When LHRH agonists are initiated, a testosterone flare may occur, causing pain in bony metastatic disease. Antiandrogens given for the first 7 days may reduce this uncomfortable symptom. The most common uses of LHRH agonists are the following: (1) in the adjuvant and neoadjuvant setting in combination with radiation therapy; (2) after radical prostatectomy; and (3) in the treatment of recurrence indicated by an elevation in the PSA but without clinical or x-ray evidence. Medical and surgical castration causes hot flushing because these treatment modalities increase hypothalamic activity, which stimulates the thermoregulatory centers of the body.

The management of hormone-refractory prostate cancer remains somewhat controversial. Another category of medication used as a second-line hormonal intervention is called adrenal ablating drugs. Ketoconazole (Nizoral) is used to inhibit cytochrome P450 enzymes, which are required for the synthesis of androgens and other steroids. High-dose ketoconazole lowers testosterone by decreasing both testicular and endocrine production of androgen. Administration of this medication requires steroid supplementation to prevent adrenal insufficiency.

Hypogonadism is responsible for the adverse effects of ADT, which include vasomotor flushing, loss of libido, decreased bone density (resulting in osteoporosis and fractures), anemia, fatigue, increased fat mass, lipid alterations, decreased muscle mass, gynecomastia (increased breast tissue), and mastodynia (breast/nipple tenderness). Hypogonadism is associated with an increased risk of diabetes, resulting from insulin resistance, metabolic syndrome, and cardiovascular disease (Michaelson, et al., 2008).

Chemotherapy

Recent studies have shown clear benefits in terms of survival with chemotherapy treatment that includes a

docetaxel-based regimen for non-androgen-dependent prostate cancer (NCCN, 2008; Pienta & Smith, 2005). Other studies are under way to determine the importance of the vascular endothelial growth factor system. Tumor angiogenesis is essential for tumor growth, including growth of prostate carcinomas and other high-grade cancers. Therefore, antiangiogenic treatment in combination with conventional therapies may play a future role in treatment. Gene-based therapy in prostate cancer is an emerging and promising adjuvant to conventional treatment strategies.

Complications related to chemotherapy are specific to the type of chemotherapy administered. These are discussed in detail in Chapter 16.

Other Therapies

Cryosurgery of the prostate is used to ablate prostate cancer in patients who cannot tolerate surgery and in those with recurrent prostate cancer. Transperineal probes are inserted into the prostate under ultrasound guidance to freeze the tissue directly.

Keeping the urethral passage patent may require repeated TURPs. If this is impractical, catheter drainage is instituted by way of the suprapubic or transurethral route. For men with advanced prostate cancer, palliative measures are indicated. Although cure is unlikely with advanced prostate cancer, many men survive for long periods, free of debilitating symptoms.

Bone lesions that result from metastasis of prostate cancer can be very painful and result in pathologic fractures. Opioid and nonopioid medications are used to control bone pain. EBRT can be delivered to skeletal lesions to relieve pain. Radiopharmaceuticals, such as strontium or samarium, can be injected intravenously to treat multiple sites of bone metastasis. Antiandrogen therapies are used in an effort to reduce the circulating androgens. If antiandrogen therapies are not effective, medications such as prednisone have been effective in reducing pain and improving quality of life. Bisphosphonate therapy with pamidronate (Aredia) can be administered to reduce the risk of pathologic fracture. In advanced prostate cancer, blood transfusions are administered to maintain adequate hemoglobin levels when bone marrow is replaced by tumor.

More than one third of men with a diagnosis of prostate cancer elect to use some form of complementary and alternative medicine (CAM). Because of lack of research on many forms of CAM, patients often rely on anecdotal information to make decisions about its use. Nurses play a vital role in assisting patients to locate and evaluate available information about CAM to ensure that harmful forms are avoided. The National Center for Complementary and Alternative Medicine's Web site (see Resources at the end of the chapter) can assist nurses in providing patients with evidence-based information.

The Patient Undergoing Prostate Surgery

Prostate surgery may be indicated for the patient with BPH or prostate cancer. The objectives before prostate surgery are to assess the patient's general health status and to establish optimal renal function. Prostate surgery should be per-

formed before acute urinary retention develops and damages the upper urinary tract and collecting system or, in the case of prostate cancer, before cancer progresses.

Surgical Procedures

Several approaches can be used to remove the hypertrophied portion of the prostate gland: TURP, suprapubic prostatectomy, perineal prostatectomy, retropubic prostatectomy, TUIP, and laparoscopic radical prostatectomy and robotic-assisted laparoscopic radical prostatectomy (Table 49-4). With these approaches, the surgeon removes all cancerous or hyperplastic tissue, leaving behind only the capsule of the prostate. The transurethral approaches (TURP, TUIP) are closed procedures; the other three are open procedures (ie, a surgical incision is required) and the two laparoscopic approaches are minimally invasive. The procedure chosen depends on the underlying disorder, the patient's age and physical status, patient preference, and the skill of the surgeon.

Transurethral Resection of the Prostate

TURP, the most common procedure used, can be carried out through endoscopy. The surgical and optical instrument is introduced directly through the urethra to the prostate, which can then be viewed directly. The gland is removed in small chips with an electrical cutting loop (Fig. 49-4A). This procedure eliminates the risk of transurethral resection syndrome (hyponatremia, hypovolemia). Transurethral resection syndrome is a potential but rare complication of TURP that occurs in approximately 2% of men who undergo the procedure (Chart 49-4).

TURP usually requires an overnight hospital stay. Urethral strictures are more frequent than with non-transurethral procedures, and repeated procedures may be necessary because the residual prostatic tissue grows back. TURP rarely causes erectile dysfunction but may trigger retrograde ejaculation, because removal of prostatic tissue at the bladder neck can cause the seminal fluid to flow backward into the bladder rather than forward through the urethra during ejaculation.

Suprapubic Prostatectomy

In suprapubic prostatectomy, an incision is made into the bladder, and the prostate gland is removed from above (Fig. 49-4B). Such an approach can be used for a gland of any size, and few complications occur, although blood loss may be greater than with the other methods. Another disadvantage is the need for an abdominal incision, which has the risks associated with any major abdominal surgical procedure.

Perineal Prostatectomy

In perineal prostatectomy, the prostate gland is removed through an incision in the perineum (Fig. 49-4C). This procedure is practical when other approaches are not possible and is useful for an open biopsy. However, incontinence, sexual dysfunction, and rectal injury are more likely with this approach.

Retropubic Prostatectomy

Retropubic prostatectomy is used more commonly than the suprapubic approach. The surgeon makes a low abdominal incision and approaches the prostate gland between the

Table 49-4 COMPARING SURGICAL APPROACHES FOR TREATMENT OF PROSTATE DISORDERS

The surgical approach of choice depends on (1) the size of the gland, (2) the severity of the obstruction, (3) the age of the patient, (4) the condition of the patient, and (5) the presence of associated diseases.

Surgical Approach	Advantages	Disadvantages	Nursing Implications
Transurethral resection (TURP) (Removal of prostatic tissue by instrument introduced through urethra; used for glands of varying size. Ideal for patients who are poor surgical risks.)	Avoids abdominal incision Safer for surgical-risk patient Shorter hospitalization and recovery periods Lower morbidity rate Causes less pain Can be used as a palliative approach with history of radiation therapy	Requires highly skilled surgeon Recurrent obstruction, urethral trauma, and stricture may develop Delayed bleeding may occur	Monitor for hemorrhage Observe for symptoms of urethral stricture (dysuria, straining, weak urinary stream)
Open surgical removal Suprapubic approach (Removal of prostatic tissue through abdominal incision; can be used for gland of any size.)	Technically simple Offers wide area of exploration Permits exploration for cancerous lymph nodes Allows more complete removal of obstructing gland Permits treatment of associated bladder lesions	Requires surgical approach through the bladder Control of hemorrhage difficult Urine may leak around the suprapubic tube. Recovery may be prolonged and uncomfortable.	Monitor for indications of hemorrhage and shock. Provide meticulous aseptic care to the area around suprapubic tube.
Perineal approach (Removal of gland through an incision in the perineum; preferred approach for obese patients.)	Offers direct anatomic approach Permits gravity drainage Particularly effective for radical cancer therapy Allows hemostasis under direct vision Low mortality rate Low incidence of shock Ideal for very old, frail, and poor surgical-risk patients with large prostate	Higher postoperative incidence of impotence and urinary incontinence Possible damage to rectum and external sphincter Restricted operative field Greater potential for contamination and infection of incision	Avoid using rectal tubes or thermometers and enemas after perineal surgery Use drainage pads to absorb excess urinary drainage Provide foam rubber ring for patient comfort in sitting Anticipate urinary leakage around the wound for several days after the catheter is removed
Retropubic approach (Low abdominal incision; bladder is not entered.)	Avoids incision into the bladder Permits surgeon to see and control bleeding Shorter recovery period Less bladder sphincter damage Suitable for removal of large glands	Cannot treat associated bladder disease Increased incidence of hemorrhage from prostatic venous plexus; pubic osteitis	Monitor for hemorrhage Anticipate posturinary leakage for several days after removing the catheter
Transurethral incision (TUIP) (Urethral approach; 1–2 cuts are made in the prostate and prostate capsule to reduce pressure on the urethra and to reduce urethral constriction.)	Results comparable to TURP Low incidence of erectile dysfunction and retrograde ejaculation No bladder neck contracture	Requires highly skilled surgeon Recurrent obstruction and urethral trauma Delayed bleeding	Monitor for hemorrhage
Laparoscopic radical prostatectomy	Minimally invasive technique Improved patient satisfaction and quality of life Shorter hospital stay Short convalescence More rapid return to normal activity Short indwelling catheter duration Decreased blood loss to 400 mL Reduced infection risk Less scarring Better visualization of surgical field than other approaches	Lack of tactile sensation available with open prostatectomy Inability to palpably assess for induration and palpable nodules Inability to delineate the proximity of involvement of the neurovascular bundles due to lack of palpation Technically demanding Long surgical time (4–5 hours)	Observe for symptoms of urethral stricture (dysuria), straining, weak urinary stream Monitor for hemorrhage and shock Provide meticulous aseptic care to the area around suprapubic tube Monitor for changes in bowel function Avoid using rectal tubes or thermometers and enemas after perineal surgery Use drainage pads to absorb excess urinary drainage Provide foam rubber ring for patient comfort in sitting Anticipate urinary leakage around the wound for several days after the catheter is removed

Table 49-4 COMPARING SURGICAL APPROACHES FOR TREATMENT OF PROSTATE DISORDERS (Continued)

Surgical Approach	Advantages	Disadvantages	Nursing Implications
Robotic-assisted laparoscopic radical prostatectomy (Involves using computer console and da Vinci robotic system. Six small incisions are made in the abdomen; laparoscopic instruments inserted through the incisions are used to dissect the prostate.)	Minimally invasive technique Improved patient satisfaction and quality of life Shorter hospital stay Short convalescence More rapid return to normal activity Short indwelling catheter duration Decreased blood loss to 150 mL Improved magnification of operative field, using a 3-dimensional view (includes, magnification, high resolution and depth perception) Less postoperative pain Reduced infection risk Less scarring Laparoscopic instruments have six degrees of movement with joints, allowing extensive range of motion and precision Nerve-sparing with less incontinence and sexual dysfunction	Lack of tactile sensation available with open prostatectomy Inability to palpably assess for induration and palpable nodules Inability to delineate the proximity of involvement of the neurovascular bundles due to lack of palpation Technically demanding	Observe for symptoms of urethral stricture (dysuria), straining, weak urinary stream Monitor for hemorrhage and shock Provide meticulous aseptic care to the area around suprapubic tube Monitor for changes in bowel function Avoid using rectal tubes or thermometers and enemas after perineal surgery Use drainage pads to absorb excess urinary drainage Provide foam rubber ring for patient comfort in sitting Anticipate urinary leakage around the wound for several days after the catheter is removed

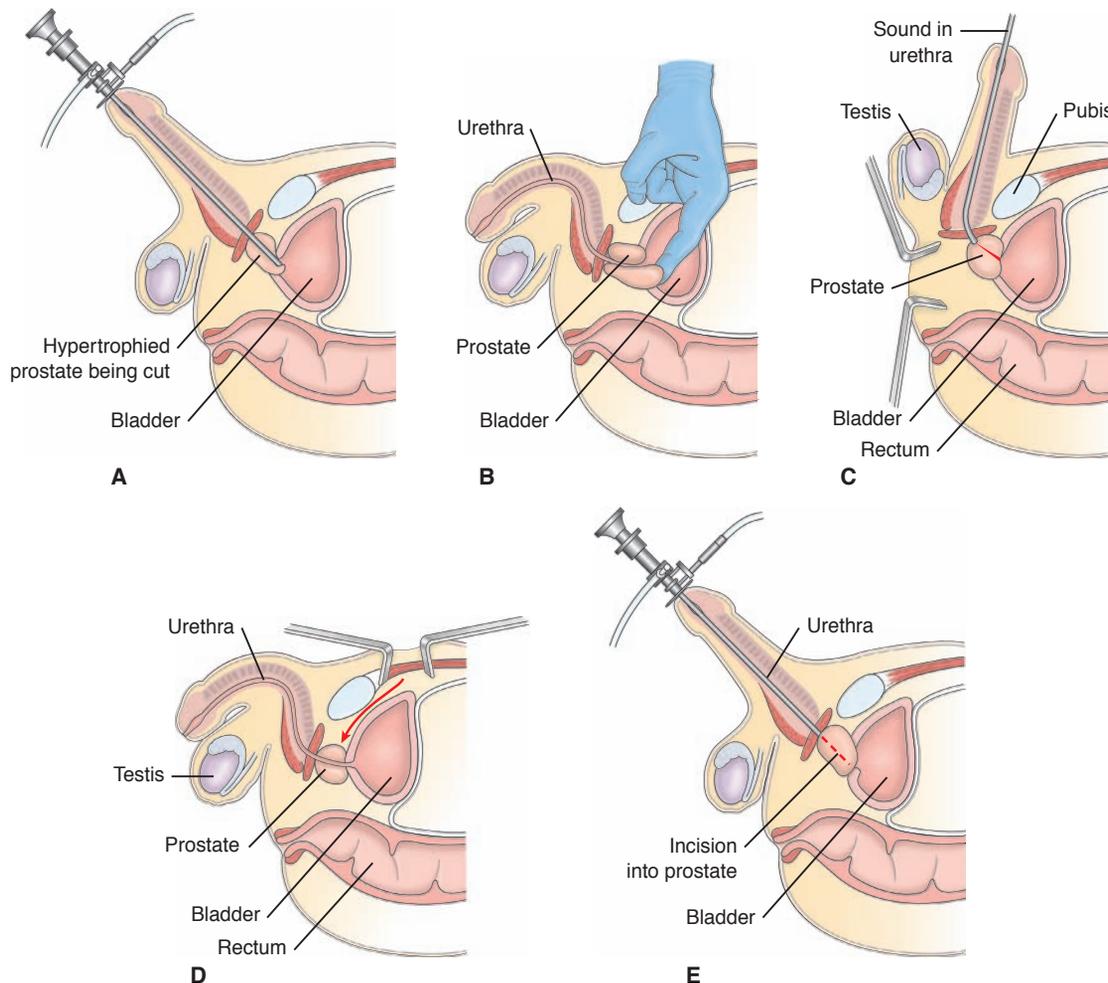

Figure 49-4 Prostate surgery procedures. **A**, Transurethral resection (TUR). A loop of wire connected with a cutting current is rotated in the cystoscope to remove shavings of prostate at the bladder orifice. **B**, Suprapubic prostatectomy. With an abdominal approach, the prostate is shelled out of its bed. **C**, Perineal prostatectomy. Two retractors on the left spread the perineal incision to provide a view of the prostate. **D**, Retropubic prostatectomy is performed through a low abdominal incision. Note two abdominal retractors and arrow pointing to the prostate gland. **E**, Transurethral incision of prostate (TUIP) involves one or two incisions into the prostate to reduce pressure on the urethra.

Chart 49-4 • Transurethral Resection Syndrome

Transurethral resection syndrome is a rare but potentially serious complication of transurethral prostatectomy (TURP).

Signs and symptoms are caused by neurologic, cardiovascular, and electrolyte imbalances associated with absorption of the solution used to irrigate the surgical site during the surgical procedure. Hyponatremia, hypovolemia, and occasionally hyperammonemia may occur (Eaton, 2003).

Signs and Symptoms

- Lethargy and confusion
- Hypotension
- Tachycardia
- Nausea and vomiting
- Collapse
- Headache
- Muscle spasms
- Seizures

Interventions

- Discontinue irrigation
- Administer diuretics as prescribed
- Replace bladder irrigation with normal saline
- Monitor intake and output
- Monitor the patient's vital signs and level of consciousness
- Differentiate lethargy and confusion of TUR syndrome from postoperative disorientation and hyponatremia
- Maintain patient safety during times of confusion
- Assess lung and heart sounds for indications of pulmonary edema, heart failure, or both as fluid moves back into the intravascular space

pubic arch and the bladder without entering the bladder (Fig. 49-4D). This procedure is suitable for large glands located high in the pelvis. Although blood loss can be better controlled and the surgical site is easier to visualize, infections can readily start in the retropubic space.

Transurethral Incision of the Prostate

TUIP is another procedure used to treat BPH. An instrument is passed through the urethra (Fig. 49-4E). TUIP is indicated when the prostate gland is small (30 g or less), and it is an effective treatment for many cases of BPH. TUIP can be performed on an outpatient basis and has a lower complication rate than other invasive prostate procedures.

Laparoscopic Radical Prostatectomy

In contrast to the single abdominal incision made for the radical prostatectomy, a laparoscopic radical prostatectomy is performed through four to six small (0.5 in [1 cm]) incisions in the midabdomen. Instruments, including a lighted viewing instrument (laparoscope), are inserted and allow the surgeon to remove the prostate gland. The laparoscopic approach reduces the risk of postoperative erectile dysfunction and urinary dysfunction. Laparoscopic radical prostatectomy results in less bleeding, reduced need for blood transfusion, a shorter hospital stay, less postoperative pain, and more rapid return to normal activity compared with open radical prostatectomy (Rigdon, 2006). Further research is needed to assess long-term outcomes.

Robotic-Assisted Laparoscopic Radical Prostatectomy

Robotic-assisted laparoscopic radical prostatectomy is a new minimally invasive approach that uses a computer console and da Vinci robot to move the tips of microscopic instruments, replicating the movements of the surgeon's hands (Rigdon, 2006; Starnes & Sims, 2006).

Pelvic Lymph Node Dissection

Pelvic lymph node dissection (PLND) is not always performed. It may be used in some patients to provide information for staging the tumor and to remove an area of

microscopic metastasis. The planned treatment may influence the surgeon's decision to perform PLND and the extent (limited versus extended) of the dissection. Dissection of nodes anterior and lateral to the external iliac vessels is associated with an increased risk of lymphedema (NCCN, 2009).

Complications

Postoperative complications depend on the type of prostatectomy performed and may include hemorrhage, clot formation, catheter obstruction, and sexual dysfunction. All prostatectomies carry a risk of impotence because of potential damage to the pudendal nerves. In most instances, sexual activity may be resumed in 6 to 8 weeks, the time required for the prostatic fossa to heal. During ejaculation, the seminal fluid goes into the bladder and is excreted with the urine. The anatomic changes in the posterior urethra lead to retrograde ejaculation. A vasectomy may be performed during surgery to prevent infection from spreading from the prostatic urethra through the vas and into the epididymis.

After total prostatectomy (usually for cancer), the risk for impotence is high. For the patient for whom this is unacceptable, options are available to produce erections sufficient for sexual intercourse: prosthetic penile implants, negative-pressure (vacuum) devices, and pharmacologic interventions (see earlier discussion and Table 49-2).

NURSING PROCESS**PATIENT UNDERGOING PROSTATECTOMY****Assessment**

The nurse assesses how the underlying disorder (BPH or prostate cancer) has affected the patient's lifestyle. Questions to ask during assessment include the following: Has the patient's activity level or activity tolerance changed? What is his presenting urinary problem (described in the patient's own words)? Has he experienced decreased force of urinary flow, decreased ability to initiate voiding, urgency, frequency, nocturia, dysuria, urinary retention, or hema-

turia? Does the patient report back pain, flank pain, and lower abdominal or suprapubic discomfort? Possible causes of such discomfort include infection, retention, and renal colic. Has the patient experienced erectile dysfunction or changes in frequency or enjoyment of sexual activity?

The nurse obtains further information about the patient's family history of cancer and heart or kidney disease, including hypertension. Has he lost weight? Does he appear pale? Can he raise himself out of bed and return to bed without assistance? Can he perform usual activities of daily living? This information helps determine how soon the patient will be able to return to normal activities after prostatectomy.

Diagnosis

Preoperative Nursing Diagnoses

Based on the assessment data, the patient's major nursing diagnoses may include the following.

- Anxiety about surgery and its outcome
- Acute pain related to bladder distention
- Deficient knowledge about factors related to the disorder and the treatment protocol

Postoperative Nursing Diagnoses

- Acute pain related to the surgical incision, catheter placement, and bladder spasms
- Deficient knowledge about postoperative care

Collaborative Problems/Potential Complications

Based on the assessment data, the potential complications may include the following:

- Hemorrhage and shock
- Infection
- Deep vein thrombosis
- Catheter obstruction
- Sexual dysfunction

Planning and Goals

The major preoperative goals for the patient may include reduced anxiety and learning about his prostate disorder and the perioperative experience. The major postoperative goals may include maintenance of fluid volume balance, relief of pain and discomfort, ability to perform self-care activities, and absence of complications.

Preoperative Nursing Interventions

Reducing Anxiety

The patient is frequently admitted to the hospital or surgical center on the morning of surgery. Because contact with the patient may be limited before surgery, the nurse must establish communication with the patient to assess his understanding of the diagnosis and of the planned surgical procedure. The nurse clarifies the nature of the surgery and expected postoperative outcomes. In addition, the nurse familiarizes the patient with the preoperative and postoperative routines and initiates measures to reduce anxiety. Because the patient may be sensitive and embarrassed discussing problems related to the genitalia and sexuality, the nurse provides privacy and establishes a trusting and professional relationship. Guilt feelings often surface if the patient falsely assumes a cause-and-effect relationship

between sexual practices and his current problems. He is encouraged to verbalize his feelings and concerns.

Relieving Discomfort

If the patient experiences discomfort before surgery, bed rest is prescribed, analgesic agents are administered, and measures are initiated to relieve anxiety. If he is hospitalized, the nurse monitors his voiding patterns, watches for bladder distention, and assists with catheterization if indicated. An indwelling catheter is inserted if the patient has continuing urinary retention or if close monitoring is needed because of laboratory test results that indicate azotemia (accumulation of nitrogenous waste products in the blood). The catheter can help decompress the bladder gradually over several days, especially if the patient is elderly and hypertensive and has diminished renal function or urinary retention that has existed for many weeks. For a few days after the bladder begins draining, the blood pressure may fluctuate and renal function may decline. If the patient cannot tolerate a urinary catheter, he is prepared for a cystostomy (and insertion of a suprapubic catheter).

Providing Instruction

Before surgery, the nurse reviews with the patient the anatomy of the affected structures and their function in relation to the urinary and reproductive systems, using diagrams and other teaching aids if indicated. This instruction often takes place during the preadmission testing visit or in the urologist's office. The nurse explains what will take place while the patient is prepared for diagnostic tests and then for surgery (depending on the type of prostatectomy planned). The nurse also reinforces information given by the surgeon about the type of incision, which varies with the surgical approach (directly over the bladder, low on the abdomen, or in the perineal area; four to six small incisions with laparoscopic and robotic-assisted approaches; and no incision with a transurethral procedure), and describes the likely type of urinary drainage system (urethral or suprapubic) and the recovery room procedure. The amount of information given is based on the patient's needs and questions. The nurse explains procedures expected to occur during the immediate perioperative period, answers questions the patient or family may have, and provides emotional support. In addition, the nurse provides the patient with information about postoperative pain management.

Preparing the Patient

If the patient is scheduled for a prostatectomy, the preoperative preparation described in Chapter 18 is provided. Anti-embolism stockings are applied before surgery and are particularly important to prevent deep vein thrombosis (DVT) if the patient is placed in a lithotomy position during surgery. An enema is usually administered at home on the evening before surgery or on the morning of surgery to prevent postoperative straining, which can induce bleeding.

Postoperative Nursing Interventions

Maintaining Fluid Balance

During the postoperative period, the patient is at risk for imbalanced fluid volume because of the irrigation of the surgical site during and after surgery. With irrigation of the

urinary catheter to prevent its obstruction by blood clots, fluid may be absorbed through the open surgical site and retained, increasing the risk of excessive fluid retention, fluid imbalance, and water intoxication. The urine output and the amount of fluid used for irrigation must be closely monitored to determine whether irrigation fluid is being retained and to ensure an adequate urine output. An intake and output record, including the amount of fluid used for irrigation, must be maintained. The patient is also monitored for electrolyte imbalances (eg, hyponatremia), increasing blood pressure, confusion, and respiratory distress. These signs and symptoms are documented and reported to the surgeon. The risk of fluid and electrolyte imbalance is greater in elderly patients with preexisting cardiovascular or respiratory disease.

Relieving Pain

After a prostatectomy, the patient is assisted to sit and dangle his legs over the side of the bed on the day of surgery. The next morning, he is assisted to ambulate. If pain is present, the cause and location are determined and the severity of pain and discomfort is assessed. The pain may be related to the incision or may be the result of excoriation of the skin at the catheter site. It may be in the flank area, indicating a kidney problem, or it may be caused by bladder spasms. Bladder irritability can initiate bleeding and result in clot formation, leading to urinary retention.

Patients experiencing bladder spasms may report an urgency to void, a feeling of pressure or fullness in the bladder, and bleeding from the urethra around the catheter. Medications that relax the smooth muscles can help ease the spasms, which can be intermittent and severe; these medications include flavoxate (Urispas) and oxybutynin (Ditropan). Warm compresses to the pubis or sitz baths may also relieve the spasms.

The nurse monitors the drainage tubing and irrigates the system as prescribed to relieve any obstruction that may cause discomfort. Usually, the catheter is irrigated with 50 mL of irrigating fluid at a time. It is important to make sure that the same amount is recovered in the drainage receptacle. Securing the catheter drainage tubing to the leg or abdomen can help decrease tension on the catheter and prevent bladder irritation. Discomfort may be caused by dressings that are too snug, saturated with drainage, or improperly placed. Analgesic agents are administered as prescribed. The nurse notifies the physician if the analgesic medications do not relieve the patient's pain and obtains a prescription for new doses or different medications.

After the patient is ambulatory, he is encouraged to walk but not to sit for prolonged periods, because this increases intra-abdominal pressure and the possibility of discomfort and bleeding. Prune juice and stool softeners are provided to ease bowel movements and to prevent excessive straining. An enema, if prescribed, is administered with caution to avoid rectal perforation.

Monitoring and Managing Potential Complications

After prostatectomy, the patient is monitored for major complications such as hemorrhage, infection, DVT, catheter obstruction, and sexual dysfunction.

HEMORRHAGE. Although patients have discontinued all aspirin, nonsteroidal anti-inflammatory drugs, and platelet

inhibitors 10 to 14 days before the surgery to prevent excessive bleeding, bleeding and hemorrhagic shock remain the greatest risks. The risk is increased with BPH because a hyperplastic prostate gland is very vascular. Bleeding may occur from the prostatic bed. Bleeding may also result in the formation of clots, which then obstruct urine flow. The drainage normally begins as reddish-pink and then clears to a light pink within 24 hours after surgery. Bright red bleeding with increased viscosity and numerous clots usually indicates arterial bleeding. Venous blood appears darker and less viscous. Arterial hemorrhage usually requires surgical intervention (eg, suturing or transurethral coagulation of bleeding vessels), whereas venous bleeding may be controlled by applying prescribed traction to the catheter so that the balloon holding the catheter in place applies pressure to the prostatic fossa. The surgeon applies traction by securely taping the catheter to the patient's thigh if hemorrhage occurs. Less blood loss (150 mL) is expected with robotic-assisted laparoscopic radical prostatectomy, compared with 500 to 900 mL, which may occur with open prostatectomy.

Nursing management includes assistance in implementing strategies to stop the bleeding and to prevent or reverse hemorrhagic shock. If blood loss is extensive, fluids and blood component therapy may be administered. If hemorrhagic shock occurs, treatments described in Chapter 15 are initiated.

Nursing interventions include closely monitoring vital signs; administering medications, IV fluids, and blood component therapy as prescribed; maintaining an accurate record of intake and output; and carefully monitoring drainage to ensure adequate urine flow and patency of the drainage system. The patient who experiences hemorrhage and his family are often anxious and benefit from explanations and reassurance about the event and the procedures that are performed.

INFECTION. After perineal prostatectomy, the surgeon usually changes the dressing on the first postoperative day. Further dressing changes may become the responsibility of the nurse or home care nurse. Careful aseptic technique is used because the potential for infection is great. Dressings can be held in place by a double-tailed, T-binder bandage or a padded athletic supporter. The tails cross over the incision to give double thickness, and then each tail is drawn up on either side of the scrotum to the waistline and fastened.

Rectal thermometers, rectal tubes, and enemas are avoided because of the risk of injury and bleeding in the prostatic fossa. After the perineal sutures are removed, the perineum is cleansed as indicated. A heat lamp may be directed to the perineal area to promote healing. The scrotum is protected with a towel while the heat lamp is in use. Sitz baths are also used to promote healing.

UTIs and epididymitis are possible complications after prostatectomy. The patient is assessed for their occurrence; if they occur, the nurse administers antibiotics as prescribed. Because the risk of infection continues after discharge from the hospital, the patient and family need to be instructed to monitor for signs and symptoms of infection (fever, chills, sweating, myalgia, dysuria, urinary frequency, and urgency). The patient and family are instructed to contact the urologist if these symptoms occur.

DEEP VEIN THROMBOSIS. Patients undergoing prostatectomy are at risk for DVT and pulmonary embolism; therefore, the nurse assesses the patient frequently after surgery for manifestations of DVT. Further, anti-embolism stockings are used to reduce the risk of DVT and pulmonary embolism. Early postoperative ambulation is essential to reduce the risk of DVT. Nursing and medical management of DVT and pulmonary embolism are described in Chapters 31 and 23, respectively. In addition, if the patient is at high risk for clot formation, IV heparin or subcutaneous enoxaparin (Lovenox) may be administered.

OBSTRUCTED CATHETER. After a TURP, the catheter must drain well; an obstructed catheter produces distention of the prostatic capsule and resultant hemorrhage. Furosemide (Lasix) may be prescribed to promote urination and initiate postoperative diuresis, thereby helping to keep the catheter patent.

The nurse observes the lower abdomen to ensure that the catheter has not become blocked. A distinct, rounded swelling above the pubis is a manifestation of an overdistended bladder.

The drainage bag, dressings, and surgical incision are examined for bleeding. The color of the urine is noted and documented; a change in color from pink to amber indicates reduced bleeding. Blood pressure, pulse, and respirations are monitored and compared with baseline preoperative vital signs to detect hypotension. The nurse also observes the patient for restlessness, diaphoresis, pallor, any drop in blood pressure, and an increasing pulse rate.

Drainage of the bladder may be accomplished by gravity through a closed sterile drainage system. A three-way drainage system is useful in irrigating the bladder and preventing clot formation (Fig. 49-5). Continuous irrigation may be used with TURP. Some urologists leave an indwelling catheter attached to a dependent drainage system. Gentle irrigation of the catheter may be prescribed to remove any obstructing clots.

If the patient complains of pain, the tubing is examined. The drainage system is irrigated with irrigating fluid (usually 50 mL), if indicated and prescribed, to clear any obstruction. The amount of fluid recovered in the drainage bag must equal the amount of fluid instilled. Overdistention of the bladder is avoided because it can induce secondary hemorrhage by stretching the coagulated blood vessels in the prostatic capsule.

To prevent traction on the bladder, the drainage tube (not the catheter) is taped to the shaved inner thigh. If a cystostomy catheter is in place, it is taped to the abdomen. The nurse explains the purpose of the catheter to the patient and assures him that the urge to void results from the presence of the catheter and from bladder spasms. He is cautioned not to pull on the catheter because this causes bleeding and subsequent catheter blockage, which leads to urinary retention.

COMPLICATIONS WITH CATHETER REMOVAL. After the catheter is removed (usually when the urine appears clear), urine may leak around the wound for several days in the patient who has undergone perineal, suprapubic, or retropubic surgery. The cystostomy tube may be removed before or after the urethral catheter is removed. Some urinary inconti-

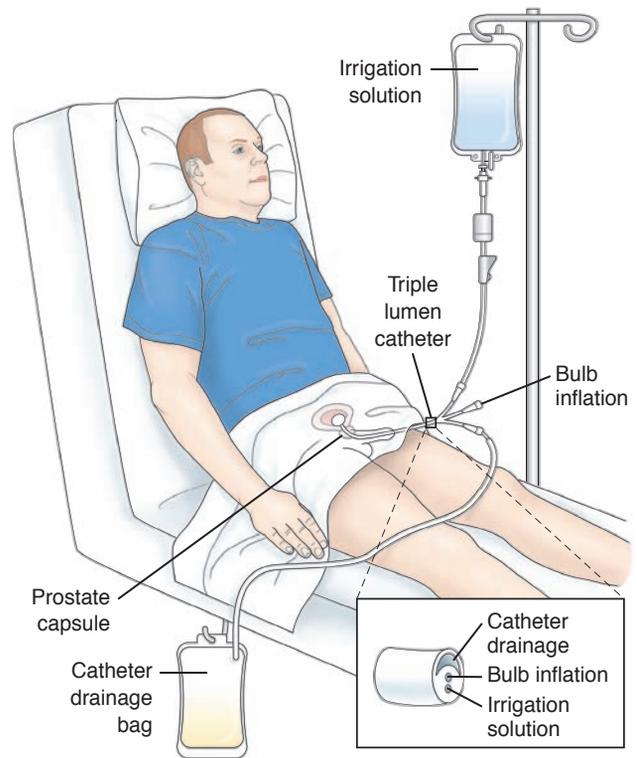

Figure 49-5 A three-way system for bladder irrigation.

nence may occur after catheter removal, and the patient is informed that this is likely to subside over time (see below).

URINARY INCONTINENCE. Postoperative urinary incontinence, a devastating complication of prostatectomy, occurs in 80% to 95% of patients. Urinary incontinence often decreases over time—although it may last as long as 1 to 2 years following surgery. Factors associated with postoperative continence are younger age, preservation of both neurovascular bundles, absence of an anastomotic stricture, eversion of the bladder neck, and a smaller prostate volume. The nurse can encourage the patient who experiences incontinence to take steps to prevent incontinence, improve continence, anticipate leakage, and cope with lack of complete control (Yu Ko & Sawatzky, 2008). Preventing incontinence involves increasing voiding frequency, avoiding positions that encourage the urge to void, and decreasing fluid intake prior to activities. Promoting continence involves pelvic floor exercises (see Teaching Patients Self-Care below), biofeedback, and electrical stimulation. Anticipating leakage may entail lifestyle modifications such as using absorbent pads and carrying extra clothes to prevent urinary accidents; this can improve confidence when bathroom access is limited. It also helps to know the location of public bathrooms. Coping long term with complete lack of control may involve collagen injections, artificial sphincter implants, medications, and leg bags (Michaelson, et al., 2008; Yu Ko & Sawatzky, 2008).

SEXUAL DYSFUNCTION. Depending on the type of surgery, the patient may experience sexual dysfunction related to erectile dysfunction, decreased libido, and fatigue.

These issues may become a concern to the patient soon after surgery or in the weeks to months of rehabilitation. With nerve-sparing radical prostatectomy, the likelihood of recovering the ability to have erections is better for men who are younger and men in whom both neurovascular bundles are spared. A decrease in libido is usually related to the impact of the surgery on the body. Reassurance that the usual level of libido will return after recuperation from surgery is often helpful for the patient and his partner. The patient should be aware that he may experience fatigue during rehabilitation from surgery. This fatigue may also decrease his libido and alter his enjoyment of usual activities.

Several options to restore erectile function are discussed with the patient by the surgeon or urologist. These options may include medications, surgically placed implants, or negative-pressure devices. PDE-5 inhibitors (see Table 49-3) may be effective for treatment of erectile dysfunction in men after radical prostatectomy, especially if the neurovascular bundles have been preserved. They may also improve erectile function in men with partial or moderate erectile dysfunction after radiation therapy for localized prostate cancer.

Nursing interventions include assessing for sexual dysfunction after surgery. Providing a private and confidential environment to discuss issues of sexuality is important. The emotional challenges of prostate surgery and its consequences need to be carefully explored with the patient and his partner. Providing the opportunity to discuss these issues can be very beneficial to the patient. For patients who have significant difficulty adjusting to sexual dysfunction, a referral to a sex therapist may be indicated.

Promoting Home and Community-Based Care

TEACHING PATIENTS SELF-CARE. The patient undergoing prostatectomy may be discharged within several days. The length of the hospital stay depends on the surgical approach used and may range from 1 to 2 days for robotic-assisted laparoscopic prostatectomy to 3 to 5 days for open prostatectomy. The patient and family require instructions about how to manage the drainage system, how to assess for complications, and how to promote recovery. The nurse provides verbal and written instructions about the need to

maintain the drainage system and to monitor urinary output, about wound care, and about strategies to prevent complications, such as infection, bleeding, and thrombosis. In addition, the patient and family need to know about signs and symptoms that should be reported to the physician (eg, blood in urine, decreased urine output, fever, change in wound drainage, calf tenderness).

As the patient recovers and drainage tubes are removed, he may become discouraged and depressed because he cannot regain bladder control immediately. Furthermore, urinary frequency and burning may occur after the catheter is removed. Teaching the patient the following exercises may help him regain urinary control:

- Tense the perineal muscles by pressing the buttocks together, hold this position, and then relax. This exercise can be performed 10 to 20 times each hour while sitting or standing.
- Try to interrupt the urinary stream after starting to void; wait a few seconds and then continue to void.

Perineal exercises should continue until the patient gains full urinary control. The patient is instructed to urinate as soon as he feels the first urge to do so. It is important that the patient know that regaining urinary control is a gradual process; he may continue to “dribble” after being discharged from the hospital, but this should gradually diminish (usually within 1 year). The urine may be cloudy for several weeks after surgery but should clear as the prostate area heals.

While the prostatic fossa heals (6 to 8 weeks), the patient should avoid activities that produce Valsalva effects (straining, heavy lifting) because this may increase venous pressure and produce hematuria. He should avoid long motor trips and strenuous exercise, which increase the tendency to bleed. He should also know that spicy foods, alcohol, and coffee may cause bladder discomfort. The patient should be cautioned to drink enough fluids to avoid dehydration, which increases the tendency for a blood clot to form and obstruct the flow of urine. Signs of complications, such as bleeding, passage of blood clots, a decrease in the urinary stream, urinary retention, or symptoms of UTIs, should be reported to the physician (Chart 49-5). Patients who have undergone robotic-assisted prostatectomy are often able to return to their usual activities in approximately 7 to 10 days (Rigdon, 2006).

CHART
49-5

HOME CARE CHECKLIST Postprostatectomy Care

At the completion of the home care instruction, the patient or caregiver will be able to:	PATIENT	CAREGIVER
• Demonstrate appropriate measures to relieve postoperative pain and discomfort.	✓	✓
• Demonstrate appropriate care of urinary catheter and collection receptacle.	✓	✓
• Demonstrate appropriate wound care.	✓	✓
• Demonstrate performance of perineal muscle exercises to facilitate bladder control.	✓	
• Demonstrate increased activity and ambulation.	✓	
• Identify activities to avoid, such as lifting heavy objects.	✓	✓
• Identify signs and symptoms of complications that should be reported to surgeon.	✓	✓

CONTINUING CARE. Referral for home care may be indicated if the patient is elderly or has other health problems, if the patient and family cannot provide care in the home, or if the patient lives alone without available supports. The home care nurse assesses the patient's physical status (cardiovascular and respiratory status, fluid and nutritional status, patency of the urinary drainage system, wound and nutritional status) and provides catheter and wound care, if indicated. The nurse reinforces previous teaching and assesses the ability of the patient and family to manage required care. The home care nurse encourages the patient to ambulate and to carry out perineal exercises as prescribed. The patient may need to be reminded that return of bladder control may take time.

The patient is reminded about the importance of routine health screening and other health promotion activities. If the prostatectomy was performed to treat prostate cancer, the patient and family are also instructed about the importance of follow-up and monitoring with the physician.

Evaluation

Expected Preoperative Patient Outcomes

Expected preoperative patient outcomes may include the following:

1. Demonstrates reduced anxiety
2. States that pain and discomfort are decreased
3. Relates understanding of the surgical procedure and postoperative course and practices perineal muscle exercises and other techniques useful in facilitating bladder control

Expected Postoperative Patient Outcomes

Expected postoperative patient outcomes may include the following:

1. Reports relief of discomfort
2. Exhibits fluid and electrolyte balance
 - a. Irrigation fluid and urinary output are within parameters determined by surgeon
 - b. Experiences no signs or symptoms of fluid retention
3. Participates in self-care measures
 - a. Increases activity and ambulation daily
 - b. Produces urine output within normal ranges and consistent with intake
 - c. Performs perineal exercises and interrupts urinary stream to promote bladder control
 - d. Avoids straining and lifting heavy objects
4. Is free of complications
 - a. Maintains vital signs within normal limits
 - b. Exhibits wound healing, without signs of inflammation or hemorrhage
 - c. Maintains acceptable level of urinary elimination
 - d. Maintains optimal drainage of catheter and other drainage tubes
 - e. Reports understanding of changes in sexual function

CONDITIONS AFFECTING THE TESTES AND ADJACENT STRUCTURES

Orchitis

Orchitis is a rare, acute inflammatory response of one or both testes as a complication of systemic infection or as an extension of an associated epididymitis caused by bacterial, viral, spirochetal, or parasitic organisms. Micro-organisms may reach the testes through the blood, lymphatic system, or, more commonly, by traveling through the urethra, vas deferens, and epididymis; bacteria usually spread from an associated epididymitis in sexually active men. Causative organisms include *Neisseria gonorrhoeae*, *Chlamydia trachomatis*, *E. coli*, *Klebsiella*, *Pseudomonas aeruginosa*, *Staphylococcus* species, and *Streptococcus* species. A more common cause of isolated orchitis is mumps. Orchitis develops in approximately 30% of postpubertal men with mumps 4 to 6 days after parotitis starts, and one third of men have some testicular atrophy.

Signs and symptoms of orchitis include fever; pain, which may range from mild to severe; tenderness in one or both testicles; bilateral or unilateral testicular swelling; penile discharge; blood in the semen; and leukocytosis.

Treatment of orchitis is based on whether the causative organism is bacterial or viral. Bacterial orchitis is treated with antibiotics and supportive comfort measures. If the cause of the orchitis is an STD, the partner should be treated as well. Viral orchitis is treated using supportive treatments of rest, elevation of the scrotum, ice packs to reduce scrotal edema, analgesic agents, and anti-inflammatory medications. Bilateral orchitis can cause sterility in some men. Mumps vaccination is recommended for postpubertal men who have not had mumps or received inadequate immunization in childhood.

Epididymitis

Epididymitis is an infection of the epididymis, which usually spreads from an infected urethra, bladder, or prostate. The incidence is less than 1 in 1000 males per year. Prevalence is greatest in men 19 to 35 years of age. Acute epididymitis occurs bilaterally in 5% to 10% of affected patients. Risk factors for epididymitis include recent surgery or a procedure involving the urinary tract, participation in high-risk sexual practices, personal history of an STD, past prostate infections or UTIs, lack of circumcision, history of an enlarged prostate, and the presence of a chronic indwelling urinary catheter.

Pathophysiology

A causative organism can be identified in 80% of patients. In prepubertal males, older men, and homosexual men, the predominate causal organism is *E. coli*, although in older men, the condition may also be a result of urinary obstruction. In sexually active men ages 35 years of age and younger, the pathogens usually are related to bacteria associated with STDs (eg, *C. trachomatis*, *N. gonorrhoeae*). The

infection moves in an upward direction, through the urethra and the ejaculatory duct, and then along the vas deferens to the epididymis.

Clinical Manifestations

Epididymitis often slowly develops over 1 to 2 days, beginning with a low-grade fever, chills, and heaviness in the affected testicle. The testicle becomes increasingly tender to pressure and traction. The patient may report unilateral pain, soreness in the inguinal canal along the course of the vas deferens, and pain and swelling in the scrotum and the groin. The epididymis becomes increasingly swollen, with extreme pain in the lower abdomen and pelvis. Occasionally, there may be discharge from the urethra, blood in the semen, pus (pyuria) and bacteria (bacteriuria) in the urine, and pain during intercourse and ejaculation. The patient may report urinary frequency, urgency, or dysuria, and testicular pain aggravated by bowel movement.

Assessment and Diagnostic Findings

Laboratory assessment includes urinalysis, complete blood cell count, Gram stain of urethral drainage, urethral culture or DNA probe, and referral for syphilis and HIV testing in sexually active patients. Acute testicular pain should never be ignored, and it should be distinguished from testicular torsion, which is a surgical emergency.

Medical Management

The selection of an antibiotic depends on the causative organism; if epididymitis is associated with an STD, the patient's partner should also receive antimicrobial therapy. The spermatic cord may be infiltrated with a local anesthetic agent to relieve pain if the patient is seen within the first 24 hours after onset of pain. Supportive interventions also include reduction in physical activity, scrotal support and elevation, ice packs, anti-inflammatory agents, analgesics, including nerve blocks, and sitz baths. Urethral instrumentation (eg, catheter insertion) is avoided. The patient is observed for scrotal abscess formation as well.

In chronic epididymitis, a 4- to 6-week course of antibiotics for bacterial pathogens is prescribed. An epididymectomy (excision of the epididymis from the testis) may be performed for patients who have recurrent, refractory, incapacitating episodes of this infection. With long-term epididymitis, the passage of sperm may be obstructed. If the obstruction is bilateral, infertility may result.

Nursing Management

Bed rest is prescribed, and the scrotum is elevated with a scrotal bridge or folded towel to prevent traction on the spermatic cord, to promote venous drainage, and to relieve pain. Antimicrobial agents are administered as prescribed until the acute inflammation subsides. Intermittent cold compresses to the scrotum may help ease the pain. Later, local heat or sitz baths may help resolve the inflammation. Analgesic medications are administered for pain relief as prescribed.

The nurse instructs the patient to avoid straining, lifting, and sexual stimulation until the infection is under control. He should continue taking analgesic agents and antibiotics as prescribed and using ice packs if necessary to relieve

discomfort. He needs to know that it may take 4 weeks or longer for the inflammation to resolve.

Testicular Torsion

Testicular torsion is a surgical emergency requiring immediate diagnosis to avoid loss of the testicle. Torsion of the testis is rotation of the testis, which twists the blood vessels in the spermatic cord, and, therefore, impedes the arterial and venous supply to the testicle and surrounding structures in the scrotum. The patient presents with sudden pain in the testicle, developing over 1 to 2 hours, with or without a predisposing event. Nausea, lightheadedness, and swelling of the scrotum may develop. On physical examination, testicular tenderness, an elevated testis, a thickened spermatic cord, and a swollen, painful scrotum may be present. If the torsion cannot be reduced manually, surgery to untwist the spermatic cord and anchor both testes in their correct position to prevent recurrence should occur within 6 hours of the onset of symptoms in order to save the testis. After 6 hours of impaired blood supply, the risk for loss of the testicle increases.

Testicular Cancer

Although only accounting for about 1% of all cancers in men, **testicular cancer** is the most common cancer diagnosed in men between 15 and 35 years of age; approximately 8400 new cases and 380 deaths occur in the United States annually (ACS, 2009). It is the second most common malignancy in those 35 to 39 years of age. For unknown reasons, worldwide incidence of testicular tumors has more than doubled in the past 40 years. Because of advances in cancer therapy, testicular cancer is a highly treatable and usually curable form of cancer. The 5-year relative survival rate for all testicular cancers is more than 95% and approaches 99% if the cancer has not spread outside of the testes (ACS, 2009). After treatment, most patients with testicular cancer have a near-normal life expectancy.

Classification of Testicular Tumors

The testicles contain several types of cells, each of which may develop into one or more types of cancer. The type of cancer cell determines the appropriate treatment and affects the prognosis. Testicular cancer is classified as germinal or nongerminal (stromal). Secondary testicular cancers may also occur.

Germinal Tumors

Germinal tumors make up approximately 90% of all cancers of the testis; germinal tumors are further classified as seminomas or nonseminomas. These cancers grow from the germ cells that produce sperm, thus the name germinal tumors. Seminomas are slow-growing forms of testicular cancer that are usually found in men in their 30s and 40s. Although seminomas can spread to the lymph nodes, the cancer is usually localized in the testes. Nonseminomas are more common and tend to grow more quickly than seminomas. Nonseminomas are often made up of different cell

types and are identified according to the cells in which they start to grow. Nonseminoma testicular cancers include choriocarcinomas (rare), embryonal carcinomas, teratomas, and yolk sac tumors. It is crucial to distinguish between seminomas and nonseminomas because the differences affect prognosis and treatment.

Nongerminal Tumors

Nongerminal tumors account for less than 10% of testicular cancers. These cancers may develop in the supportive and hormone-producing tissues, or stroma, of the testicles. The two main types of stromal tumors are Leydig cell tumors and Sertoli cell tumors. Although these tumors infrequently spread beyond the testicle, a small number metastasize and tend to be resistant to chemotherapy and radiation therapy.

Secondary Testicular Tumors

Secondary testicular tumors are those that have metastasized to the testicle from other organs. Lymphoma is the most common cause of secondary testicular cancer. Cancers may also spread to the testicles from the prostate gland, lung, skin (melanoma), kidney, and other organs. The prognosis with these cancers is usually poor because they typically also spread to other organs. Treatment depends on the specific type of cancer (ACS, 2009).

Risk Factors

Risk factors for testicular cancer include undescended testicles (**cryptorchidism**), family history of testicular cancer, and personal history of testicular cancer (ACS, 2009; Gilligan, 2007). Other risk factors include race and ethnicity: Caucasian American men have a five times greater risk than African American men and more than two to three times greater risk than Asian, Native American, and Hispanic American men. The risk of developing testicular cancer is higher in HIV-positive men (ACS, 2009). Occupational hazards, including exposure to chemicals encountered in mining, oil and gas production, and leather processing, have been suggested as possible risk factors. No evidence has linked testicular cancer to prenatal exposure to diethylstilbestrol or to vasectomy (ACS, 2009).

Clinical Manifestations

The symptoms appear gradually, with a mass or lump on the testicle and usually painless enlargement of the testis. The patient may report heaviness in the scrotum, inguinal area, or lower abdomen. Backache (from retroperitoneal node extension), abdominal pain, weight loss, and general weakness may result from metastasis. Enlargement of the testis without pain is a significant diagnostic finding. Some testicular tumors tend to metastasize early, spreading from the testis to the lymph nodes in the retroperitoneum and to the lungs.

Assessment and Diagnostic Findings

At this time, screening for testicular cancer is not recommended; however, educating young men about testicular cancer and the need for urgent evaluation of any mass or enlargement or unexplained testicular pain is key to early detection (Gilligan, 2007). Teaching TSE, starting in

adolescence, alerts men to the importance of seeking medical attention if a testicle becomes indurated, enlarged, atrophied, nodular, or painful (Chart 49-6). TSE should be performed monthly. Testicular cancers generally grow rapidly and are easily detected against a typically smooth and homogeneous texture. Annual testicular examination by a clinician can reveal signs and lead to early diagnosis and treatment of testicular cancer. Promoting awareness of this disease is an important health promotion intervention; men should seek medical evaluation for signs or symptoms of testicular cancer without delay (Gilligan, 2007). Any suspicious testicular mass warrants prompt evaluation with a thorough history and physical examination, focusing on palpation of the affected testicle.

The tumor markers alpha-fetoprotein (AFP) and beta-human chorionic gonadotropin (beta-hCG) may be elevated in patients with testicular cancer. Tumor marker levels in the blood are used for diagnosis, staging, and monitoring the response to treatment. Blood chemistry, including lactate dehydrogenase, is also necessary.

A chest x-ray to assess for metastasis in the lungs and a transscrotal testicular ultrasound will be performed. Microscopic analysis of tissue is the only definitive way to determine if cancer is present, but it is usually performed at the time of surgery rather than as a part of the diagnostic workup to reduce the risk of promoting spread of the cancer (ACS, 2009). Inguinal orchiectomy is the standard way to establish the diagnosis of testicular cancer. Other staging tests to determine the extent of the disease in the retroperitoneum, pelvis, and chest include an abdominal/pelvic CT and chest CT (if the abdominal CT or chest x-ray is abnormal). A brain MRI and bone scan may be obtained if indicated (NCCN, 2008). Discussion of the option to bank sperm should take place prior to orchiectomy and treatment.

Medical Management

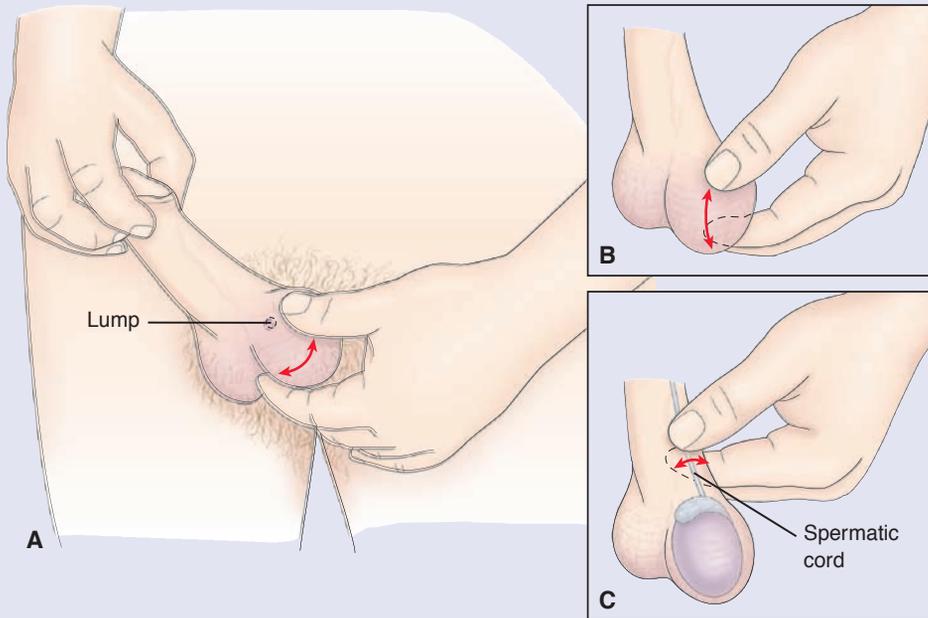

Testicular cancer, one of the most curable solid tumors, is highly responsive to treatment. Early-stage disease is curable more than 95% of the time; thus, prompt diagnosis and treatment are essential. The NCCN practice consensus guidelines for testicular cancer are used to guide diagnostic workup, primary treatment, follow-up, and salvage therapy (treatment given when the cancer does not respond to standard treatment) for both seminomas and nonseminomas (NCCN, 2008). The goals of management are to eradicate the disease and achieve a cure. Therapy is based on the cell type, the stage of the disease, and risk classification tables (determined as good, intermediate, and poor risk). Primary treatment includes removal of the affected testis by orchiectomy through an inguinal incision with a high ligation of the spermatic cord. The patient is offered the option of implantation of a testicular prosthesis during the orchiectomy. Although most patients experience no impairment of endocrine function after unilateral orchiectomy for testicular cancer, some patients have decreased hormonal levels, suggesting that the unaffected testis is not functioning normally. Retroperitoneal lymph node dissection (RPLND) may be performed after orchiectomy to diagnose and prevent lymphatic spread of the cancer. Alternatives to the more invasive open RPLND for

CHART
49-6

PATIENT EDUCATION

Testicular Self-Examination

Testicular self-examination (TSE) is to be performed once a month. The test is neither difficult nor time-consuming. A convenient time is usually after a warm bath or shower when the scrotum is more relaxed.

1. Use both hands to palpate the testis. The normal testicle is smooth and uniform in consistency.
2. With the index and middle fingers under the testis and the thumb on top, roll the testis gently in a horizontal plane between the thumb and fingers (**A**).
3. Feel for any evidence of a small lump or abnormality.
4. Follow the same procedure and palpate upward along the testis (**B**).
5. Locate and palpate the epididymis (**C**), a cordlike structure on the top and back of the testicle that stores and transports sperm. Also locate and palpate the spermatic cord.
6. Repeat the examination for the other testis, epididymis, and spermatic cord. It is normal to find that one testis is larger than the other.
7. If you find any evidence of a small, pealike lump or if the testis is swollen (possibly from an infection or tumor), consult your physician.

early-stage germ cell testicular cancer include nerve-sparing and laparoscopic RPLND, which improve sexual function and promote rapid recovery (Tanagho & McAninch, 2008). Although libido and orgasm are usually unimpaired after RPLND, ejaculatory dysfunction with resultant infertility may develop. Two thirds of men who are newly diagnosed with testicular cancer may be considering future fatherhood, and sperm quality is reduced in men with testicular cancer; therefore, sperm banking before treatment may be considered (Fossa & Dahl, 2008; Girasole, Cookson, Smith, et al., 2006). Half of patients will not recover fertility as a result of radiation therapy, cytotoxic therapy, unilateral excision of a testis, and RPLND. Counseling about fertility issues may help the patient make the appropriate choices (Brydøy, Fosså, Klepp, et al., 2005; Gospodarowicz, 2008).

Radiation therapy is more effective with seminomas than with nonseminomas. Postoperatively, radiation may be used in early-stage seminomas. It is delivered only to the affected side; the other testis is shielded from radiation to pre-

serve fertility. Radiation is also used in patients whose disease does not respond to chemotherapy and in those for whom lymph node surgery is not recommended.

Chemotherapy may be used for seminomas, nonseminomas, and advanced metastatic disease. Cisplatin (Platinol-AQ) can be used in combination with other chemotherapeutic agents, such as etoposide (Toposar), bleomycin (Blenoxane), paclitaxel (Taxol), ifosfamide (Ifex), and vinblastine (Velban), and results in a high percentage of complete remissions. With nonseminomas, aggressive surgical resection of all residual masses following chemotherapy is standard therapy. Good results may also be obtained by combining different types of treatment, including surgery, radiation therapy, and chemotherapy. Even with metastatic testicular cancer, the prognosis is favorable because of advances in treatment. However, for patients who do not respond to high-dose salvage chemotherapy, the cancer is nearly always incurable.

A patient with a history of one testicular tumor has a greater chance of developing subsequent tumors. Late

relapse of testicular cancer is currently defined as tumor recurrence more than 2 years after complete remission following primary treatment that included chemotherapy. The most common site of recurrence is the retroperitoneum. Follow-up studies include chest x-rays, excretory urography, radioimmunoassay of beta-hCG and AFP levels, and examination of lymph nodes.

Long-term side effects associated with treatment for testicular cancer include renal insufficiency from kidney damage, hearing problems, gonadal damage, peripheral neuropathy, and, rarely, secondary cancers. Management of a patient with testicular carcinoma is therapy aimed at cure followed by close monitoring to detect and promptly treat any recurrences (NCCN, 2008). Investigations of new medications, combinations of chemotherapeutic agents, and stem cell transplantation are ongoing.

Nursing Management

Nursing management includes assessment of the patient's physical and psychological status and monitoring of the patient for response to and possible effects of surgery, chemotherapy, and radiation therapy (see Chapter 16). Preoperative and postoperative care is described in Chapters 18 and 20, respectively. In addition, because the patient may have difficulty coping with his condition, issues related to body image and sexuality should be addressed.

Patients may be required to endure a long course of therapy and will need encouragement to maintain a positive attitude. Once patients complete treatment, they enter a follow-up surveillance period. Nurses educate these cancer survivors about the importance of adhering to follow-up appointments for early detection of cancer recurrence (most often occurring within 2 years posttreatment), evaluation of late effects of treatment, including secondary cancers, infertility, cardiotoxicity, neurotoxicity, nephrotoxicity, pulmonary toxicity, metabolic syndrome, and alterations in quality of life (Gospodarowicz, 2008; Zoltick, Jacobs & Vaughn, 2005). The nurse reminds the patient about the importance of performing TSE in the treated or remaining testis. The patient is encouraged to participate in healthy behaviors, including smoking cessation, healthy diet, minimization of alcohol intake, and cancer screening activities (Shinn, Basen-Engquist, Thornton, et al., 2007). Most experts agree that couples should use birth control for 18 to 24 months after the last cycle of chemotherapy (Paduch, 2006).

Hydrocele

A **hydrocele** is a collection of fluid most commonly located between the visceral and parietal layers of the tunica vaginalis of the testis, although it may also collect within the spermatic cord. This condition is the most common cause of scrotal swelling. At birth, 1 in 10 infants has a hydrocele, which usually resolves without treatment within the first year of life. Acute hydroceles primarily develop in adults older than 40 years of age; they may occur in association with inflammation (eg, radiation therapy), infection, epididymitis, local injury, or systemic infectious disease (eg,

mumps). Chronic hydroceles may occur related to the imbalance between fluid secretion and reabsorption in the tunica vaginalis. On physical examination, an easily transilluminated, painless, extratesticular mass is found. Hydrocele can be differentiated from a hernia by transillumination; a hydrocele transmits light, whereas a hernia does not. Ultrasonography is recommended for large hydroceles to differentiate them from testicular tumors.

Treatment is usually not required unless the hydrocele is large, bulky, tense, or uncomfortable; compromises testicular circulation; or causes an undesirable appearance. Treatment may involve surgical excision or needle aspiration. Surgical excision (hydrocelectomy) may be performed in an outpatient setting under general or spinal anesthesia with the goal of prevention of recurrence by excising the tunica vaginalis or sclerosing the visceral and parietal layers. Surgical excision involves resection or suturing together the two layers. A drainage tube may be required, and the patient is advised to wear a bulky dressing over the incisional site for a few days after the procedure. To reduce swelling, ice packs are applied to the scrotal area during the first 24 hours. A scrotal athletic supporter may be worn for a period of time postoperatively for comfort and support. Surgical risks include hematoma in the loose scrotal tissues, infection, or injury to the scrotum.

Needle aspiration is another option used to remove the fluid in the scrotum. Because it is common for fluid to reaccumulate, this treatment may be followed by the injection of a sclerosing agent to prevent this recurrence. This option may be used for men who are poor surgical risks. Potential risks include infection and scrotal pain.

Varicocele

A **varicocele** is an abnormal dilation of the pampiniform venous plexus and the internal spermatic vein in the scrotum (the network of veins from the testis and the epididymis that constitute part of the spermatic cord). Varicoceles occur in approximately 15% to 20% of healthy adult men and 40% of infertile men, the large majority (95%) in the left testicle. Although men may report scrotal pain, tenderness, heaviness in the inguinal area, and infertility, varicoceles are often asymptomatic.

If the varicocele is mild and fertility is not an issue, no treatment is required, and a scrotal support is usually sufficient to relieve symptoms of heaviness. If the condition results in ongoing, distressing symptoms or fertility is an issue, the varicocele can be corrected surgically. Postprocedural education and care include an ice pack applied to the scrotum for the first few hours after surgery to relieve edema, dressing removal after 48 hours, nonstrenuous exercise for the first 2 days, scrotal support, pain control, and reporting complications such as infection and hematoma.

Vasectomy

Vasectomy, or male sterilization, involves the surgical interruption of both vas deferens, which are the tubes that carry the sperm from the testicles and epididymis to the

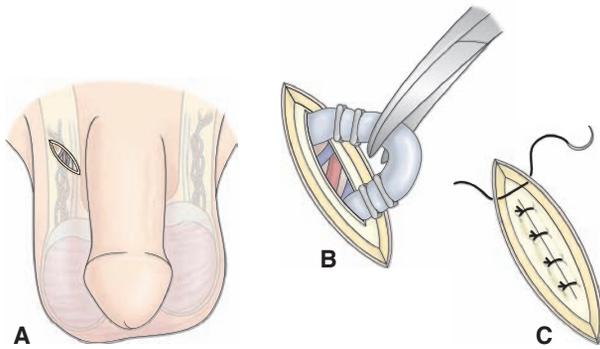

Figure 49-6 A vasectomy is a resection of the vas deferens to prevent passage of sperm from the testes to the urethra during ejaculation. **A**, An incision or small puncture is made to expose the vas deferens. **B**, The vas deferens is isolated and severed. **C**, The severed ends are occluded with ligatures or clips, or the lumen of each vas is sealed by electrocautery and the incision is sutured closed. (Suturing may not be required if a puncture approach has been used.)

seminal vesicles, to prevent fertilization of an egg after ejaculation. During the outpatient procedure, the surgeon exposes the vas deferens through a small surgical opening or puncture in the scrotum using a sharp, curved hemostat (Fig. 49-6). The vas is then ligated (cut) or cauterized (burned), with the severed ends occluded by ties or clips to seal the lumens and then placed back into the scrotum. A section of the vas deferens may or may not be removed. The spermatozoa, which are manufactured in the testes, cannot travel up the vas deferens after this surgery.

Because seminal fluid is manufactured predominantly in the seminal vesicles and prostate gland, which are unaffected by vasectomy, no noticeable decrease in the amount of ejaculate occurs (volume decreases approximately 3%), even though it contains no spermatozoa. Because the sperm cells have no exit, they are resorbed into the body. A vasectomy usually has no effect on sexual potency, erection, ejaculation, or production of male hormones and provides no protection against STDs.

Couples who were once worried about pregnancy resulting from contraceptive failure often report a decrease in concern and an increase in spontaneous sexual arousal after vasectomy. Concise and factual preoperative explanations may minimize or relieve the patient's concerns related to pain and reduced masculinity. The patient is advised that he will be sterile but that potency will not be altered after a bilateral vasectomy. On rare occasions, a spontaneous reanastomosis of the vas deferens occurs, making it possible to impregnate a partner.

Complications of vasectomy include scrotal ecchymoses and swelling, superficial wound infection, vasitis (inflammation of the vas deferens), epididymitis or epididymo-orchitis, hematomas, chronic pain, and spermatic granuloma. A spermatic granuloma is an inflammatory response to the collection of sperm leaking from the severed end of the proximal vas deferens into the scrotal tissue. A painless small lump is formed, which usually does not require surgical intervention.

Nursing Management

Nursing education focuses on self-management of swelling and discomfort postvasectomy. Applying ice bags intermittently to the scrotum for several hours after surgery can reduce swelling and relieve discomfort. The nurse advises the patient to wear snug, cotton underwear or a scrotal support for added comfort and support. Explanation of expected discoloration of the scrotal skin and superficial swelling may alleviate anxiety and concerns. These conditions may be relieved by sitz baths.

Sexual intercourse may be resumed as desired, usually after 1 week. Fertility remains for a varying time after vasectomy until the spermatozoa stored distally in the seminal vesicles have been evacuated. Sterility is often achieved after 10 to 20 ejaculations after the vasectomy procedure but may take longer. A reliable method of contraception should be used until infertility is confirmed by examination of an ejaculate specimen in the urologist's office at a follow-up appointment, usually 4 to 8 weeks after the vasectomy.

Vasovasostomy (Sterilization Reversal)

Although men choosing to undergo vasectomy should not consider the surgical procedure as reversible, microsurgical techniques can be used to reverse a vasectomy (vasovasotomy) and restore patency to the vas deferens. Many men have sperm in their ejaculate after a reversal, and 50% to 70% can impregnate a partner. The success of the procedure depends on the vasectomy method performed and the amount of time since the vasectomy. The procedure can be very costly, is not covered by insurance, is not permanent with occlusion of the vas recurring 2 or more years after vasovasotomy, and results in sperm counts at lower than prevasectomy levels.

Semen Cryopreservation (Sperm Banking)

Storing fertile semen in a sperm bank before a vasectomy is an option for men who experience a major life change and may want to father a child at a later time. In addition, if a man is about to undergo a procedure or treatment (eg, radiation therapy to the pelvis, chemotherapy, orchiectomy) that may affect his fertility, sperm banking may be considered. This procedure usually requires several visits to the facility where the sperm is stored under hypothermic conditions. The semen is obtained by masturbation and collected in a sterile container for storage. Insurance carriers rarely cover the cost of semen collection and banking. The costs of semen cryopreservation vary according to facility, method of sperm retrieval, number of specimens, and length of time in storage, making the process cost-prohibitive for some men.

CONDITIONS AFFECTING THE PENIS

Phimosis

Phimosis is a condition in which the foreskin (prepuce) cannot be retracted over the glans in uncircumcised males. With the trend away from routine circumcision of newborns,

early instruction should be given to parents about cleansing the foreskin and the need for retraction to cleanse the glans. If the glans is not cleaned, secretions accumulate, causing inflammation of the glans penis (balanitis), which can later lead to adhesions and fibrosis. Phimosis often develops in adults as a result of inflammation, edema, and constriction because of poor hygiene or underlying medical conditions such as diabetes mellitus. The thickened secretions (smegma) can become encrusted with urinary salts and calcify, forming calculi in the prepuce and increasing the risk of penile carcinoma. Treatment for phimosis secondary to inflammation is the application of steroidal cream to the foreskin to soften and correct the narrowness, resulting in decreased constriction. Although phimosis is the most common indication for adult circumcision, it is rarely necessary to surgically correct the condition by loosening or removing the foreskin.

Paraphimosis is a condition in which the foreskin, once retracted over the glans, cannot be returned to its usual position. Chronic inflammation under the foreskin leads to formation of a tight ring of skin when the foreskin is retracted behind the glans, causing venous congestion, edema, and enlargement of the glans, which makes the condition worse. As the condition progresses, arterial occlusion and necrosis of the glans may occur. Paraphimosis usually can be treated by firmly compressing the glans for 5 minutes to reduce the tissue edema and size and then pushing the glans back while simultaneously moving the foreskin forward (manual reduction). The constricting skin ring may require incision under local anesthesia. Circumcision is usually indicated after the inflammation and edema subside (Tanagho & McAninch, 2008).

Cancer of the Penis

Penile cancer is rare, occurring in less than 1% of cancers among men in the United States. It accounts for an estimated 1290 new cancer cases and 300 expected deaths each year (ACS, 2009). The 5-year survival rates for cancer localized to the penis approaches 80%, but this statistic drops to 52% if the lymph nodes are involved and to 18% if the cancer has spread beyond the inguinal lymph nodes (Tanagho & McAninch, 2008). Penile cancer is much more common in some parts of Africa and South America, where it accounts for up to 10% of cancers in men. Because the penis contains different cell types, penile cancer can arise in each type of cell, which determines the prognosis. Types of penile cancer include squamous cell carcinoma (most common; 95% of cases), epidermoid penile cancer, verrucous carcinoma, adenocarcinoma, in situ carcinomas (erythroplasia of Queyrat and Bowen's disease), basal cell penile cancer, melanoma, and sarcomas (Blanco-Yarosh, 2007). Several risk factors for penile cancer have been identified, including lack of circumcision, poor genital hygiene, phimosis, HPV, smoking, ultraviolet light treatment of psoriasis on the penis, increasing age (two thirds of cases occur in men older than 65 years of age), lichen sclerosus, and balanitis xerotica obliterans. However, the exact cause remains unclear.

Because of the rarity of penile cancer, there has been little improvement in diagnostic and staging tests, understanding of risk factors, and development of treatment modalities.

Clinical Manifestations

The penile lesion usually alerts the patient to the presence of penile cancer; however, a man may delay seeking treatment for more than a year because of embarrassment, fear, or lack of understanding. Common clinical presentations are a painless lump, ulcer, or wartlike growth on the skin of the penis; a change in skin color such as a red rash, bluish growths, or whitish patches; and malodorous and persistent discharge in late stages.

Assessment and Diagnostic Findings

Penile cancer involves the glans most frequently (48%), followed by lesions of the foreskin (21%), the coronal sulcus (6%), the penile shaft (less than 2%), the urethra, and regional or distant lymph nodes (Wein, et al., 2007). A thorough physical examination is necessary, including assessment and palpation of the penis and the inguinal lymph nodes. The size, location, borders, consistency, fixation, and character and time of onset of the penile lesions should be noted. Incisional or excisional biopsy is performed to determine the cell types of the penile cancer. Further staging tests using ultrasonography, MRI, or CT may be obtained to determine the extent of local lesions, if metastatic disease is present, and treatment options.

Prevention

The best way to reduce the risk of penile cancer is to avoid known risk factors whenever possible (ACS, 2009). Avoidance of sexual practices that are likely to result in HPV infection may reduce the risk of penile cancer. Gardasil, a vaccine that protects against infection with HPV, the cause of 90% of genital warts, is being evaluated for possible use in males. Although uncircumcised men have a greater incidence of penile cancer than circumcised men, the more important factor in preventing penile cancer is good genital hygiene. Circumcision is not recommended as a prevention strategy (ACS, 2009).

Medical Management

Treatment varies depending on the type and stage of penile cancer, location of the lesion, overall physical health, and personal preferences about treatments and side effects. During the past 25 years, therapeutic options have largely remained unchanged (Busby & Pettaway, 2005). The goal of treatment in invasive penile cancer is complete excision with adequate margins. Surgery is the most common treatment method used in all forms of the disease. Depending on the stage and invasiveness of the cancer, therapeutic options may include simple excision, electrodesiccation and curettage, cryosurgery, Mohs' surgery (microscopically controlled surgery), yttrium aluminum garnet (YAG) laser surgery, wide local excision, circumcision, and surgical removal of part of the penis or the entire penis (penectomy). Organ-sparing surgical approaches are

preferable. Partial penectomy is preferred to total penectomy because patients can then participate in sexual intercourse, stand for urination, and maintain cosmesis. Modern reconstructive surgical techniques are providing more options for patients. The shaft of the penis can still respond to sexual arousal with an erection and has the sensory capacity for orgasm and ejaculation. Total penectomy is indicated if the tumor is not amenable to conservative treatment. After a total penectomy, the patient may still experience orgasm with stimulation of the perineum and scrotal area.

Topical chemotherapy with 5-fluorouracil cream or biologic therapy may also be effective. Radiation therapy is used to treat small squamous cell carcinomas of the penis and for palliation in advanced tumors or cases of lymph node metastasis.

Penile cancer spreads primarily to the inguinal lymph nodes; thus, appropriate lymph node management plays a significant role in survival. Because enlarged inguinal lymph nodes are caused by inflammation in 50% of cases, patients who present with enlarged lymph nodes should undergo treatment of the primary lesion followed by a 4- to 6-week course of oral broad-spectrum antibiotics. Persistent enlarged lymph nodes after antibiotic therapy should be considered to be metastatic disease and treated with either a sentinel lymph node biopsy (to determine presence of cancer) or with bilateral inguinal and PLND. If extensive pelvic lymph node involvement is present, the patient should receive adjuvant or neoadjuvant chemotherapy and postoperative radiation therapy (Micali, Nasca, Innocenzi, et al., 2006).

Priapism

Priapism, a relatively uncommon disorder, is defined as a persistent penile erection that may or may not be related to sexual stimulation. The penis becomes large, hard, and painful. Priapism results from either neural or vascular causes, including sickle cell disease, leukemic cell infiltration, polycythemia, spinal cord tumors or injury, and tumor invasion of the penis or its vessels. It may also occur with use of vasoactive agents that affect the central nervous system, antihypertensive agents, antipsychotic and antidepressant medications, substances injected into the penis to treat erectile dysfunction, alcohol, and cocaine. There are three forms of priapism: ischemic (veno-occlusive; low flow), nonischemic (high flow), and stuttering (intermittent).

The ischemic form, which is described as nonsexual, persistent erection with little or no cavernous blood flow, must be treated promptly to prevent permanent damage to the penis. The goal of therapy is to improve venous drainage of the corpora cavernosa to prevent ischemia, fibrosis, and impotence. The initial treatment is directed at relieving the erection, preventing penile damage and simultaneously treating the underlying disease. Recommended treatment is aspiration of the corpora cavernosa (with or without irrigation) or intracavernous injection of sympathomimetics (eg, phenylephrine). Repeated injections may be needed to resolve priapism. Surgical shunts are used to reestablish penile

circulation if repeated injections of the sympathomimetic are ineffective (Burnett & Bivalacqua, 2007).

Nonischemic priapism and stuttering are generally not considered emergencies and often resolve without treatment. Conservative treatment (eg, application of ice and site-specific compression to the injury) may be used. If repeated episodes occur, surgical shunting is considered. Patients with the intermittent form of priapism may be instructed in intracavernosal self-injection of phenylephrine.

Peyronie's Disease

Peyronie's disease is an acquired, benign condition that involves the buildup of fibrous plaques in the sheath of the corpus cavernosum. These plaques are not visible when the penis is relaxed. However, when the penis is erect, curvature occurs that can be painful and can make sexual intercourse difficult or impossible. Peyronie's disease typically begins between 45 and 65 years of age. Medical management in the first year of active disease includes systemic, topical, intralesional, or extracorporeal techniques, with 50% of men experiencing spontaneous resolution. Surgical removal of mature plaques is used to treat severe disease. Patients should be fully informed of available treatment options and their likely outcomes (Taylor & Levine, 2007).

Urethral Stricture

Urethral stricture is a condition in which a section of the urethra is narrowed. It can occur congenitally or from a scar along the urethra. Traumatic injury to the urethra (eg, from instrumentation or infections) can result in strictures that restrict urine flow and decrease the urinary stream, leading to spraying or double stream, postvoiding dribbling, and dilation of the proximal urethra and prostatic ducts. Prostatitis is a common complication. Treatment involves dilation of the urethra or, in severe cases, urethrotomy (surgical removal of the stricture). Antimicrobial agents are necessary for resolution of UTIs, followed by long-term prophylactic therapy until the stricture is corrected. Treatment should not be considered successful until at least 1 year has passed, because strictures may recur anytime during that period (Tanagho & McAninch, 2008).

Circumcision

Circumcision is the surgical excision of the foreskin (prepuce) of the glans penis. One of the oldest surgical procedures, it is the fifth most common procedure performed in the United States. In adults, circumcision may be indicated as part of treatment for phimosis, paraphimosis, and recurrent infections of the glans and foreskin. It also may be performed at the patient's request.

The primary method of circumcision in adults is surgical excision. Postoperatively, a petrolatum (Vaseline) gauze dressing is applied and changed as indicated. The patient is observed for bleeding. Because considerable pain may occur

after circumcision, analgesic agents are administered as needed.

CRITICAL THINKING EXERCISES

1 One of your patients, a 59-year-old man who has diabetes and a history of cardiac disease, asks about various treatments of erectile dysfunction. How would you respond, and what information would you give him about medications and nonpharmacologic methods to treat erectile dysfunction? How would your approach differ if your patient was a 32-year-old man with sexual dysfunction caused by multiple sclerosis and who has limited hand dexterity?

EBP 2 During a community health fair, you are approached by a 44-year-old African American man who asks you about his risk of prostate cancer and the risk to his 20-year-old son. His father has been recently diagnosed with prostate cancer and is scheduled for surgery the following week. How would you address this issue with him at the health fair? Provide a rationale for your plan. How would your responses differ if you saw the patient during an office visit to follow-up an elevated prostate-specific antigen (PSA) test result? What health counseling is indicated for the man and his son? What is the evidence base for the health advice you develop?

EBP 3 A 63-year-old biology professor has been diagnosed with prostate cancer. His Gleason score is 6 and he is currently undergoing tests to determine if there is any metastasis of the cancer beyond the prostate gland. He is struggling to make a decision about treatment and has asked for further information about strategies that he has discussed with his physician: radical prostatectomy, suprapubic prostatectomy, and robotic-assisted radical prostatectomy. Compare the advantages and disadvantages of these three treatment strategies with watchful waiting. Identify the evidence for each of these strategies and how you would explain them to the patient.

4 A 26-year-old patient is scheduled for surgery to treat testicular cancer. He is depressed and apprehensive about the outcomes of surgery related to sexual function and fertility. Describe your approach to caring for this patient preoperatively and postoperatively. What recommendations for follow-up health care and preventive screening are relevant for this patient?

Immunologic Function

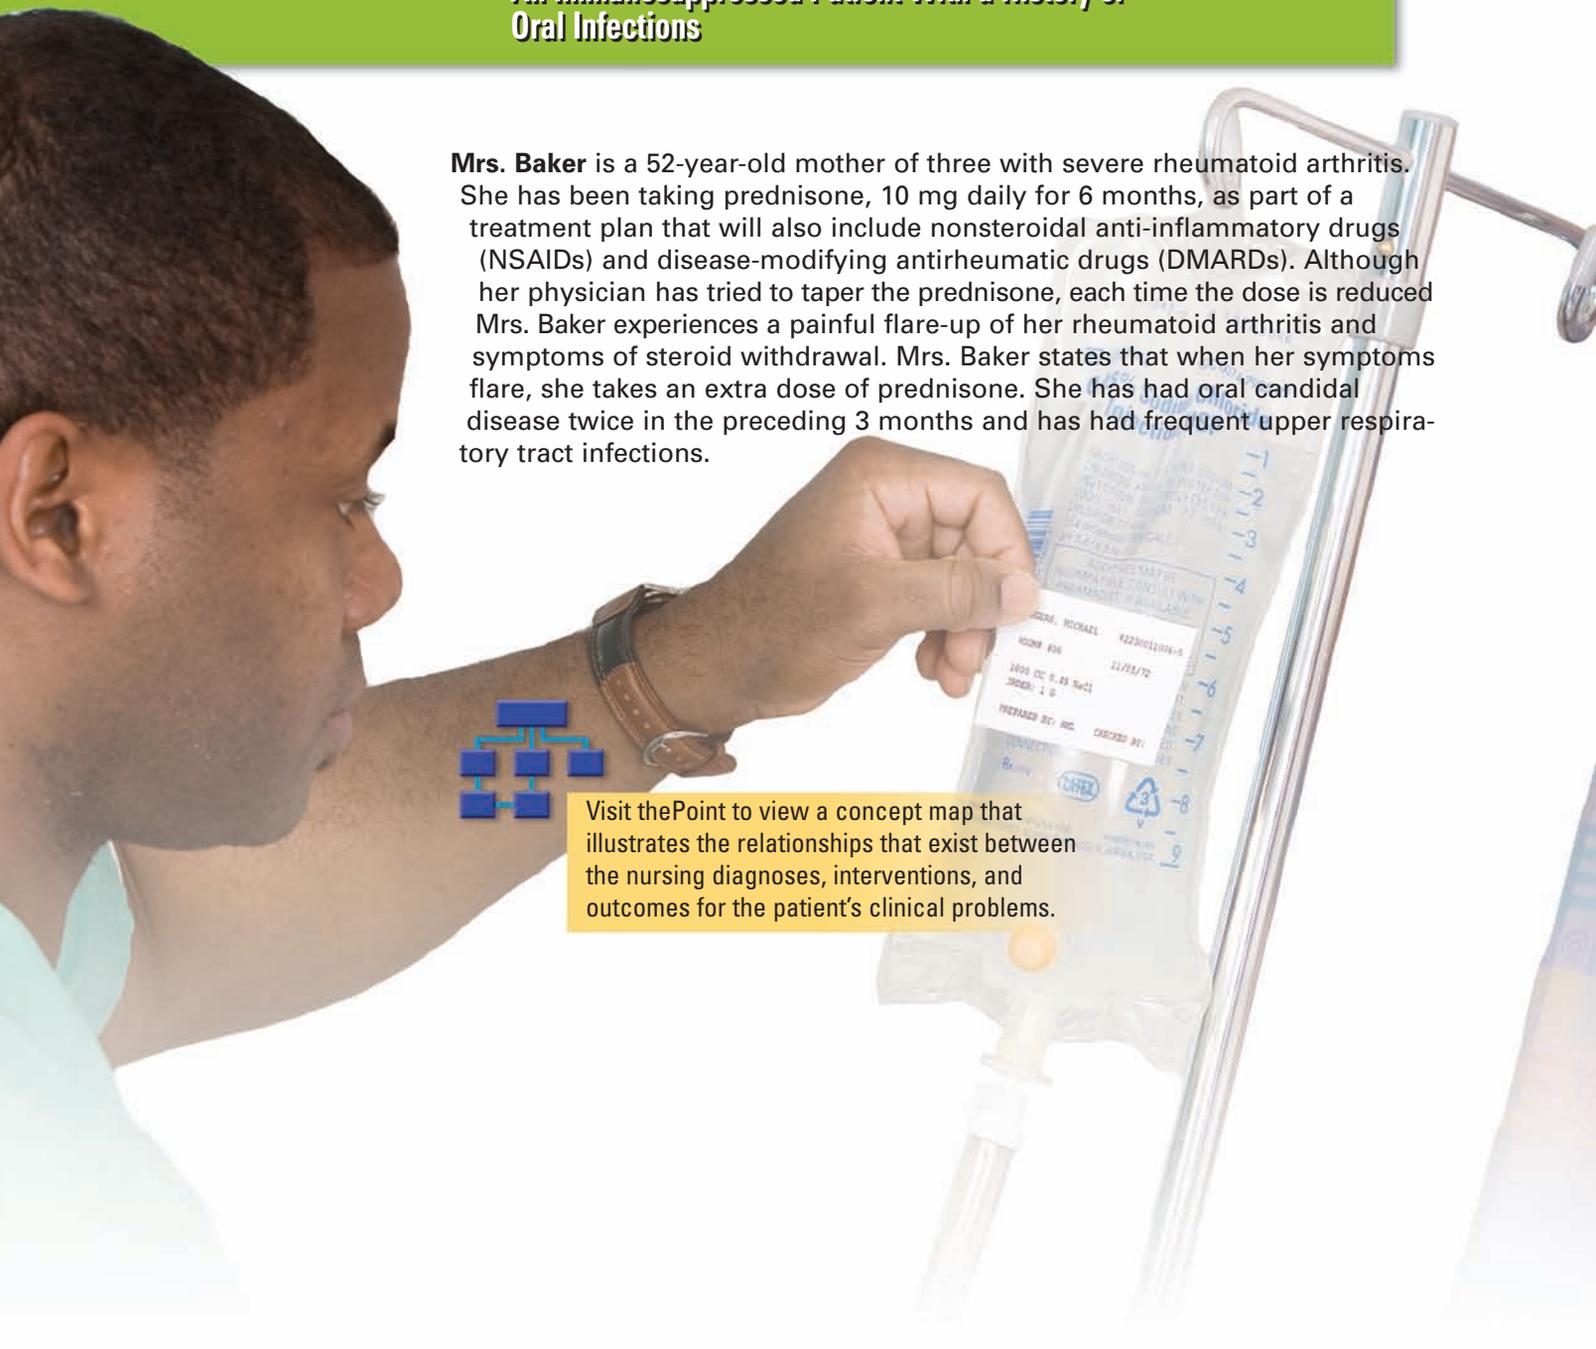

Case Study • Applying Concepts From NANDA, NIC, and NOC

An Immunosuppressed Patient With a History of Oral Infections

Mrs. Baker is a 52-year-old mother of three with severe rheumatoid arthritis. She has been taking prednisone, 10 mg daily for 6 months, as part of a treatment plan that will also include nonsteroidal anti-inflammatory drugs (NSAIDs) and disease-modifying antirheumatic drugs (DMARDs). Although her physician has tried to taper the prednisone, each time the dose is reduced Mrs. Baker experiences a painful flare-up of her rheumatoid arthritis and symptoms of steroid withdrawal. Mrs. Baker states that when her symptoms flare, she takes an extra dose of prednisone. She has had oral candidal disease twice in the preceding 3 months and has had frequent upper respiratory tract infections.

chapter 50

Assessment of Immune Function

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

- 1 Describe the body's general immune responses.
- 2 Discuss the stages of the immune response.
- 3 Differentiate between cellular and humoral immune responses.
- 4 Describe the effects of selected variables on function of the immune system.
- 5 Use assessment parameters for determining the status of patients' immune function.

GLOSSARY

agglutination: clumping effect occurring when an antibody acts as a cross-link between two antigens

antibody: a protein substance developed by the body in response to and interacting with a specific antigen

antigen: substance that induces the production of antibodies

antigenic determinant: the specific area of an antigen that binds with an antibody combining site and determines the specificity of the antigen-antibody reaction

apoptosis: programmed cell death that results from the digestion of deoxyribonucleic acid by endonucleases

B cells: cells that are important for producing a humoral immune response

cellular immune response: the immune system's third line of defense, involving the attack of pathogens by T cells

complement: series of enzymatic proteins in the serum that, when activated, destroy bacteria and other cells

cytokines: generic term for nonantibody proteins that act as intercellular mediators, as in the generation of immune response

cytotoxic T cells: lymphocytes that lyse cells infected with virus; also play a role in graft rejection

epitope: any component of an antigen molecule that functions as an antigenic determinant by permitting the attachment of certain antibodies

GLOSSARY (Continued)

genetic engineering: emerging technology designed to enable replacement of missing or defective genes

helper T cells: lymphocytes that attack foreign invaders (antigens) directly

humoral immune response: the immune system's second line of defense; often termed the antibody response

immune response: the coordinated response of the components of the immune system to a foreign agent or organism

immune system: the collection of organs, cells, tissues, and molecules that mediate the immune response

immunity: the body's specific protective response to a foreign agent or organism; resistance to disease, specifically infectious diseases

immunopathology: study of diseases resulting in dysfunctions within the immune system

immunoregulation: complex system of checks and balances that regulates or controls immune responses

interferons: proteins formed when cells are exposed to viral or foreign agents; capable of activating other components of the immune system

lymphokines: substances released by sensitized lymphocytes when they come in contact with specific antigens

memory cells: cells that are responsible for recognizing antigens from previous exposure and mounting an immune response

natural killer (NK) cells: lymphocytes that defend against microorganisms and malignant cells

null lymphocytes: lymphocytes that destroy antigens already coated with the antibody

opsonization: the coating of antigen-antibody molecules with a sticky substance to facilitate phagocytosis

phagocytic cells: cells that engulf, ingest, and destroy foreign bodies or toxins

phagocytic immune response: the immune system's first line of defense, involving white blood cells that have the ability to ingest foreign particles

stem cells: precursors of all blood cells; reside primarily in bone marrow

suppressor T cells: lymphocytes that decrease B-cell activity to a level at which the immune system is compatible with life

T cells: cells that are important for producing a cellular immune response

The term **immunity** refers to the body's specific protective response to a foreign agent or organism. The **immune system** functions as the body's defense mechanism against invasion and allows a rapid response to foreign substances in a specific manner. Genetic and cellular responses result. Any qualitative or quantitative change in the components of the immune system can produce profound effects on the integrity of the human organism. Immune function is affected by a variety of factors, such as central nervous system integrity, general physical and emotional status, medications, dietary patterns, and the stress of illness, trauma, or surgery. Dysfunctions involving the immune system occur across the lifespan. Many are genetically based; others are acquired. Immune memory is a property of the immune system that provides protection against harmful microbial agents despite the timing of re-exposure to the agent. Tolerance is the mechanism by which the immune system is programmed to eliminate foreign substances such as microbes, toxins, and cellular mutations but maintains the ability to accept self-antigens. Some credence is given to the concept of surveillance, in which the immune system is in a perpetual state of vigilance, screening and rejecting any invader that is recognized as foreign to the host. The term **immunopathology** refers to the study of diseases that result from dysfunctions within the immune system. Disorders of the immune system may stem from excesses or deficiencies of immunocompetent cells, alterations in the function of these cells, immunologic attack on self-antigens, or inappropriate or exaggerated responses to specific antigens (Table 50-1).

A growing number of patients with immunologic disorders live to adulthood. Thus, nurses in many practice settings need to understand how the immune system functions as well as immunopathologic processes. In addition, knowledge about assessment and care of people with immunologic disorders enables nurses to make appropriate management decisions.

Anatomic and Physiologic Overview

Anatomy of the Immune System

The immune system is composed of an integrated collection of various cell types, each with a designated function in defending against infection and invasion by other organisms.

Table 50-1 IMMUNE SYSTEM DISORDERS

Disorder	Description
Autoimmunity	Normal protective immune response paradoxically turns against or attacks the body, leading to tissue damage
Hypersensitivity	Body produces inappropriate or exaggerated responses to specific antigens
Gammopathies	Immunoglobulins are overproduced
Immune deficiencies	
Primary	Deficiency results from improper development of immune cells or tissues; usually congenital or inherited
Secondary	Deficiency results from some interference with an already developed immune system; usually acquired later in life

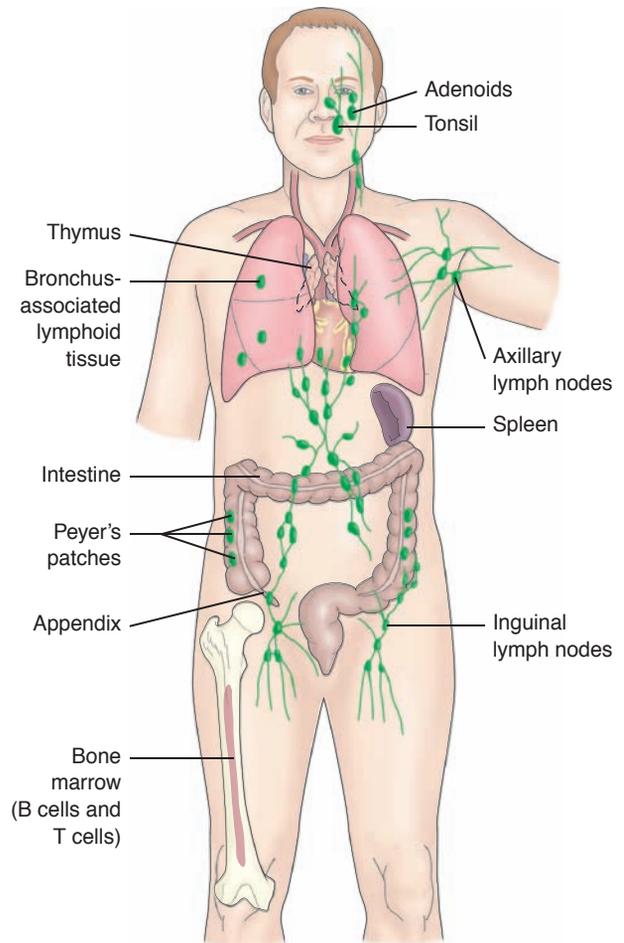

Figure 50-1 Central and peripheral lymphoid organs, tissues, and cells. Adapted from Porth, C. M. & Matfin, G. (2009). *Pathophysiology: Concepts of altered health states* (8th ed., p. 371). Philadelphia: Lippincott Williams & Wilkins.

Supporting this system are molecules that are responsible for the interactions, modulations, and regulation of the system. These molecules and cells participate in specific interactions with immunogenic **epitopes** (antigenic determinants) present on foreign materials, initiating a series of actions in a host, including the inflammatory response, the lysis of microbial agents, and the disposal of foreign toxins. The major components of the immune system include central and peripheral organs, tissues, and cells (Fig. 50-1).

Bone Marrow

The white blood cells (WBCs) involved in immunity are produced in the bone marrow (Fig. 50-2). Like other blood cells, lymphocytes are generated from **stem cells**, which are undifferentiated cells. There are two types of lymphocytes—B lymphocytes (**B cells**) and T lymphocytes (**T cells**) (Fig. 50-3). B lymphocytes mature in the bone marrow and then enter the circulation. T lymphocytes move from the bone marrow to the thymus, where they mature into several kinds of cells with different functions.

Lymphoid Tissues

The spleen, composed of red and white pulp, acts somewhat like a filter. The red pulp is the site where old and injured

Physiology ■ Pathophysiology

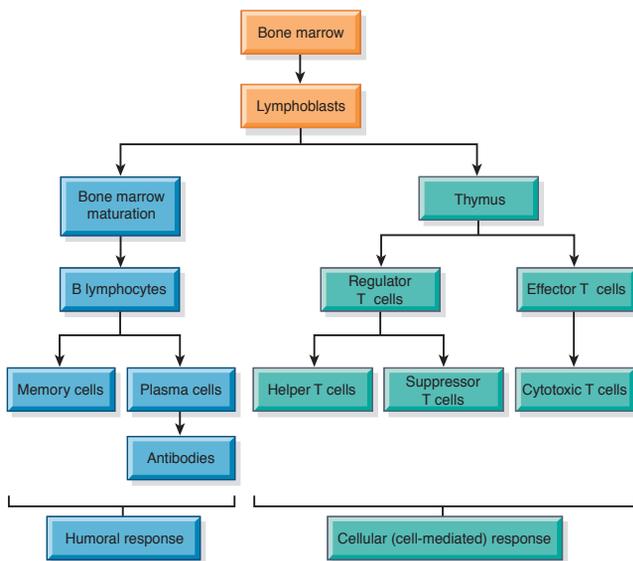

Figure 50-2 Development of cells of the immune system.

red blood cells (RBCs) are destroyed. The white pulp contains concentrations of lymphocytes. The lymph nodes, which are connected by lymph channels and capillaries, are distributed throughout the body. They remove foreign material from the lymph system before it enters the bloodstream. The lymph nodes also serve as centers for immune

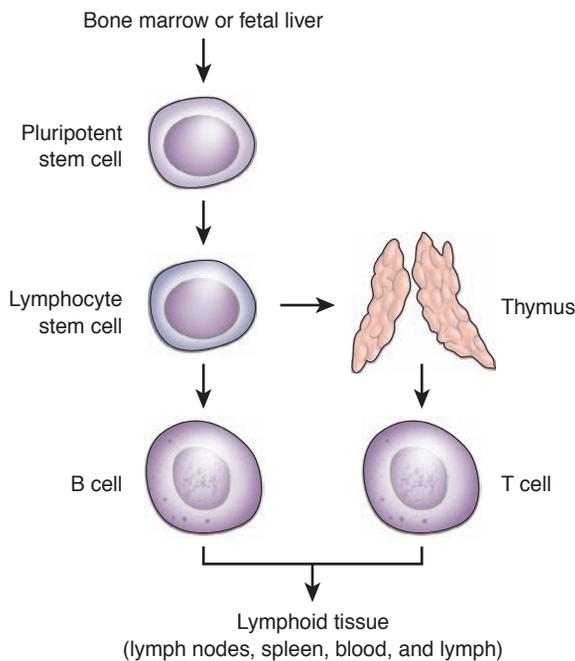

Figure 50-3 Lymphocytes originate from stem cells in the bone marrow. B lymphocytes mature in the bone marrow before entering the bloodstream, whereas T lymphocytes mature in the thymus, where they also differentiate into cells with various functions. Redrawn from Porth, C. M. & Matfin, G. (2009). *Pathophysiology: Concepts of altered health states* (8th ed., p. 362). Philadelphia: Lippincott Williams & Wilkins.

cell proliferation. The remaining lymphoid tissues contain immune cells that defend the body's mucosal surfaces against microorganisms (Levinson, 2008).

Function of the Immune System

The basic function of the immune system is to remove foreign antigens such as viruses and bacteria to maintain homeostasis. There are two general types of immunity, natural (innate) and acquired (adaptive). Natural immunity or nonspecific immunity is present at birth. Acquired or specific immunity develops after birth. Each type of immunity has a distinct role in defending the body against harmful invaders, but the various components are usually interdependent (Levinson, 2008).

Natural Immunity

Natural immunity, which is nonspecific, provides a broad spectrum of defense against and resistance to infection. It is considered the first line of host defense following antigen exposure, because it protects the host without “remembering” prior contact with an infectious agent (Kin & Sanders, 2006). Responses to a foreign invader are very similar from one encounter to the next, regardless of the number of times the invader is encountered. Natural (innate) immunity co-ordinates the initial response to pathogens through the production of cytokines and other effector molecules, which either activate cells for control of the pathogen (by elimination) or promote the development of the acquired **immune response**. The cells involved in this response are monocytes, macrophages, dendritic cells, **natural killer (NK) cells**, basophils, eosinophils, and granulocytes. The early events in this process are critical in determining the nature of the adaptive immune response. Natural immune mechanisms can be divided into two stages: immediate (generally occurring within 4 hours) and delayed (occurring between 4 and 96 hours after exposure) (Madoff & Kasper, 2008).

White Blood Cell Action

Cellular response is key to the effective initiation of the immune response. WBCs, or leukocytes, participate in both the natural and the acquired immune responses. Granular leukocytes, or granulocytes (so called because of granules in their cytoplasm), fight invasion by foreign bodies or toxins by releasing cell mediators, such as histamine, bradykinin, and prostaglandins, and engulfing the foreign bodies or toxins. Granulocytes include neutrophils, eosinophils, and basophils.

Neutrophils (polymorphonuclear leukocytes [PMNs]) are the first cells to arrive at the site where inflammation occurs. Eosinophils and basophils, other types of granulocytes, increase in number during allergic reactions and stress responses. Nongranular leukocytes include monocytes or macrophages (referred to as histiocytes when they enter tissue spaces) and lymphocytes. Monocytes also function as **phagocytic cells**, engulfing, ingesting, and destroying greater numbers and quantities of foreign bodies or toxins than granulocytes do. Lymphocytes, consisting of B cells and T cells, play major roles in humoral and cell-mediated

immune responses. About 60% to 70% of lymphocytes in the blood are T cells, and about 10% to 20% are B cells (Abbas, Lichtman & Baker, 2008).

Inflammatory Response

The inflammatory response is a major function of the natural immune system that is elicited in response to tissue injury or invading organisms. Chemical mediators assist this response by minimizing blood loss, walling off the invading organism, activating phagocytes, and promoting formation of fibrous scar tissue and regeneration of injured tissue. The inflammatory response (discussed further in Chapter 6) is facilitated by physical and chemical barriers that are part of the human organism.

Physical and Chemical Barriers

Activation of the natural immunity response is enhanced by processes inherent in physical and chemical barriers. Physical surface barriers include intact skin, mucous membranes, and cilia of the respiratory tract, which prevent pathogens from gaining access to the body. The cilia of the respiratory tract, along with coughing and sneezing responses, filter and clear pathogens from the upper respiratory tract before they can invade the body further. Chemical barriers, such as mucus, acidic gastric secretions, enzymes in tears and saliva, and substances in sebaceous and sweat secretions, act in a nonspecific way to destroy invading bacteria and fungi. Viruses are countered by other means, such as interferon (see discussion later in chapter).

Immune Regulation

Regulation of the immune response involves balance and counterbalance. Dysfunction of the natural immune system can occur when the immune components are inactivated or when they remain active long after their effects are beneficial. A successful immune response eliminates the responsible antigen. If an immune response fails to develop and clear an antigen sufficiently, the host is considered to be immunocompromised or immunodeficient. If it is overtly robust or misdirected, allergies, asthma, or autoimmune disease results. The immune system's recognition of one's own tissues as "foreign" rather than as self is the basis of many autoimmune disorders. Despite the fact that the immune response is critical to the prevention of disease, it must be well controlled to curtail immunopathology. Most microbial infections induce an inflammatory response mediated by T cells and cytokines, which, in excess, can cause tissue damage. Therefore, regulatory mechanisms must be in place to suppress or halt the immune response. This is mainly achieved by the production of cytokines and transformation of growth factor that inhibits macrophage activation. In some cases, T-cell activation is so overwhelming that these mechanisms fail, and pathology develops. Ongoing research on **immunoregulation** holds the promise of preventing graft rejection and aiding the body in eliminating cancerous or infected cells (Kin & Sanders, 2006). Although natural immunity can effectively combat infections, many pathogenic microbes have evolved that resist natural immunity. Acquired immunity is necessary to defend against these resistant agents.

Acquired Immunity

Acquired (adaptive) immunity usually develops as a result of prior exposure to an antigen through immunization (vaccination) or by contracting a disease, both of which generate a protective immune response. Weeks or months after exposure to the disease or vaccine, the body produces an immune response that is sufficient to defend against the disease on re-exposure. In contrast to the rapid but nonspecific natural immune response, this form of immunity relies on the recognition of specific foreign antigens. The acquired immune response is broadly divided into two mechanisms: (1) the cell-mediated response, involving T-cell activation, and (2) effector mechanisms, involving B-cell maturation and production of antibodies.

The two types of acquired immunity are known as active and passive and are strongly interrelated. Active acquired immunity refers to immunologic defenses developed by the person's own body. This immunity typically lasts many years or even a lifetime. Passive acquired immunity is temporary immunity transmitted from a source outside the body that has developed immunity through previous disease or immunization. Examples are immune globulin or immunity resulting from the transfer of antibodies from the mother to an infant in utero or through breast-feeding. Active and passive acquired immunity involve humoral and cellular (cell-mediated) immunologic responses (described later).

Response to Invasion

When the body is invaded or attacked by bacteria, viruses, or other pathogens, it has three means of defense:

- The phagocytic immune response
- The humoral or antibody immune response
- The cellular immune response

The first line of defense, the **phagocytic immune response**, primarily involves the WBCs (granulocytes and macrophages), which have the ability to ingest foreign particles and destroy the invading agent; eosinophils are only weakly phagocytic. Phagocytes also remove the body's own dying or dead cells. Cells in necrotic tissue that are dying release substances that trigger an inflammatory response. **Apoptosis**, or programmed cell death, is the body's way of destroying worn-out cells such as blood or skin cells or cells that need to be renewed.

A second protective response, the **humoral immune response** (sometimes called the **antibody response**), begins with the B lymphocytes, which can transform themselves into plasma cells that manufacture antibodies. These antibodies are highly specific proteins that are transported in the bloodstream and attempt to disable invaders. The third mechanism of defense, the **cellular immune response**, also involves the T lymphocytes, which can turn into special cytotoxic (or killer) T cells that can attack the pathogens.

The structural part of the invading or attacking organism that is responsible for stimulating antibody production is called an **antigen** (or an immunogen). For example, an antigen can be a small patch of proteins on the outer surface of a microorganism. Not all antigens are naturally immunogenic; some must be coupled to other molecules to stimulate the immune response. A single bacterium or large molecule, such as a diphtheria or tetanus toxin, may have several

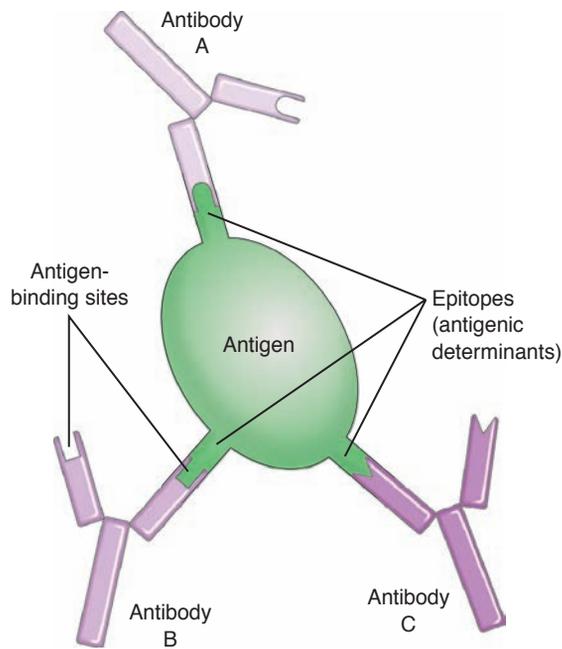

Figure 50-4 Complement-mediated immune responses. Redrawn from Porth, C. M. & Matfin, G. (2009). *Pathophysiology: Concepts of altered health states* (8th ed.). Philadelphia: Lippincott Williams & Wilkins.

antigens, or markers, on its surface, thus inducing the body to produce a number of different antibodies. Once produced, an antibody is released into the bloodstream and carried to the attacking organism. There, it combines with the antigen, binding with it like an interlocking piece of a jigsaw puzzle (Fig. 50-4). There are four well-defined stages in an immune response: recognition, proliferation, response, and effector (Fig. 50-5).

Recognition Stage

Recognition of antigens as foreign, or non-self, by the immune system is the initiating event in any immune response. Recognition involves the use of lymph nodes and lymphocytes for surveillance. Lymph nodes are widely distributed internally throughout the body and in the circulating blood, as well as externally near the body's surfaces. They continuously discharge small lymphocytes into the bloodstream. These lymphocytes patrol the tissues and vessels that drain the areas served by that node. Lymphocytes recirculate from the blood to lymph nodes and from the lymph nodes back into the bloodstream, in a continuous circuit. The exact way in which they recognize antigens on foreign surfaces is not known; however, recognition is thought to depend on specific receptor sites on the surface of the lymphocytes. Macrophages play an important role in helping the circulating lymphocytes process the antigens. Both macrophages and neutrophils have receptors for antibodies and complement; as a result, they coat microorganisms with antibodies, complement, or both, thereby enhancing phagocytosis.

In a streptococcal throat infection, for example, the streptococcal organism gains access to the mucous membranes of the throat. A circulating lymphocyte moving

through the tissues of the throat comes in contact with the organism. The lymphocyte recognizes the antigens on the microbe as different (non-self) and the streptococcal organism as antigenic (foreign). This triggers the second stage of the immune response—proliferation.

Proliferation Stage

The circulating lymphocytes containing the antigenic message return to the nearest lymph node. Once in the node, these sensitized lymphocytes stimulate some of the resident T and B lymphocytes to enlarge, divide, and proliferate. T lymphocytes differentiate into cytotoxic (or killer) T cells, whereas B lymphocytes produce and release antibodies. Enlargement of the lymph nodes in the neck in conjunction with a sore throat is one example of the immune response.

Response Stage

In the response stage, the differentiated lymphocytes function in either a humoral or a cellular capacity. This stage begins with the production of antibodies by the B lymphocytes in response to a specific antigen. The cellular response stimulates the resident lymphocytes to become cells that attack microbes directly rather than through the action of antibodies. These transformed lymphocytes are known as cytotoxic (killer) T cells.

Viral rather than bacterial antigens induce a cellular response. This response is manifested by the increasing number of T lymphocytes (lymphocytosis) seen in the blood tests of people with viral illnesses such as infectious mononucleosis. (Cellular immunity is discussed in further detail later in this chapter.) Most immune responses to antigens involve both humoral and cellular responses, although one usually predominates. For example, during transplant rejection, the cellular response predominates, whereas in the bacterial pneumonias and sepsis, the humoral response plays the dominant protective role (Chart 50-1).

Effector Stage

In the effector stage, either the antibody of the humoral response or the cytotoxic (killer) T cell of the cellular response reaches and connects with the antigen on the surface of the foreign invader. This initiates activities involving interplay of antibodies (humoral immunity), complement, and action by the cytotoxic T cells (cellular immunity).

Humoral Immune Response

The humoral response is characterized by the production of antibodies by B lymphocytes in response to a specific antigen. While B lymphocytes are responsible for the production of antibodies, both the macrophages of natural immunity and the special T lymphocytes of cellular immunity are involved in recognition.

Antigen Recognition

Several theories explain the mechanisms by which B lymphocytes recognize the invading antigen and respond by producing antibodies. It is known that B lymphocytes recognize and respond to invading antigens in more than one way.

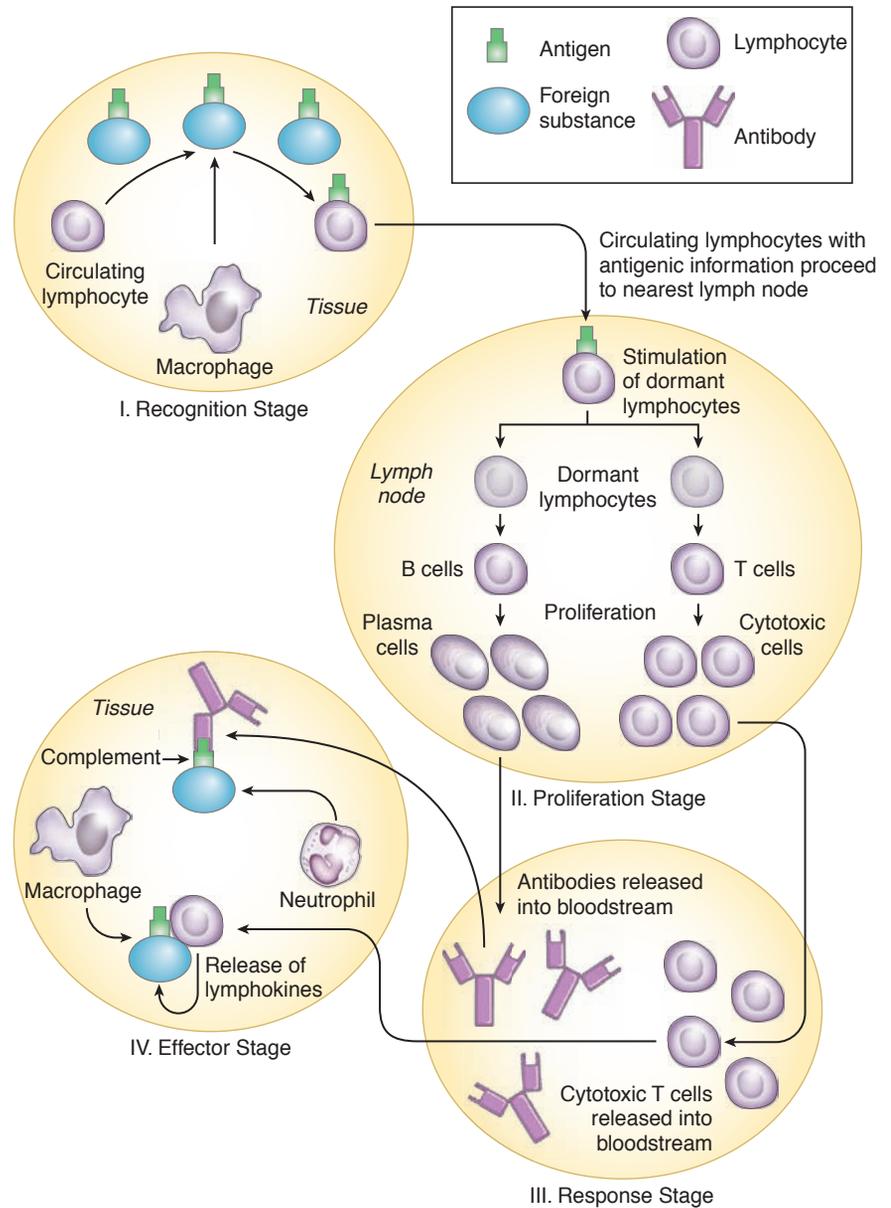

Figure 50-5 Stages of the immune response. **I**, In the *recognition stage*, antigens are recognized by circulating lymphocytes and macrophages. **II**, In the *proliferation stage*, the dormant lymphocytes proliferate and differentiate into cytotoxic (killer) T cells or B cells responsible for formation and release of antibodies. **III**, In the *response stage*, the cytotoxic T cells and the B cells perform cellular and humoral functions, respectively. **IV**, In the *effector stage*, antigens are destroyed or neutralized through the action of antibodies, complement, macrophages, and cytotoxic T cells.

Chart 50-1 • Comparison of Cellular and Humoral Immune Responses

Humoral Responses (B Cells)

- Bacterial phagocytosis and lysis
- Anaphylaxis
- Allergic hay fever and asthma
- Immune complex disease
- Bacterial and some viral infections

Cellular Responses (T Cells)

- Transplant rejection
- Delayed hypersensitivity (tuberculin reaction)
- Graft-versus-host disease
- Tumor surveillance or destruction
- Intracellular infections
- Viral, fungal, and parasitic infections

The B lymphocytes respond to some antigens by directly triggering antibody formation; however, in response to other antigens, they need the assistance of T cells to trigger antibody formation. With the help of macrophages, the T lymphocytes are believed to recognize the antigen of a foreign invader. The T lymphocyte picks up the antigenic message, or “blueprint,” of the antigen and returns to the nearest lymph node with that message. B lymphocytes stored in the lymph nodes are subdivided into thousands of clones, which are stimulated to enlarge, divide, proliferate, and differentiate into plasma cells capable of producing specific antibodies to the antigen. Other B lymphocytes differentiate into B-lymphocyte clones with a memory for the antigen. These memory cells are responsible for the more exaggerated and rapid immune response in a person who is repeatedly exposed to the same antigen.

Role of Antibodies

Antibodies are large proteins, called immunoglobulins, that consist of two subunits, each containing a light and a heavy peptide chain held together by a chemical link composed of disulfide bonds. Each subunit has one portion that serves as a binding site for a specific antigen and another portion that allows the antibody molecule to take part in the complement system.

Antibodies defend against foreign invaders in several ways, and the type of defense used depends on the structure and composition of both the antigen and the immunoglobulin. The antibody molecule has at least two combining sites, or Fab fragments (Fig. 50-6). One antibody can act as a cross-link between two antigens, causing them to bind or clump together. This clumping effect, referred to as **agglutination**, helps clear the body of the invading organism by facilitating phagocytosis. Some antibodies assist in removal of offending organisms through **opsonization**. In this process, the antigen–antibody molecule is coated with a sticky substance that also facilitates phagocytosis.

Antibodies also promote the release of vasoactive substances, such as histamine and slow-reacting substances, two of the chemical mediators of the inflammatory response. Antibodies do not function in isolation; rather, they mobilize other components of the immune system to defend against the invader.

The body can produce five different types of immunoglobulins (Ig). Each of the five types, or classes, is identified by a specific letter of the alphabet, IgA, IgD, IgE, IgG, and IgM. Classification is based on the chemical structure and biologic role of the individual immunoglobulin. Major characteristics of the immunoglobulins are summarized in Chart 50-2. The normal laboratory values for the three major immunoglobulins (IgA, IgG and IgM) can be found in Table 54-1 and Appendix A.

Antigen–Antibody Binding

The portion of the antigen involved in binding with the antibody is referred to as the **antigenic determinant**. The most

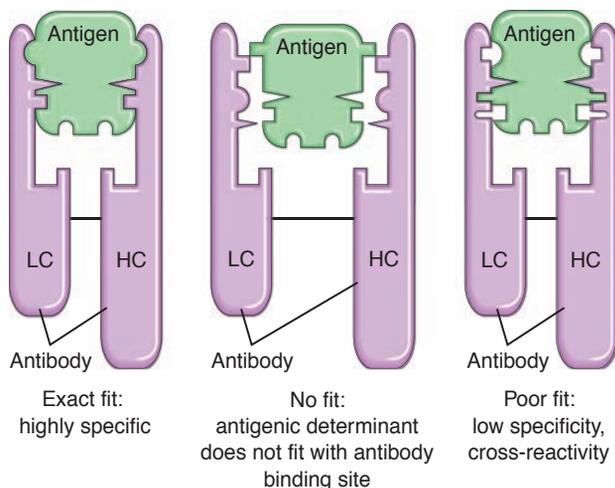

Figure 50-6 Antigen–antibody binding. (Left) A highly specific antigen–antibody complex. (Center) No match and, therefore, no immune response. (Right) Poor fit or match with low specificity; antibody reacts to antigen with similar characteristics, producing cross-reactivity. HC = heavy chain; LC = light chain.

Chart 50-2 • Major Characteristics of the Immunoglobulins

IgG (75% of Total Immunoglobulin)

- Appears in serum and tissues (interstitial fluid)
- Assumes a major role in bloodborne and tissue infections
- Activates the complement system
- Enhances phagocytosis
- Crosses the placenta

IgA (15% of Total Immunoglobulin)

- Appears in body fluids (blood, saliva, tears, breast milk, and pulmonary, gastrointestinal, prostatic, and vaginal secretions)
- Protects against respiratory, gastrointestinal, and genitourinary infections
- Prevents absorption of antigens from food
- Passes to neonate in breast milk for protection

IgM (10% of Total Immunoglobulin)

- Appears mostly in intravascular serum
- Appears as the first immunoglobulin produced in response to bacterial and viral infections
- Activates the complement system

IgD (0.2% of Total Immunoglobulin)

- Appears in small amounts in serum
- Possibly influences B-lymphocyte differentiation, but role is unclear

IgE (0.004% of Total Immunoglobulin)

- Appears in serum
- Takes part in allergic and some hypersensitivity reactions
- Combats parasitic infections

efficient immunologic responses occur when the antibody and antigen fit like a lock and key. Poor fit can occur with an antibody that was produced in response to a different antigen. This phenomenon is known as cross-reactivity. For example, in acute rheumatic fever, the antibody produced against *Streptococcus pyogenes* in the upper respiratory tract may cross-react with the patient's heart tissue, leading to heart valve damage.

Cellular Immune Response

The T lymphocytes are primarily responsible for cellular immunity. Stem cells continuously migrate from the bone marrow to the thymus gland, where they develop into T cells. Despite the partial degeneration of the thymus gland that occurs at puberty, T cells continue to develop here. Several types of T cells exist, each with designated roles in the defense against bacteria, viruses, fungi, parasites, and malignant cells. T cells attack foreign invaders directly rather than by producing antibodies.

Cellular reactions are initiated, with or without the assistance of macrophages, by the binding of an antigen to an antigen receptor located on the surface of a T cell. The T cells then carry the antigenic message, or blueprint, to the lymph nodes, where the production of other T cells is stimulated. Some T cells remain in the lymph nodes and retain a memory for the antigen. Other T cells migrate from the lymph nodes into the general circulatory system and

ultimately to the tissues, where they remain until they either come in contact with their respective antigens or die (Sompayrac, 2008).

Types of T Lymphocytes

T cells include effector T cells, suppressor T cells, and memory T cells. The two major categories of effector T cells—helper T cells and cytotoxic T cells—participate in the destruction of foreign organisms. T cells interact closely with B cells, indicating that humoral and cellular immune responses are not separate, unrelated processes, but rather branches of the immune response that interact.

Helper T cells are activated on recognition of antigens and stimulate the rest of the immune system. When activated, helper T cells secrete **cytokines**, which attract and activate B cells, cytotoxic T cells, NK cells, macrophages, and other cells of the immune system. Separate subpopulations of helper T cells produce different types of cytokines and determine whether the immune response will be the production of antibodies or a cell-mediated immune response. Helper T cells also produce **lymphokines**, one category of cytokines (Table 50-2).

Cytotoxic T cells (killer T cells) attack the antigen directly by altering the cell membrane and causing cell lysis (disintegration) and by releasing cytolytic enzymes and cytokines. Lymphokines can recruit, activate, and regulate other lymphocytes and WBCs. These cells then assist in destroying the invading organism. Delayed-type hypersensitivity is an example of an immune reaction that protects the

body from antigens through the production and release of lymphokines (see later discussion).

Suppressor T cells have the ability to decrease B-cell production, thereby keeping the immune response at a level that is compatible with health (eg, sufficient to fight infection adequately without attacking the body's healthy tissues). **Memory cells** are responsible for recognizing antigens from previous exposure and mounting an immune response (Table 50-3).

Null Lymphocytes and Natural Killer Cells

Null lymphocytes and NK cells are other lymphocytes that assist in combating organisms. These cells are distinct from B cells and T cells and lack the usual characteristics of those cells. **Null lymphocytes**, a subpopulation of lymphocytes, destroy antigens already coated with antibody. These cells have special receptor sites on their surface that allow them to connect with the end of antibodies; this is known as antibody-dependent, cell-mediated cytotoxicity.

NK cells are a class of lymphocytes that recognize infected and stressed cells and respond by killing these cells and by secreting macrophage-activating cytokine. The helper T cells contribute to the differentiation of null and NK cells.

Complement System

Circulating plasma proteins, known as **complement**, are made in the liver and activated when an antibody connects with its antigen. Complement plays an important role in

Table 50-2 CYTOKINES AND THEIR BIOLOGIC ACTIVITY

Cytokine*	Biologic Activity
Interleukin-1 (α and β)	Promotes differentiation of T and B lymphocytes, natural killer (NK) cells, and null cells
Interleukin-2	Stimulates growth of T lymphocytes and special activated killer lymphocytes (known as lymphocyte-activated killer cells [LAK cells])
Interleukin-3	Stimulates growth of mast cells and other blood cells
Interleukin-4	Stimulates growth of T and B lymphocytes, mast cells, and macrophages
Interleukin-5	Stimulates antibody responses
Interleukin-6	Stimulates growth and function of B lymphocytes and antibodies
Interleukin-7	Stimulates growth of pre-B, CD4+ and CD8+ T lymphocytes and activates mature T lymphocytes
Interleukin-8	Promotes chemotaxis and activation of neutrophils
Interleukin-9	Stimulates growth and proliferation of T lymphocytes
Interleukin-10	Inhibits interferon-gamma and mononuclear cell inflammation
Interleukin-11	Promotes induction of acute phase proteins
Interleukin-12	Introduces helper T lymphocytes
Interleukin-13	Inhibits mononuclear phagocyte inflammation and promotes differentiation of B cells
Interleukin-16	Promotes chemotaxis CD4+ T lymphocytes and eosinophils
Permeability factor	Increases vascular permeability, allowing white cells into area
Interferon- γ	Activates macrophages; increases expression of class I and II MHC antigen processing and presentation
Interferon (type 1 α and type β)	Exerts antiviral activity in body cells; induces class I antigen expression; activates NK cells
Migration inhibitory factor	Suppresses movement of macrophages, keeping macrophages in area of foreign cells
Skin reactive factor	Induces inflammatory response
Cytotoxic factor (lymphotoxin)	Kills certain antigenic cells
Macrophage chemotactic factor	Attracts macrophages into the area
Lymphocyte blastogenic factor	Stimulates more lymphocytes, recruiting additional lymphocytes into the area
Macrophage aggregation factor	Causes clumping of macrophages and lymphocytes
Macrophage activation factor	Allows macrophages to adhere to surfaces more readily
Proliferation inhibitor factor	Inhibits growth of certain antigenic cells
Cytophilic antibody	Binds to an Fc receptor on macrophages, thereby permitting macrophages to bind to antigens
Tumor necrosis factor-alpha	Stimulates inflammation, wound healing, and tissue remodeling
Tumor necrosis factor-beta	Mediates inflammation and graft rejection

*Cytokines are biologically active substances that are released by cells to regulate growth and function of other cells within the immune system.

Lymphocytes produce lymphokines, and monocytes and macrophages produce monokines. This table lists some of the cytokines that play a role in immune system functioning. MHC = major histocompatibility complex.

Type of Immune Response	Cell Type	Function
Humoral	B lymphocyte	Produces antibodies or immunoglobulins (IgA, IgD, IgE, IgG, IgM)
Cellular	T lymphocyte	
	Helper T	Attacks foreign invaders (antigens) directly Initiates and augments inflammatory response
	Helper T ₁	Increases activated cytotoxic T cells
	Helper T ₂	Increases B cell antibody production
	Suppressor T Memory T	Suppresses the immune response Remembers contact with an antigen and on subsequent exposures mounts an immune response
	Cytotoxic T (killer T)	Lyses cells infected with virus; plays a role in graft rejection
Nonspecific	Non-T or non-B lymphocyte Null cell	Destroys antigens already coated with antibody
	Natural killer (NK) cell (granular lymphocyte)	Defends against microorganisms and some types of malignant cells; produces cytokines

the defense against microbes. Destruction of an invading or attacking organism or toxin is not achieved merely by the binding of the antibody and antigens; it also requires activation of complement, the arrival of killer T cells, or the attraction of macrophages. Complement has three major physiologic functions: defending the body against bacterial infection, bridging natural and acquired immunity, and disposing of immune complexes and the byproducts associated with inflammation (Porth & Matfin, 2009).

The proteins that comprise complement interact sequentially with one another in a cascading effect. The complement cascade is important to modifying the effector arm of the immune system. Activation of complement allows important events, such as removal of infectious agents and initiation of the inflammatory response, to take place. These events involve active parts of the pathway that enhance chemotaxis of macrophages and granulocytes, alter blood vessel permeability, change blood vessel diameters, cause cells to lyse, alter blood clotting, and cause other points of modification. These macrophages and granulocytes continue the body's defense by devouring the antibody-coated microbes and by releasing bacterial products.

The complement cascade may be activated by any of three pathways: classic, lectin, and alternative. The classic pathway is triggered after antibodies bind to microbes or other antigens and is part of the humoral type of adaptive immunity. The lectin pathway is activated when a plasma protein (mannose-binding lectin) binds to terminal mannose residue on the surface glycoproteins of microbes. The alternative pathway is triggered when complement proteins are activated on microbial surfaces. This pathway is part of natural immunity.

Complement components, prostaglandins, leukotrienes, and other inflammatory mediators all contribute to the recruitment of inflammatory cells, as do chemokines, a group of cytokines. The activated neutrophils pass through the vessel walls to accumulate at the site of infection, where they phagocytose complement-coated microbes (Abbas, et al., 2008). This response is usually therapeutic and can be lifesaving if the cell attacked by the complement system is a true foreign invader. However, if that cell is part of the human organism, the result can be devastating disease and even death. Many autoimmune diseases and disorders characterized by chronic infection are thought to be caused in part by continued or chronic activation of complement, which in turn results in chronic inflammation. The RBCs and platelets have complement receptors and, as a result, play an important role in the clearance of immune complexes that consist of antigen, antibody, and components of the complement system (Abbas, et al., 2008).

Immunomodulators

While antimicrobial agents and vaccines have yielded considerable therapeutic success and the immune system usually works effectively, many infectious diseases remain difficult clinical challenges. Treatment success may be compromised by defects of the immune system; in this case, enhancement of the host immune response may be therapeutically beneficial. An immunomodulator (also known as a biologic response modifier) affects the host via direct or indirect effects on one or more components of the immunoregulatory network. Interferons and colony-stimulating factors are two of the more commonly used immunomodulators (Liles, 2005).

Interferons

Interferon, one type of biologic response modifier, is a non-specific viricidal protein that is naturally produced by the body and is capable of activating other components of the immune system. These substances continue to be investigated to determine their roles in the immune system and their potential therapeutic effects in disorders characterized by disturbed immune responses. Interferons have antiviral and antitumor properties. In addition to responding to viral infection, interferons are produced by T lymphocytes, B lymphocytes, and macrophages in response to antigens. They are thought to modify the immune response by suppressing antibody production and cellular immunity. They also facilitate the cytolytic role of macrophages and NK cells. Interferons are used to treat immune-related disorders (eg, multiple sclerosis) and chronic inflammatory conditions (eg, chronic hepatitis). Research continues to evaluate the effectiveness of interferons in treating tumors and acquired immunodeficiency syndrome (AIDS).

Colony-Stimulating Factors

Colony-stimulating factors are a group of naturally occurring glycoprotein cytokines that regulate production, differentiation, survival, and activation of hematopoietic cells. Erythropoietin stimulates RBC production. Thrombopoietin plays a key regulatory role in the growth and differentiation of bone marrow cells. Interleukin-5 (IL-5) stimulates the growth and survival of eosinophils and basophils.

Stem cell factor and IL-3 serve as stimuli for multiple hematopoietic cell lines. Granulocyte colony-stimulating factor, granulocyte-macrophage colony-stimulating factor, and macrophage colony-stimulating factor all serve as growth factors for specific cell lines. These cytokines have attracted considerable interest for their potential role in immunomodulation (McInnes, 2005; Nelson, 2007).

Advances in Immunology

Genetic Engineering

One of the more remarkable evolving technologies is **genetic engineering**, which uses recombinant deoxyribonucleic acid (DNA) technology. Two facets of this technology exist. The first permits scientists to combine genes from one type of organism with genes of a second organism. This type of technology allows cells and microorganisms to manufacture proteins, monokines, and lymphokines, which can alter and enhance immune system function. The second facet of recombinant DNA technology involves gene therapy. If a particular gene is abnormal or missing, experimental recombinant DNA technology may be capable of restoring normal gene function. For example, a recombinant gene is inserted onto a virus particle. When the virus particle splices its genes, the virus automatically inserts the missing gene and theoretically corrects the genetic anomaly. Extensive research into recombinant DNA technology and gene therapy is ongoing (Abbas, et al., 2008).

Stem Cells

Stem cells are capable of self-renewal and differentiation; they continually replenish the body's entire supply of both RBCs and WBCs. Some stem cells, described as totipotent cells, have tremendous capacity to self-renew and differentiate. Embryonic stem cells, described as pluripotent, give rise to numerous cell types that are able to form tissues. Research has shown that stem cells can restore an immune system that has been destroyed. Stem cell transplantation has been carried out in humans with certain types of immune dysfunction, such as severe combined immunodeficiency (SCID); clinical trials using stem cells are under way in patients with a variety of disorders having an autoimmune component, including systemic lupus erythematosus, rheumatoid arthritis, scleroderma, and multiple sclerosis. Research with embryonic stem cells has enabled investigators to make substantial gains in developmental biology, gene therapy, therapeutic tissue engineering, and the treatment of a variety of diseases. However, along with these remarkable opportunities, many ethical challenges arise, which are largely based on concerns about safety, efficacy, resource allocation, and human cloning (Goldman, 2007).

Assessment of the Immune System

An assessment of immune function begins during the health history and physical examination. Areas to be assessed include nutritional status; infections and immunizations; allergies; disorders and disease states, such as

autoimmune disorders, cancer, and chronic illnesses; surgeries; medications; and blood transfusions. In addition to inspection of general characteristics, palpation of the lymph nodes and examinations of the skin, mucous membranes, and respiratory, gastrointestinal, musculoskeletal, genitourinary, cardiovascular, and neurosensory systems are performed (Moorhead, Johnson, Mass, et al., 2008) (Chart 50-3).

Health History

The history should note the patient's age along with information about past and present conditions and events that may provide clues to the status of the patient's immune system.

CHART
50-3

Assessing for Immune Dysfunction

Be alert for the following signs and symptoms:

Respiratory System

- Changes in respiratory rate
- Cough (dry or productive)
- Abnormal lung sounds (wheezing, crackles, rhonchi)
- Rhinitis
- Hyperventilation
- Bronchospasm

Cardiovascular System

- Hypotension
- Tachycardia
- Dysrhythmia
- Vasculitis
- Anemia

Gastrointestinal System

- Hepatosplenomegaly
- Colitis
- Vomiting
- Diarrhea

Genitourinary System

- Frequency and burning on urination
- Hematuria
- Discharge

Musculoskeletal System

- Joint mobility, edema, and pain

Skin

- Rashes
- Lesions
- Dermatitis
- Hematomas or purpura
- Edema or urticaria
- Inflammation
- Discharge

Neurosensory System

- Cognitive dysfunction
- Hearing loss
- Visual changes
- Headaches and migraines
- Ataxia
- Tetany

Gender

There are differences in the immune system functions of men and women. For example, many autoimmune diseases have a higher incidence in females than in males, a phenomenon believed to be correlated with sex hormones. Sex hormones have long been recognized for their role in reproductive function, and in the past two decades research has revealed that these hormones are integral signaling modulators of the immune system. Sex hormones play definitive roles in lymphocyte maturation, activation, and synthesis of antibodies and cytokines. In autoimmune disease, expression of sex hormones is altered, and this change contributes to immune dysregulation (Ackerman, 2006).

Gerontologic Considerations

Immunosenescence is a complex route in which the aging process stimulates changes in the immune system. The immune system undergoes age-associated alterations that lead to a progressive deterioration in the ability to respond to infections. The capacity for self-renewal of hematopoietic stem cells diminishes. There is a notable decline in the total number of phagocytes, coupled with an intrinsic reduction in their activity. The cytotoxicity of NK cells decreases, contributing to a decline in humoral immunity (Kovalou & Gribeck-Loebenstein, 2006). Acquired immunity may be negatively affected; the efficacy of vaccines is frequently decreased in older adults. Natural immunity, however, continues to function reasonably well, perhaps as an adaptive response to the deterioration of cell-mediated immunity in old age (Aw, Silva & Palmer, 2007).

The incidence of autoimmune diseases also increases with age, possibly from a decreased ability of antibodies to differentiate between self and non-self. Failure of the surveillance system to recognize mutant or abnormal cells also

may be responsible, in part, for the high incidence of cancer associated with increasing age.

Age-related changes in many body systems also contribute to impaired immunity (Table 50-4). Decreased gastric secretions and motility allow normal intestinal flora to proliferate and produce infection, causing gastroenteritis and diarrhea. Decreased renal circulation, filtration, absorption, and excretion contribute to the risk for urinary tract infections. Moreover, prostatic enlargement or a neurogenic bladder can impede urine passage and impair bacterial clearance through the urinary system. Urinary stasis permits the growth of microorganisms (Bengmark, 2006). Prolonged exposure to tobacco and environmental toxins impairs pulmonary function and decreases the elasticity of lung tissue, the effectiveness of cilia, and the ability to cough effectively. These impairments hinder the removal of infectious organisms and toxins, increasing the older person's susceptibility to pulmonary infections and cancers. The skin becomes thinner and less elastic. Impaired skin integrity predisposes older people to infection from organisms that are part of normal skin flora. Secondary changes, including malnutrition and poor circulation, as well as the breakdown of natural mechanical barriers such as the skin, place the aging immune system at even greater disadvantage against infection. In addition, the increased incidence of peripheral neuropathy and the accompanying decreased sensation and circulation may lead to stasis ulcers, pressure ulcers, abrasions, and burns.

The effects of the aging process and psychological stress interact, with the potential to negatively influence immune integrity (Graham, Christian & Kiecolt-Glaser, 2006; Sandman-Goddard, Peeva & Shoenfeld, 2007). Consequently, continual assessment of the physical and emotional status of the elderly is imperative, because early recognition and management of factors influencing immune response

Table 50-4

AGE-RELATED CHANGES IN IMMUNOLOGIC FUNCTION

Body System	Changes	Consequences
Immune	<ul style="list-style-type: none"> Impaired function of B and T lymphocytes Failure of lymphocytes to recognize mutant or abnormal cells Decreased antibody production Failure of immune system to differentiate "self" from "non-self" Suppressed phagocytic immune response 	<ul style="list-style-type: none"> Suppressed responses to pathogenic organisms with increased risk for infection Increased incidence of cancers Anergy (lack of response to antigens applied to the skin [allergens]) Increased incidence of autoimmune diseases Absence of typical signs and symptoms of infection and inflammation Dissemination of organisms usually destroyed or suppressed by phagocytes (eg, reactivation or spread of tuberculosis)
Gastrointestinal	<ul style="list-style-type: none"> Decreased gastric secretions and motility Decreased phagocytosis by the liver's Kupffer cells Altered nutritional intake with inadequate protein intake 	<ul style="list-style-type: none"> Proliferation of intestinal organisms resulting in gastroenteritis and diarrhea Increased incidence and severity of hepatitis B; increased incidence of liver abscesses Suppressed immune response
Urinary	<ul style="list-style-type: none"> Decreased kidney function and changes in lower urinary tract function (enlargement of prostate gland, neurogenic bladder). Altered genitourinary tract flora 	<ul style="list-style-type: none"> Urinary stasis and increased incidence of urinary tract infections
Pulmonary	<ul style="list-style-type: none"> Impaired ciliary action due to exposure to smoke and environmental toxins 	<ul style="list-style-type: none"> Impaired clearance of pulmonary secretions; increased incidence of respiratory infections
Integumentary	<ul style="list-style-type: none"> Thinning of skin with less elasticity; loss of adipose tissue 	<ul style="list-style-type: none"> Increased risk of skin injury, breakdown, and infection
Circulatory	<ul style="list-style-type: none"> Impaired microcirculation 	<ul style="list-style-type: none"> Stasis and pressure ulcers
Neurologic function	<ul style="list-style-type: none"> Decreased sensation and slowing of reflexes 	<ul style="list-style-type: none"> Increased risk of injury, skin ulcers, abrasions, and burns

may prevent or mitigate the high morbidity and mortality seen with illness in the elderly population (Pawelec, 2006; Woodland & Blackman, 2006).

Nutrition

The relationship of infection to nutritional status is a key determinant of human health. Traditionally, this relationship focused on the effect of nutrients on host defenses and the effect of infection on nutritional needs. This has expanded in scope to encompass the role of specific nutrients in acquired immune function—the modulation of inflammatory processes and the virulence of the infectious agent itself. Iron may have beneficial or deleterious effects on the immune system, and further research is needed (Munoz, Rios, Olivos, et al., 2007). The list of nutrients affecting infection, immunity, inflammation, and cell injury has expanded from traditional proteins to several vitamins, multiple minerals, and more recently specific lipid components of the diet (Puertollano, Puertollano, Alvarez de Cienfuegos, et al., 2007). Vitamin D deficiency has been associated with increased risk of common cancers, autoimmune diseases, and infectious diseases (Maggini, Wintergerst, Beveridge, et al., 2007). More recently, the role of micronutrients and fatty acids on the response of cells and tissues to hypoxic and toxic damage has been recognized, suggesting that there is another dimension to the relationship. Micronutrients such as zinc, copper, manganese, and selenium may have widespread negative effects on the immune response, which can be reversed by supplementation (Overbeck, Rink & Hasse, 2008).

The effects exerted by polyunsaturated fatty acids on immune system functions are under investigation. Studies show that these elements play a role in diminishing the incidence and severity of inflammatory disorders. Recent studies show that diets high in olive oil are not as immunosuppressive as diets rich in fish oil. The contribution of immune modulation by lipids to the high risk of infectious complications associated with the use of parenteral nutrition is unclear (Hise, Compher, Harlan, et al., 2006).

Depletion of protein reserves results in atrophy of lymphoid tissues, depression of antibody response, reduction in the number of circulating T cells, and impaired phagocytic function. As a result, susceptibility to infection is greatly increased. During periods of infection or serious illness, nutritional requirements may be further altered, potentially contributing to depletion of protein, fatty acid, vitamin, and trace elements and causing even greater risk of impaired immune response and sepsis. Nutritional intake that supports a competent immune response plays an important role in reducing the incidence of infections; patients whose nutritional status is compromised have a delayed postoperative recovery and often experience more severe infections and delayed wound healing. The nurse must assess the patient's nutritional status, caloric intake, and quality of foods ingested. There is evidence that nutrition plays a role in the development of cancer and that diet and lifestyle can alter the risk of cancer development as well as other chronic diseases (Valdes-Ramos, Benitez & Alejandra, 2007). The nurse is responsible for assuming a proactive role in ensuring the best possible nutritional intake for all patients as a vital step in preventing disease and poor outcomes (Morse & High, 2005).

Infection and Immunization

The patient is asked about childhood and adult immunizations, including vaccinations, to provide protection against influenza, pneumococcal disease (Pneumovax), pertussis, herpes simplex, and the usual childhood diseases (eg, measles, mumps). Herpes simplex virus (HSV) infections have a significant impact on health, causing a wide range of diseases (eg, oral and genital herpes). Teaching about the importance of adhering to the recommended schedule for these vaccines should be initiated. Known past or present exposure to tuberculosis is assessed, and the dates and results of any tuberculin tests (purified protein derivative [PPD] or tine test) and chest x-rays are documented. Recent exposure to any infections and the exposure dates are elicited. It is important for the nurse to assess whether the patient has been exposed to any sexually transmitted diseases (STDs) or bloodborne pathogens such as hepatitis A, B, C, D, and E viruses and human immunodeficiency virus (HIV). A history of STDs such as gonorrhea, syphilis, human papillomavirus (HPV) infection, and chlamydia can alert the nurse that the patient may have been exposed to HIV or hepatitis. A history of past and present infections and the dates and types of treatments, along with a history of any multiple persistent infections, fevers of unknown origin, lesions or sores, or any type of drainage, as well as the response to treatment are obtained.

Allergy

The patient is asked about any allergies, including types of allergens (eg, pollens, dust, plants, cosmetics, food, medications, vaccines, latex), the symptoms experienced, and seasonal variations in occurrence or severity in the symptoms. A history of testing and treatments, including prescribed and over-the-counter medications that the patient has taken or is currently taking for these allergies and the effectiveness of the treatments, is obtained. All medication and food allergies are listed on an allergy alert sticker and placed on the front of the patient's health record or chart to alert others. Continued assessment for potential allergic reactions in the patient is vital.

Disorders and Diseases

Autoimmune Disorders

Autoimmune disorders affect people of both genders of all ages, ethnicities, and social classes. Specific autoimmune disorders affect approximately 5% of the U.S. population. As mentioned previously, they tend to be more common in women because estrogen tends to enhance immunity. Androgen, on the other hand, tends to be immunosuppressive. Autoimmune diseases are the fifth leading cause of death by disease in females of reproductive age.

The patient is asked about any autoimmune disorders, such as lupus erythematosus, rheumatoid arthritis, multiple sclerosis, or psoriasis. The onset, severity, remissions and exacerbations, functional limitations, treatments that the patient has received or is currently receiving, and effectiveness of the treatments are described. The occurrence of different autoimmune diseases within a family strongly suggests a genetic predisposition to more than one autoimmune disease (Hawker, 2008; Yurasov & Nussenzeig, 2007).

Neoplastic Disease

If there is a history of cancer in the family, the type of cancer, age at onset, and relationship (maternal or paternal) of the patient to the affected family members is noted. Dates and results of any cancer screening tests for the patient are documented. A history of cancer in the patient is also obtained, along with the type of cancer, date of diagnosis, and treatment modalities used. Immunosuppression contributes to the development of cancers; however, cancer itself is immunosuppressive, as is the treatment for cancer. Large tumors can release antigens into the blood, and these antigens combine with circulating antibodies and prevent them from attacking the tumor cells. Furthermore, tumor cells may possess special blocking factors that coat tumor cells and prevent their destruction by killer T lymphocytes. During the early development of tumors, the body may fail to recognize the tumor antigens as foreign and subsequently fail to initiate destruction of the malignant cells. Hematologic cancers, such as leukemia and lymphoma, are associated with altered production and function of WBCs and lymphocytes.

All treatments that the patient has received or is currently receiving, such as radiation or chemotherapy, are recorded in the health history. In addition, the nurse should elicit information related to complementary or alternative modalities that have been used and the response to these efforts. Radiation destroys lymphocytes and decreases the ability to mount an effective immune response. The size and extent of the irradiated area determine the extent of immunosuppression. Whole-body irradiation may leave the patient totally immunosuppressed. Chemotherapy also affects bone marrow function, destroying cells that contribute to an effective immune response and resulting in immunosuppression (Sompayrac, 2008).

Chronic Illness and Surgery

The health assessment includes a history of chronic illness, such as diabetes mellitus, renal disease, chronic obstructive pulmonary disease (COPD), or fibromyalgia. The onset and severity of illnesses, as well as treatment that the patient is receiving for the illness, are obtained. Chronic illness may contribute to immune system impairments in various ways. Renal failure is associated with a deficiency in circulating lymphocytes. In addition, immune defenses may be altered by acidosis and uremic toxins. In diabetes, an increased incidence of infection has been associated with vascular insufficiency, neuropathy, and poor control of serum glucose levels. Recurrent respiratory tract infections are associated with COPD as a result of altered inspiratory and expiratory function and ineffective airway clearance. Additionally, a history of organ transplantation or surgical removal of the spleen, lymph nodes, or thymus is noted, because these conditions may place the patient at risk for impaired immune function (Doering, Martinez-Maza, Vredevoe, et al., 2008).

Special Problems

Conditions such as burns and other forms of injury and infection may contribute to altered immune system function. Major burns cause impaired skin integrity and compromise the body's first line of defense. Loss of large amounts of

serum occurs with burn injuries and depletes the body of essential proteins, including immunoglobulins. The physiologic and psychological stressors associated with surgery or injury stimulate cortisol release from the adrenal cortex; increased serum cortisol also contributes to suppression of normal immune responses (Shankar, Melstrom & Gamelli, 2007).

Medications and Blood Transfusions

A list of past and present medications is obtained. In large doses, antibiotics, corticosteroids, cytotoxic agents, salicylates, nonsteroidal anti-inflammatory drugs (NSAIDs), and anesthetic agents can cause immune suppression (Table 50-5).

A history of blood transfusions is obtained, because previous exposure to foreign antigens through transfusion may be associated with abnormal immune function. Additionally, although the risk of HIV transmission through blood transfusion is extremely low in patients who received a transfusion after 1985 (when testing of blood for HIV was initiated in the United States), a small risk remains.

The patient is also asked about use of herbal agents and over-the-counter medications. Because many of these products have not been subjected to rigorous testing, their effects have not been fully identified. It is important, therefore, to ask patients about their use of these substances, to document their use, and to educate patients about untoward effects that may alter immune responsiveness.

Lifestyle Factors

Like any other body system, the functions of the immune system depend on other body systems. Poor nutritional status, smoking, excessive consumption of alcohol, illicit drug use, STDs, and occupational or residential exposure to environmental radiation and pollutants have been associated with impaired immune function and are assessed in a detailed patient history. Although factors that are not consistent with a healthy lifestyle are predominately responsible for ineffective immune function, positive lifestyle factors can also negatively affect immune function and require assessment. For example, rigorous exercise or competitive exercise—usually considered a positive lifestyle factor—can be a physiologic stressor and cause negative effects on immune response (Friedrich, 2008). This outcome is compounded if the person also faces stressful environmental conditions while undergoing exercise. Given the cumulative impact of various environmental stressors on the immune system, every effort should be made to minimize the person's exposure to stressors other than the exercise performed (Raso, Benard, Da Silva Duarte, et al., 2007).

Psychoneuroimmunologic Factors

Patient assessment must also address psychoneuroimmunologic factors. The bidirectional pathway between the brain and immune system is referred to as psychoneuroimmunology, a field that has been the focus of research and discussion over the last several decades (Starkweather, Witek-Janusek, Peterson, et al., 2006; Steel, Geller, Gamblin, et al., 2007). It is thought that the immune response is regulated and modulated in part by neuroendocrine influences. Lymphocytes and macrophages have receptors that are capable of responding to neurotransmitters and endocrine hormones.

Table 50-5  **SELECTED MEDICATIONS AND EFFECTS ON THE IMMUNE SYSTEM**

Drug Classification (and Examples)	Effects on the Immune System
Antibiotics (in large doses) ceftriaxone (Rocefin) cefuroxime sodium (Ceftin) chloramphenicol (Chloromycetin) dactinomycin (Cosmogen) fluoroquinolones (Cipro, Levaquin, Tequin) gentamicin sulfate (Garamycin) macrolides (erythromycin, Zithromax, Biaxin) penicillins streptomycin vancomycin (Vancocin, Vancoled)	Bone Marrow Suppression Eosinophilia, hemolytic anemia, hypoprothrombinemia, neutropenia, thrombocytopenia Eosinophilia, hemolytic anemia, hypoprothrombinemia, neutropenia, thrombocytopenia Leukopenia, aplastic anemia Agranulocytosis, neutropenia Hemolytic anemia, methemoglobinemia, eosinophilia, leukopenia, pancytopenia Agranulocytosis, granulocytosis Neutropenia, leukopenia Agranulocytosis Leukopenia, neutropenia, pancytopenia Transient leukopenia
Antithyroid Drugs propylthiouracil (PTU)	Agranulocytosis, leukopenia
Nonsteroidal Anti-inflammatory Drugs (NSAIDs) (in large doses) aspirin COX-2 inhibitors ibuprofen (Advil, Motrin) indomethacin (Indocid, Indocin) phenylbutazone	Inhibit Prostaglandin Synthesis or Release Agranulocytosis Anemia, allergy, no major other adverse affects to the immune system Leukopenia, neutropenia Agranulocytosis, leukopenia Pancytopenia, agranulocytosis, aplastic anemia
Adrenal Corticosteroids prednisone	Immunosuppression
Antineoplastic Agents (cytotoxic agents) alkylating agents cyclophosphamide (Cytoxan) mechlorethamine HCl (Mustargen) cyclosporine	Immunosuppression Leukopenia, bone marrow suppression Leukopenia, neutropenia Agranulocytosis, neutropenia Leukopenia, inhibits T-lymphocyte function
Antimetabolites fluorouracil (pyrimidine antagonist) methotrexate (folic acid antagonist) mercaptopurine (6-MP) (purine antagonist)	Immunosuppression Leukopenia, eosinophilia Leukopenia, aplastic bone marrow Leukopenia, pancytopenia

Lymphocytes can produce and secrete adrenocorticotrophic hormone and endorphinlike compounds. Cells in the brain, especially in the hypothalamus, can recognize prostaglandins, interferons, and interleukins as well as histamine and serotonin, which are released during the inflammatory process. Like all other biologic systems functioning to maintain homeostasis, the immune system is integrated with other psychophysiologic processes and is subject to regulation and modulation by the brain. These relationships may have immunologic consequences (Chart 50-4).

Conversely, the immune processes can affect neural and endocrine function, including behavior. Growing evidence indicates that a measurable immune system response can be positively influenced by biobehavioral strategies such as relaxation and imagery techniques, biofeedback, humor, hypnosis, and conditioning (Stephenson, Swanson, Dalton, et al., 2007). Therefore, the assessment should address the patient's general psychological status and the patient's use of and response to these strategies.

Physical Assessment

On physical examination (see Chart 50-3), the skin and mucous membranes are assessed for lesions, dermatitis, purpura (subcutaneous bleeding), urticaria, inflammation, or

any discharge. Any signs of infection are noted. The patient's temperature is recorded, and the patient is observed for chills and sweating. The anterior and posterior cervical, axillary, and inguinal lymph nodes are palpated for enlargement; if palpable nodes are detected, their location, size, consistency, and reports of tenderness on palpation are noted. Joints are assessed for tenderness, swelling, increased warmth, and limited range of motion. The patient's respiratory, cardiovascular, genitourinary, gastrointestinal, and neurosensory systems are evaluated for signs and symptoms indicative of immune dysfunction. Any functional limitations or disabilities the patient may have are also assessed.

Diagnostic Evaluation

A series of blood tests and skin tests and a bone marrow biopsy may be performed to evaluate the patient's immune competence. Specific laboratory and diagnostic tests are discussed in greater detail along with individual disease processes in subsequent chapters in this unit. Selected laboratory and diagnostic tests used to evaluate immune competence are summarized in Chart 50-5.

CHART
50-4

NURSING RESEARCH PROFILE

Factors Affecting Immune Responses in Breast Cancer

Von Ah, D., Hang, D. & Carpenter, J. (2007). Stress, optimism and social support: Impact on immune responses in breast cancer. *Research in Nursing and Health*, 30(1), 72–83.

Purpose

The stress of a breast cancer diagnosis and initial surgical treatment can produce a variety of negative sequelae and impaired immune responses. The purpose of this study was to examine the roles of stress, optimism, and satisfaction with social support and their interactions in relation to immune responses in women who had been diagnosed with breast cancer and who had undergone surgical treatment.

Design

Researchers used a correlational, cross-sectional design to study the hypothesized relationships. They recruited, from one outpatient breast health center, a convenience sample of 54 women, 19 years of age and older, newly diagnosed with stage 0 or ductal carcinoma in situ, who were postsurgery (at least 7 days) and who had not received any other treatment. To collect demographic and medical data, investigators relied on self-report questionnaires and verified the results using medical record review. They used various measures of psychological factors: the Impact of Event Scale for perceived stress, the Life Orientation Test for optimism, and the Social Support Questionnaire for satisfaction with social support. Immunologic assessments measured natural killer cells and cytokine levels that are known to promote cell-mediated immunity and enhance natural killer cell activity.

Findings

The mean age of the participants was 55 years. They represented the racial diversity of the local population, and the

majority of women were married and well educated, with a middle-income level. Women had stage I or II breast cancer and were surgically treated with either lumpectomy or modified mastectomy. Although they reported moderately significant levels of stress, the women were generally optimistic and had exceptionally high levels of satisfaction with their social support. Women with higher levels of perceived stress had lower natural killer cell activity and cytokine levels than women with lower levels of stress. Optimism and satisfaction with social support did not have direct main effects on any of the immune responses examined.

The most robust finding was the significant negative relationship between stress and natural killer cell activity and cytokine level that underscores the negative sequelae of cancer-specific stress on immune responses in women following breast cancer surgery. In addition, the study partially supported the hypothesis that optimism and social support moderated the relationship of stress on natural killer cell activity and cytokine level. Stress significantly interacted with optimism to predict natural killer cell activity. In the significant interaction between stress and optimism, natural killer cell activity was lowest when the participant reported greater stress and lower optimism. Satisfaction with social support did not have a stress-buffering effect on any of the immune indices examined in the study.

Nursing Implications

This study illustrates the need to identify supportive interventions that will have a positive effect on the issues faced by women who are undergoing surgical treatment for breast cancer. Interventions directed to the reduction of stress and enhancing optimism in women with breast cancer are warranted to achieve quality outcomes in these patients.

Nursing Management

The nurse needs to be aware that patients undergoing evaluation for possible immune system disorders experience not only physical pain and discomfort with certain types of diagnostic procedures, but also many psychological reactions. It is the nurse's role to counsel, educate, and support

patients throughout the diagnostic process. Many patients may be extremely anxious about the results of diagnostic tests and the possible implications of those results for their employment, insurance, and personal relationships. This is an ideal time for the nurse to provide counseling and education, should these interventions be warranted.

Chart 50-5 • Selected Tests for Evaluating Immunologic Status

Various laboratory tests may be performed to assess immune system activity or dysfunction. The studies assess leukocytes and lymphocytes, humoral immunity, cellular immunity, phagocytic cell function, complement activity, hypersensitivity reactions, specific antigen–antibodies, or human immunodeficiency virus (HIV) infection.

Humoral (Antibody-mediated) Immunity Tests

- B-cell quantification with monoclonal antibody
- In vivo immunoglobulin synthesis with T-cell subsets
- Specific antibody response
- Total serum globulins and individual immunoglobulins (electrophoresis, immunoelectrophoresis, single radial immun-

odiffusion, nephelometry, and isohemagglutinin techniques)

Cellular (Cell-mediated) Immunity Tests

- Total lymphocyte count
- T-cell and T-cell-subset quantification with monoclonal antibody
- Delayed hypersensitivity skin test
- Cytokine production
- Lymphocyte response to mitogens, antigens, and allogenic cells
- Helper and suppressor T-cell functions

CRITICAL THINKING EXERCISES

1 A 70-year-old woman is referred to the allergy and immunology clinic for evaluation of her immune status. In addition to the eight medications she routinely takes, she has received several courses of antibiotics in the previous months for recurrent infections. What diagnostic tests would you expect to be ordered? What is the rationale for these? What further assessment data would you want to obtain from this patient?

EBP 2 A 38-year-old woman is hospitalized for a heart transplant, and immunosuppressant medications are prescribed. Describe how her altered immune function would affect the care that you provide. Develop an evidence-based teaching plan for the patient and her family before hospital discharge. Discuss the criteria used to assess the strength of the evidence for your teaching plan.

3 A 24-year-old woman is diagnosed with systemic lupus erythematosus (SLE), and corticosteroids are prescribed. What nursing observations and assessments are indicated? Identify patient teaching that is appropriate for the new diagnosis and prescription of steroids.

Management of Patients With Immunodeficiency

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

- 1 Compare the different types of primary immunodeficiency disorders and their causes, clinical manifestations, potential complications, and treatment modalities.
- 2 Describe the nursing management of the patient with an immunodeficiency.
- 3 Identify the essential teaching needs for a patient with an immunodeficiency.

GLOSSARY

- agammaglobulinemia:** disorder marked by an almost complete lack of immunoglobulins or antibodies
- angioneurotic edema:** condition marked by development of urticaria and an edematous area of skin, mucous membranes, or viscera
- ataxia:** loss of muscle coordination
- ataxia-telangiectasia:** autosomal recessive disorder affecting T- and B-cell immunity primarily seen in children and resulting in a degenerative brain disease
- hypogammaglobulinemia:** lack of one or more of the five immunoglobulins; caused by B-cell deficiency
- immunocompromised host:** person with a secondary immunodeficiency and associated immunosuppression
- panhypoglobulinemia:** general lack of immunoglobulins in the blood
- severe combined immunodeficiency disease:** disorder involving a complete absence of humoral and cellular immunity resulting from an X-linked or autosomal genetic abnormality
- telangiectasia:** vascular lesions caused by dilated blood vessels
- thymic hypoplasia:** T-cell deficiency that occurs when the thymus gland fails to develop normally during embryogenesis; also known as DiGeorge syndrome
- Wiskott-Aldrich syndrome:** immunodeficiency characterized by thrombocytopenia and the absence of T and B cells

Immunodeficiency disorders may be caused by a defect in or a deficiency of phagocytic cells, B lymphocytes, T lymphocytes, or the complement system. The specific symptoms and their severity, age at onset, and prognosis depend on the immune system components affected and their degree of functional impairment. Regardless of the underlying cause, the cardinal symptoms of immunodeficiency include chronic or recurrent and severe infections, infections caused by unusual organisms or by organisms that are normal body flora, poor response to standard treatment for infections, and chronic diarrhea. In addition, the patient is susceptible to a variety of secondary disorders, including autoimmune disease and lymphoreticular malignancies (Cooper & Schroeder, 2008).

Immunodeficiencies may be acquired spontaneously or as a consequence of medical treatment. These disorders can be classified as either primary or secondary and by the affected components of the immune system. Primary immunodeficiency diseases are genetic in origin and result from intrinsic defects in the cells of the immune system. In contrast, secondary immunodeficiencies result from external factors such as infection. Effective nursing care reflects knowledge of the immune system, potential secondary disorders, relevant assessment parameters, and strategies for symptom management, as well as sensitivity and responsiveness to the learning needs of the patient and caregiver.

PRIMARY IMMUNODEFICIENCIES

Primary immunodeficiencies represent inborn errors of immune function that predispose people to frequent, severe infections; autoimmunity; and cancer. Advances in medical treatment have meant that patients with primary immunodeficiencies live longer, thus increasing their overall risk of developing cancer (Salavoura, Koloalexi, Tsangaris, et al., 2008). The type of malignancy depends on the immunodeficiency, the age of the patient, and possible viral infection, which suggests that different pathogenic mechanisms are implicated in each case. Non-Hodgkin lymphomas account for the majority of cancers. The primary immunodeficiencies known to be associated with increased incidence of malignancy are common variable immunodeficiency, immunoglobulin A (IgA) deficiency, and deoxyribonucleic acid (DNA) repair disorders. More recently, investigators have shown that **severe combined immunodeficiency disease (SCID)** and **Wiskott-Aldrich syndrome** (thrombocytopenia and the absence of T and B cells) may also lead to cancer (Salavoura, et al., 2008). People with various primary immunodeficiencies, who are predisposed to cancer, exhibit immune deficits that also increase their susceptibility to fungal infections. A number of yeasts, molds, and fungi may cause infections in patients with chronic granulomatous disease, SCID, chronic mucocutaneous candidiasis, and common variable immunodeficiency (CVID); these infections may occasionally be the presenting clinical manifestation of a primary immunodeficiency. If the immune condition is misdiagnosed or mistreated, it can lead to significant morbidity and mortality (Antachopoulos, Walsh & Rollides, 2007).

The majority of primary immunodeficiencies are diagnosed in infancy, with a male-to-female ratio of 5 to 1.

However, a large fraction of primary immunodeficiencies are not diagnosed until adolescence or early adulthood, when the gender distribution equalizes. Diagnosis at this stage frequently is confounded by frequent use of antibiotics that mask symptoms. On occasion, adults present with clinical episodes of infectious diseases that are beyond the scope of normal immunocompetence. Examples include infections that are unusually persistent, recurrent, or resistant to treatment and those involving unexpected dissemination of disease or atypical pathogens. To date, more than 120 immunodeficiencies of genetic origin have been identified (Verbsky & Grossman, 2006).

Common primary immunodeficiencies include disorders of humoral immunity (affecting B-cell differentiation or antibody production), T-cell defects, combined B- and T-cell defects, phagocytic disorders, and complement deficiencies. These disorders may involve one or more components of the immune system. Symptoms of immune deficiency disorders are related to the deficient component (Table 51-1). Major signs and symptoms include multiple infections despite aggressive treatment, infections with unusual or opportunistic organisms, failure to thrive or poor growth, and a positive family history (Cooper & Schroeder, 2008).

Phagocytic Dysfunction

Pathophysiology

A variety of primary defects of phagocytes may occur; almost all of them are genetic in origin and affect the natural (innate) immune system. In some types of phagocytic disorders, the neutrophils are impaired so that they cannot exit the circulation and travel to sites of infection. As a result, the person cannot initiate a normal inflammatory response against pathogenic organisms. In some disorders, the neutrophil count may be very low; in others, it may be very high because the neutrophils remain in the vascular system. Phagocytic cell disorders are characterized by disease-specific infections, such as chronic granulomatous disease (Abbas, Lichtman & Baker, 2008).

Clinical Manifestations

In phagocytic cell disorders there is an increased incidence of bacterial and fungal infections caused by organisms that are normally nonpathogenic. People with these disorders may also develop fungal infections from *Candida* organisms and viral infections from herpes simplex or herpes zoster. These patients experience recurrent cutaneous abscesses, chronic eczema, bronchitis, pneumonia, chronic otitis media, and sinusitis. In one rare type of phagocytic disorder, hyperimmunoglobulinemia E syndrome (formerly known as Job syndrome), white blood cells cannot initiate an inflammatory response to infectious organisms. This results in recurrent bacterial infections of the skin and lung; abnormalities of connective tissue, skeleton, and dentition; and extremely elevated levels of IgE (Freeman & Holland, 2008).

Although patients with phagocytic cell disorders may be asymptomatic, severe neutropenia may present and may be accompanied by deep and painful mouth ulcers, gingivitis, stomatitis, and cellulitis. Death from overwhelming infection

Table 51-1 SELECTED PRIMARY IMMUNODEFICIENCY DISORDERS

Immune Component	Disorder	Major Symptoms	Treatment
Phagocytic cells	Hyperimmunoglobulinemia E (HIE) syndrome	Bacterial, fungal, and viral infections; deep-seated cold abscesses	Antibiotic therapy and treatment for viral and fungal infections Granulocyte-macrophage colony-stimulating factor (GM-CSF); granulocyte colony-stimulating factor (G-CSF)
B lymphocytes	Sex-linked agammaglobulinemia (Bruton's disease)	Severe pyogenic infections soon after birth	Passive pooled plasma or gamma-globulin
	Common variable immunodeficiency (CVID)	Bacterial infections, infection with <i>Giardia lamblia</i> Pernicious anemia Chronic respiratory infections	Intravenous immunoglobulin (IVIG) Metronidazole (Flagyl) Quinacrine HCl (Atabrine) Vitamin B ₁₂ Antimicrobial therapy
	Immunoglobulin A (IgA) deficiency	Predisposition to recurrent infections, adverse reactions to blood transfusions or immunoglobulin, autoimmune diseases, hypothyroidism	None
	IgC ₂ deficiency	Heightened incidence of infectious diseases	Pooled immunoglobulin
T lymphocytes	Thymic hypoplasia (DiGeorge syndrome)	Recurrent infections; hypoparathyroidism, hypocalcemia, tetany, convulsions, congenital heart disease, possible renal abnormalities; abnormal facies	Thymus graft
	Chronic mucocutaneous candidiasis	<i>Candida albicans</i> infections of mucous membrane, skin, and nails; endocrine abnormalities (hypoparathyroidism, Addison's disease)	Antifungal agents: Topical: miconazole Oral: clotrimazole, ketoconazole IV: amphotericin B
B and T lymphocytes	Ataxia-telangiectasia	Ataxia with progressive neurologic deterioration, telangiectasia (vascular lesions), recurrent infections; malignancies	Antimicrobial therapy; management of presenting symptoms; fetal thymus transplant, IVIG
	Nezelof's syndrome	Severe infections, malignancies	Antimicrobial therapy; IVIG, bone marrow transplantation; thymus transplantation; thymus factors
	Wiskott-Aldrich syndrome	Thrombocytopenia, resulting in bleeding, infections; malignancies	Antimicrobial therapy; splenectomy with continuous antibiotic prophylaxis; IVIG and bone marrow transplantation
	Severe combined immunodeficiency disease (SCID)	Overwhelming severe fatal infections soon after birth (also includes opportunistic infections)	Antimicrobial therapy; IVIG and bone marrow transplantation
Complement system	Angioneurotic edema	Episodes of edema in various parts of the body, including respiratory tract and bowels	Pooled plasma, androgen therapy
	Paroxysmal nocturnal hemoglobinuria (PNH)	Lysis of erythrocytes due to lack of decay-accelerating factor (DAF) on erythrocytes	None

occurs in about 10% of patients with severe neutropenia. Chronic granulomatous disease, another type of primary phagocytic disorder, produces recurrent or persistent infections of the soft tissues, lungs, and other organs; these are resistant to aggressive treatment with antibiotics (Tierney, McPhee & Papadakis, 2008).

Assessment and Diagnostic Findings

Diagnosis is based on the history, signs and symptoms (see Chart 50-3), and laboratory analysis by the nitroblue tetrazolium reductase test, which indicates the cytotoxic (causing death of cells) activity of the phagocytic cells. A history of recurrent infection and fever, including the treatment given, in a child, and occasionally in an adult, is an impor-

tant key to diagnosis; timely intervention can prevent morbidity and mortality (DeSilva, Gunawardena, Wickremesinghe, et al., 2007). Failure of an infection to resolve with the usual treatment is an important indicator. Warning signs of primary immunodeficiency disorders are summarized in Figure 51-1.

Medical Management

Patients with neutropenia continue to be at increased risk for development of severe infections despite substantial advances in supportive care. Epidemiologic shifts occur periodically and need to be detected early because they influence prophylactic, empiric, and specific strategies for medical management. Attention to infection control practices is

Primary immune deficiency causes children and adults to have infections that come back frequently or are unusually hard to cure. In America alone, up to half a million people suffer from one or more of the 70 known primary immune deficiency diseases.

If you or your child is affected by more than one of the following conditions, speak to your doctor about the possible presence of primary immune deficiency.

- | | |
|---|--|
| <p>1 Eight or more new ear infections within 1 year</p> | <p>6 Recurrent, deep skin or organ abscesses</p> |
| <p>2 Two or more serious sinus infections within 1 year</p> | <p>7 Persistent thrush in mouth or elsewhere on skin, after age 1</p> |
| <p>3 Two or more months on antibiotics with little effect</p> | <p>8 Need for intravenous antibiotics to clear infections</p> |
| <p>4 Two or more pneumonias within 1 year</p> | <p>9 Two or more deep-seated infections such as meningitis, osteomyelitis, cellulitis, or sepsis</p> |
| <p>5 Failure of an infant to gain weight or grow normally</p> | <p>10 A family history of primary immune deficiency</p> |

Though the primary immune deficiency diseases can be serious, they are rarely fatal and can generally be controlled. Primary immune deficiency should not be confused with AIDS. Primary immune deficiency can be diagnosed through blood tests and should be detected as soon as possible to prevent avoidable permanent damage. As with all disease, only direct examination by a physician should be used to determine the presence of primary immune deficiency.

Figure 51-1 The 10 warning signs of primary immune deficiency. Education materials developed by the Jeffrey Modell Foundation Medical Advisory Board, New York. Used with permission.

important, especially with the emergence of multidrug-resistant organisms. Although it is effective in preventing some bacterial and some fungal infections, prophylactic drug treatment must be used with caution, because it has been implicated in the emergence of resistant organisms. The choices for empiric therapy include combination regimens and monotherapy. Specific choices depend on local factors (epidemiology, susceptibility/resistance patterns, availability, cost). Home and inpatient settings are also available and the selection of setting depends on the patient's risk category. Early diagnosis and appropriate treatment of many fungal and viral infections remains suboptimal in many cases (Saria & Gosselin-Acomb, 2007).

While granulocyte transfusions are used as a medical treatment, they are seldom successful because of the short half-life of these cells. Treatment with granulocyte-macrophage colony-stimulating factor (GM-CSF) or granulocyte colony-stimulating factor (G-CSF) may prove successful, because these proteins draw nonlymphoid stem cells from the bone marrow and hasten their maturation. Cell therapy, which refers to the provision of living cells to patients for the prevention of human disease, may be effective. (The infusion of blood and blood products is the best established and most widely practiced form of cell therapy.)

Hematopoietic stem cell transplantation (HSCT), another form of cell therapy, has proven to be a successful curative modality. The stem cells may be from embryos or adults. However, toxicity and reduced efficacy are frequent limitations of HSCT (Antachopoulos, et al., 2007; DeSilva, et al., 2007). Another emerging therapy involves the use of cells as vehicles for the delivery of genes or gene products. However, gene therapy has many side effects and needs further improvement (Santilli, Thompson, Kinnon, et al., 2008).

B-Cell Deficiencies

Pathophysiology

Two types of inherited B-cell deficiencies exist. The first type results from lack of differentiation of B-cell precursors into mature B cells. As a result, plasma cells are absent, and the germinal centers from all lymphatic tissues disappear, leading to a complete absence of antibody production against invading bacteria, viruses, and other pathogens. This syndrome is called X-linked **agammaglobulinemia** (Bruton's disease), because all antibodies disappear from the patient's plasma. B cells in the peripheral blood and IgG,

IgM, IgA, IgD, and IgE are low or absent. Infants born with this disorder suffer from severe infections starting soon after birth. Males are at a high risk for having X-linked agammaglobulinemia if they have an affected male relative. More than 10% of patients with X-linked agammaglobulinemia are hospitalized for infection when they are younger than 6 months of age; prognosis depends on prompt recognition and treatment (Levinson, 2008).

Autosomal agammaglobulinemia refers to a rare instance in which normal hypogammaglobulinemia of infancy is prolonged. It can result from mutations in a variety of genes whose products are required for differentiation of B cells. However, IgG levels do rise eventually. Periodic immunologic assessment is needed to differentiate transient hypogammaglobulinemia from other forms of antibody deficiency.

The second type of B-cell deficiency results from a lack of differentiation of B cells into plasma cells. Only diminished antibody production occurs with this disorder. Although plasma cells are the most vigorous producers of antibodies, affected patients have normal lymph follicles and many B lymphocytes that produce some antibodies. This syndrome, called **hypogammaglobulinemia**, is a frequently occurring immunodeficiency. It is also called CVID; this disorder encompasses a variety of defects ranging from IgA deficiency, in which only the plasma cells that produce IgA are absent, to the other extreme, in which there is severe **panhypoglobulinemia** (general lack of immunoglobulins in the blood) (Stewart, Tian, Notorangelo, et al., 2008).

CVID is the most common primary immunodeficiency seen in adults; it can occur in people of either gender. Although it usually presents within the first two decades of life, most patients are diagnosed as adults, because CVID often goes unrecognized. Several T- and B-cell defects have been described, but the underlying cause is still unknown; the etiology is believed to be multifactorial. Patients usually have normal B-cell lymphocyte counts, but the cells are clinically diverse and immature. Although they can recognize antigens and mount a response, their ability to become memory B cells and mature plasma cells is impaired.

Clinical Manifestations

Infants with X-linked agammaglobulinemia usually become symptomatic after the natural loss of maternally transmitted immunoglobulins, which occurs at about 5 to 6 months of age. Symptoms of recurrent pyogenic infections usually occur by that time.

Besides recurrent infection, patients with CVID are at increased risk for autoimmune disease, granulomatous disease, and malignancy, indicating that CVID is a disease of abnormal immune regulation as well as of immunodeficiency. Approximately 20% to 22% of patients develop autoimmune diseases, notably autoimmune thrombocytopenic purpura and autoimmune hemolytic anemia (Seve, Bourdillon, Sarrot-Reynauld, et al., 2008). Other autoimmune diseases, such as arthritis and hypothyroidism, frequently occur. Associated fever, weight loss, anemia, thrombocytopenia, splenomegaly, lymphadenopathy, and lymphocytosis may suggest underlying lymphoid malignancy.

More than 50% of patients with CVID develop pernicious anemia. Lymphoid hyperplasia of the small intestine

and spleen as well as gastric atrophy, which is detected by biopsy of the stomach, are common findings. Gastrointestinal malabsorption may occur. Young adults who develop the disease also have an increased incidence of chronic lung disease, hepatitis, gastric cancer, and malabsorption that results in chronic diarrhea. CVID must be distinguished from secondary immunodeficiency diseases caused by protein-losing enteropathy, nephrotic syndrome, or burns.

Patients with CVID are susceptible to infections with encapsulated bacteria, such as *Haemophilus influenzae*, *Streptococcus pneumoniae*, and *Staphylococcus aureus*. Frequent respiratory tract infections typically lead to chronic progressive bronchiectasis and pulmonary failure. Commonly, infection with *Giardia lamblia* occurs. Opportunistic infections with *Pneumocystis jiroveci* pneumonia (PCP), however, are seen only in patients who have a concomitant deficiency in T-cell immunity.

Assessment and Diagnostic Findings

X-linked agammaglobulinemia may be diagnosed by the marked deficiency or complete absence of all serum immunoglobulins. The diagnosis of CVID is based on the history of repeated bacterial infections, quantification of B-cell activity, and reported signs and symptoms. The number of B lymphocytes as well as the total and specific immunoglobulin levels are measured. Measuring only the total serum globulin level is inadequate, because a compensatory overproduction of one globulin may mask the loss of another globulin or the deficiency of a globulin that is present in very low amounts. Antibody titers to confirm successful childhood vaccination are determined by specific serologic tests. Previous successful childhood immunization indicates that B cells were functioning adequately earlier in life. If the patient exhibits signs and symptoms suggestive of pernicious anemia, hemoglobin and hematocrit levels are also obtained. Biopsies of the small intestine, spleen, and stomach may also be obtained to assess for lymphoid hyperplasia.

Medical Management

Patients with primary phagocytic disorders may be treated with intravenous immunoglobulin (IVIG) (Chart 51-1). Its administration is an essential part of the prevention and treatment of complications of CVID (Kishiyama, 2005). Antibody replacement therapy is recommended for severe, recurrent infections. Other interventions aimed at overcoming the immunologic defects in CVID, such as interleukin-2 therapy, are being studied (Garcia, Espanol, Gurbindo, et al., 2007).

T-Cell Deficiencies

Pathophysiology

Defects in T cells lead to opportunistic infections. Most primary T-cell immunodeficiencies are genetic in origin. Partial T-cell immunodeficiencies constitute a heterogeneous cluster of disorders characterized by an incomplete reduction in T-cell number or activity. Unlike severe T-cell immunodeficiencies, however, partial immunodeficiencies are commonly associated with hyperimmune dysregulation,

CHART
51-1

PHARMACOLOGY

Managing an Intravenous Immunoglobulin (IVIg) Infusion

IVIg has become an important treatment for a variety of disease states that are characterized by deficient production of antibodies. It may have other indications but is commonly used for the treatment of DiGeorge syndrome, common variable immunodeficiency disease (CVID), severe combined immunodeficiency disease (SCID), Wiskott-Aldrich syndrome, and idiopathic thrombocytopenic purpura. Previously available only for intramuscular injection, immunoglobulin can now be administered for replacement therapy as an IV infusion in greater, more effective doses without painful side effects, and it can safely be given in outpatient as well as inpatient settings. Variables affecting the risk and intensity of adverse events associated with the administration of IVIg include patient age, underlying condition, history of migraine, and cardiovascular and/or renal disease; dose, concentration, and rate of infusion; and specific data related to the precise lot of the product. The nurse must assess all of these variables before starting the IVIg infusion and during the infusion process. He or she must anticipate adverse effects if any of these variables are present (Shelton, et al., 2006).

How Supplied

Immunoglobulin is supplied in a 5% solution or a lyophilized powder with a reconstituting diluent prepared from Cohn fraction II obtained from pools of 1000 to 10,000 donors. Currently, a number of different IV preparations are approved for use and have been shown to be effective and safe by the U.S. Food and Drug Administration.

Dosage

The optimal dose is determined by the patient's response. In most instances, an IV dose of 100 to 400 mg/kg of body weight is administered monthly or more frequently to ensure adequate serum levels of immunoglobulin G.

Adverse Effects

- Complaints of flank and back pain, shaking chills, dyspnea, and tightness in the chest; headache, fever, and local reaction at the infusion site
- Serious conditions, including aseptic meningitis, renal failure, thromboembolic events, and anaphylaxis. Anaphylactic reactions typically occur 30 to 60 minutes after the start of the infusion. The potential increases as the dose of IVIg increases.
- Hypotension (possible with severe reactions)

Guidelines for Nursing Management

- Pretreatment assessments should be performed before each infusion.
- Obtain height and weight before treatment to verify accurate dosing.
- Assess baseline vital signs before, during, and after treatment. An elevated temperature at the beginning of treatment may be an indication to delay the infusion to avoid misinterpretation as a reaction to the infusion.
- Premedicate with acetaminophen and diphenhydramine as prescribed 30 minutes before the start of the infusion.
- Understand that long-term tolerance of an older IVIg product does not necessarily imply tolerance to a newer product, even if it is technically superior. Caution should be exercised when changing IVIg products because they are not biologically equivalent.
- Be aware that corticosteroids may be used to prevent possible severe reactions in patients who are perceived to be at risk.
- Administer the IV infusion at a slow rate, not to exceed 3 mL/min.
- Continually assess the patient for adverse reactions; be especially aware of complaints of a tickle or lump in the throat as the precursor to laryngospasm that precedes bronchoconstriction.
- Stop the infusions at the first sign of reaction and initiate the institutional protocol to be followed in this emergent situation.
- Be aware that patients with low gammaglobulin levels have more severe reactions than those with normal levels (eg, patients who receive gammaglobulin for thrombocytopenia or Kawasaki disease).
- Keep in mind that patients who have an immunoglobulin A (IgA) deficiency have IgE antibodies to IgA, which requires administration of plasma or immunoglobulin replacement from IgA-deficient patients. Because all IV immunoglobulin preparations contain some IgA, they may cause an anaphylactic reaction in patients with IgE anti-IgA antibodies.
- Recognize that the pharmacokinetics of IgG differ when smaller doses are given more frequently, as is commonly done with subcutaneous regimens. Differences include lower peaks and higher troughs, which may be preferable for some patients.
- Remember that the risk of transmission of hepatitis, HIV, or other known viruses is extremely low.

including autoimmune disorders, inflammatory diseases, and elevated IgG production (Liston, Enders & Siggs, 2008). Although an increased susceptibility to infection is common, symptoms can vary considerably, depending on the type of T-cell defect. Because the T cells play a regulatory role in immune system function, the loss of T-cell function is usually accompanied by some loss of B-cell activity.

DiGeorge syndrome, or **thymic hypoplasia**, is an example of a primary T-cell immunodeficiency. This rare, complex, multisystem genetic abnormality, which affects multiple organ systems, has been mapped to chromosomes 10 or 22. The symptom variation is a result of differences in

the amount of genetic material affected. T-cell deficiency occurs when the thymus gland fails to develop normally during embryogenesis. The syndrome often manifests in the neonatal period as a cardiac anomaly, although hypocalcemic tetany and facial abnormalities may also occur. It is one of the few immunodeficiency disorders with symptoms that manifest almost immediately after birth (McLean-Tooke, Barge, Spickett, et al., 2008; Sullivan, 2008).

Chronic mucocutaneous candidiasis is a rare T-cell disorder, which is thought to be an autosomal recessive disorder that affects both males and females. It is considered an autoimmune disorder involving the thymus and other

endocrine glands. The disease causes extensive morbidity resulting from endocrine dysfunction.

Clinical Manifestations

Infants born with DiGeorge syndrome have hypoparathyroidism with resultant hypocalcemia resistant to standard therapy, congenital heart disease, cleft palate and lip, dysmorphic facial features, and possibly renal abnormalities. These infants are susceptible to yeast, fungal, protozoan, and viral infections and are particularly susceptible to childhood diseases (chickenpox, measles, rubella), which are usually severe and may be fatal. Infection with *Candida albicans* is almost universal in patients with severe deficiencies in T cell–mediated immunity. Many affected infants are also born with congenital heart defects, which can result in heart failure. The most frequent presenting sign in patients with DiGeorge syndrome is hypocalcemia that is resistant to standard therapy. It usually occurs within the first 24 hours of life (McLean-Tooke, et al., 2008; Sullivan, 2008).

The initial presentation of chronic mucocutaneous candidiasis may be a result of either chronic candidal infection or idiopathic endocrinopathy. The disease is characterized by persistent or recurrent candidal infections of the skin, nails, and mucous membranes or by a variable combination of endocrine failure as well as immunodeficiency (Liu & Hua, 2007). Patients may survive to the second or third decade of life. Problems may include hypocalcemia and tetany secondary to hypofunction of the parathyroid glands (see Chapter 14). Hypofunction of the adrenal cortex (Addison's disease) is the major cause of death in these patients; it may develop suddenly and without any history of previous symptoms.

Assessment and Diagnostic Findings

Prompt diagnosis is necessary for appropriate management. A comprehensive immunologic laboratory analysis is necessary. Findings in children with DiGeorge syndrome include cardiac, nutritional, and developmental abnormalities (Sullivan, 2008).

Medical Management

Patients with T-cell deficiency should receive prophylaxis for PCP. General care includes management of hypocalcemia and correction of cardiac abnormalities. Hypocalcemia is controlled by oral calcium supplementation in conjunction with administration of vitamin D or parathyroid hormone. Congenital heart disease frequently results in heart failure, and these patients may require immediate surgical intervention in a tertiary care center. Transplantation of fetal thymus, postnatal thymus, or human leukocyte antigen (HLA)-matched bone marrow has been used for permanent reconstitution of T-cell immunity (Mazzolari, Forino, Guerci, et al, 2007). In children with DiGeorge syndrome, attention must be given to cardiac, nutritional, and developmental needs (Sullivan, 2008). IVIG may be used if an antibody deficiency exists. This therapy may also be used to control recurrent infections. T-cell function improves with age and often is normal by 5 years of age. Prolonged survival has been reported after spontaneous remission of immunodeficiency, which occurs in some patients (Markert, 2008).

Combined B-Cell and T-Cell Deficiencies

Pathophysiology

T-cell and B-cell immune deficiencies comprise a heterogeneous group of disorders, all characterized by profound impairment in the development or function of the cellular, the humoral, or both parts of the immune system. A variety of inherited (autosomal recessive and X-linked) conditions fit this description. These conditions are typified by disruption of the normal communication system of B cells and T cells and impairment of the immune response, and they appear early in life (Cooper & Schroeder, 2008).

Ataxia-telangiectasia is an autosomal recessive neurodegenerative disorder characterized by cerebellar **ataxia** (loss of muscle coordination), **telangiectasia** (vascular lesions caused by dilated blood vessels), and immune deficiency. The immunologic defects reflect abnormalities of the thymus. The disorder is characterized by some degree of T-cell deficiency, which becomes more severe with advancing age. In 40% of patients, a selective IgA deficiency exists. In addition, IgG and IgE deficiencies have been identified. Immunodeficiency is manifested by recurrent and chronic sinus and pulmonary infections, leading to bronchiectasis. Frequent causes of death are chronic pulmonary disease and malignancy. While lymphomas are most common, other carcinomas occur. The disease is also associated with neurologic, vascular, endocrine, hepatic, and cutaneous abnormalities (Levinson, 2008).

Severe combined immunodeficiency disease is a disorder in which both B cells and T cells are missing. Consequently, both cell-mediated and humoral functions are affected. In addition, SCID is marked by susceptibility to serious fungal, bacterial, and viral infections. It refers to a wide variety of congenital and hereditary immunologic defects characterized by early onset of infections, defects in both B-cell and T-cell systems, lymphoid aplasia, and thymic dysplasia. It is one of the most common causes of primary immunodeficiencies. Inheritance of this disorder can be X linked, autosomal recessive, or sporadic. The exact incidence of SCID is unknown; it is recognized as a rare disease in most population groups, with an incidence of about 1 case in 1,000,000. This illness occurs in all racial groups and both genders.

Wiskott-Aldrich syndrome (WAS), a variation of SCID, is an inherited immunodeficiency caused by a variety of mutations in the gene encoding the WAS protein. It is characterized by frequent infections, thrombocytopenia with small platelets, eczema, and increased risk of autoimmune disorders and malignancies. Vasculitides and autoimmune hemolytic anemia are the two most common autoimmune manifestations and often cause considerable morbidity and mortality. The prognosis is poor, because most affected people develop overwhelming fatal infections.

Clinical Manifestations

The onset of ataxia and telangiectasia occurs in the first 4 years of life. Many patients, however, remain symptom-free for 10 years or longer. As the patient approaches the

second decade of life, chronic lung disease, cognitive impairment, neurologic symptoms, and physical disability become severe. Long-term survivors develop progressive deterioration of immunologic and neurologic functions. Some affected patients have lived until the fifth decade of life. The primary causes of death in these patients are overwhelming infection and lymphoreticular or epithelial cancer.

The onset of symptoms occurs within the first 3 months of life in most patients with SCID. Symptoms include respiratory infections and pneumonia (often secondary to PCP infection), thrush, diarrhea, and failure to thrive. Many of these infections are resistant to treatment. Shedding of viruses such as respiratory syncytial virus or cytomegalovirus from the respiratory and gastrointestinal tracts is persistent. Maculopapular and erythematous skin rashes may occur. Vomiting, fever, and a persistent rash are also common manifestations (Geha & Rosen, 2007).

Medical Management

Treatment of ataxia-telangiectasia includes early management of infections with antimicrobial therapy, management of chronic lung disease with postural drainage and physical therapy, and management of other presenting symptoms. Other treatments include transplantation of fetal thymus tissue and IVIG administration (see Chart 51-1).

Treatment options for SCID include stem cell and bone marrow transplantation. HSCT is the definitive therapy for SCID; the best outcome is achieved if the disease is recognized and treated early in life. Improvements continue in the use of HSCT to treat patients with SCID, as well as other primary immunodeficiencies. The ideal donor is an HLA-identical sibling. Evidence demonstrates that transplantation of allogeneic hematopoietic stem cells can cause an enhanced improvement over time. Other treatment

options include administration of IVIG or thymus-derived factors and thymus gland transplantation. Gene therapy has been used, but the results have been disappointing (Dvorak & Cowan, 2008). For the most common forms of combined immune deficiency, gene therapy can lead to immune reconstitution in most patients, but a minority derive minimal clinical benefit and some have suffered severe adverse effects, including death (Santilli, et al., 2008; Sokolic, Kesserwan & Candotti, 2008). As treatment improves, an increasing number of patients who previously would have died in infancy are living to adulthood. Newborn screening is proposed as a means to make a prompt diagnosis and initiate treatment in all affected infants (Puck, 2007).

Nursing Management

Many patients require immunosuppression to ensure engraftment of depleted bone marrow during transplantation procedures. For this reason, nursing care must be meticulous. Appropriate infection control precautions and thorough hand hygiene are essential (Chart 51-2). Institutional policies and procedures related to protective care must be followed scrupulously until definitive evidence demonstrates that precautions are unnecessary. Continual monitoring of the patient's condition is critical, so early signs of impending infection may be detected and treated before they seriously compromise the patient's status. It also is imperative that attention be given to appropriate application of standard precautions (previously known as universal precautions), which have become one of the first-line tools for decreasing transmission of disease, whether from nurse to patient, patient to patient, or patient to nurse. Standard precautions are based on the principle that all blood and body fluids, secretions, and excretions may contain transmissible infectious agents. Some of the key elements of

NURSING RESEARCH PROFILE

Implementation of New Hygiene Practices and the Resultant Impact on Infection Rates

Larson, E., Quiros, D. & Lin, S. (2007). Dissemination of the CDC's hand hygiene guideline and impact on infection rates. *American Journal of Infection Control*, 35(10), 666–675.

Purpose

Most hospitalized patients are at high risk for infection. This study was undertaken to measure the impact of national evidence-based guidelines on practice. The objectives were to (1) evaluate implementation and compliance with clinical practices recommended in the hand hygiene guidelines of the Centers for Disease Control and Prevention (CDC), (2) compare rates of health care–associated infections (HAIs) before and after implementation of the guidelines, and (3) examine the patterns and correlates of changes in the rates of HAIs.

Design

The investigators used pre- and postguideline implementation site visits and surveys in 40 U.S. hospitals that were members of the national nosocomial infections surveillance system. They measured HAI rates 1 year before and after publication of the CDC guidelines. In addition, they used hand hygiene compliance and guideline implementation scores as outcome measures.

Findings

The 40 hospitals had changed their policies and procedures and provided products in compliance with the recommended guidelines. Of 1359 staff members surveyed anonymously, 89.8% reported that they were familiar with the guidelines. However, in 44.2% of the hospitals, there was no evidence of a multidisciplinary program to improve compliance. Hand hygiene rates remained low (56.6%), similar to the rates reported for the past few decades. Rates of central line–associated bloodstream infections were significantly lower in hospitals with higher rates of hand hygiene compliance ($p < .001$). No impact of guideline implementation or hand hygiene compliance on other HAI rates was identified.

Nursing Implications

This study confirms the observation that institutional adoption of a guideline does not guarantee practice changes. The incidence of health care–associated infections has grown significantly and has resulted in increased patient morbidity and mortality. This increase has contributed to escalating costs of hospital care. It is the professional responsibility of every practitioner to deliver care consistent with standards of safety and quality.

standard precautions include performing hand hygiene, as previously mentioned; using appropriate personal protective equipment, depending on the expected type of exposure; and using safe injection practices (Tarrac, 2008).

Deficiencies of the Complement System

The complement system is an integral part of the immune system, and deficiencies in normal levels of C2 and C3 complement result in increased susceptibility to infectious diseases and immune-mediated disorders. Improved techniques to identify the individual components of the complement system have led to a steady increase in the number of deficiencies identified.

Hereditary **angioneurotic edema** results from the deficiency of C1-esterase inhibitor, which opposes the release of inflammatory mediators. The clinical picture of this autosomal dominant disorder includes recurrent attacks of edema formation in the subcutaneous tissue, gastrointestinal tract, and upper airway (Farkas, Varga, Szeplaki, et al., 2007). Although the disease is mild in childhood and becomes more severe after puberty, first episodes have been reported later in life. Food allergy has often been linked to this disorder, although recent evidence has implicated a C1-esterase inhibitor deficiency. The fluctuations in hormone levels at the beginning of adolescence, in the perimenopausal period, during pregnancy, and during the use of oral contraceptives can precipitate edematous attacks that usually disappear after the onset of menopause. Fresh-frozen plasma has been used as a treatment option, with variable results (Prematta, Gibbs, Pratt, et al., 2007).

Paroxysmal nocturnal hemoglobinuria is an acquired clonal stem cell disorder resulting from a somatic mutation in the hematopoietic stem cell. An absent glycosylphosphatidylinositol (GPI)-anchored receptor prevents several proteins from binding to the erythrocyte membrane. These include the complement-regulatory proteins, CD55 and CD59, the absence of which results in enhanced complement-mediated lysis. Clinical manifestations may be indolent or life-threatening. The disorder is characterized by hemoglobinuria that increases during sleep, as well as intravascular hemolysis, cytopenia, infections, bone marrow hyperplasia, and a high incidence of life-threatening venous thrombosis, which occurs most commonly in the abdominal and cerebral veins. Severe fatigue, abdominal pain, and esophageal spasm may also be present. Leukopenia, thrombocytopenia, and episodic crises are common. Severe infection can occur as a result of aplastic bone marrow and splenic thrombosis. Laboratory diagnosis can include specialized tests, such as the sucrose hemolysis test, Ham acid hemolysis test, and fluorescent-activated cell analysis. A coagulation profile is also indicated.

SECONDARY IMMUNODEFICIENCIES

Secondary immunodeficiencies are more common than primary immunodeficiencies and frequently occur as a result of underlying disease processes or the treatment of these disorders. The immune system can be affected by a variety of intrinsic factors, including immunosuppressive agents, harsh environmental conditions, hereditary disorders other than

primary immunodeficiencies, and acquired metabolic disorders that cause secondary immunodeficiencies. Common causes of secondary immunodeficiencies include chronic stress, burns, uremia, diabetes mellitus, certain autoimmune disorders, certain viruses, exposure to immunotoxic medications and chemicals, and self-administration of recreational drugs and alcohol. Perhaps the best-known secondary immunodeficiency results from human immunodeficiency virus (HIV) infection, which causes acquired immunodeficiency syndrome (AIDS); however, the most prevalent cause of immunodeficiency worldwide is severe malnutrition. AIDS, the most common secondary disorder, is discussed in detail in Chapter 52.

In secondary immunodeficiencies, abnormalities of the immune system affect both natural and acquired immunity, may be subtle, and are usually heterogeneous in their clinical manifestations. Patients with secondary immunodeficiencies are known as **immunocompromised hosts**.

Medical Management

Medical management of secondary immunodeficiencies includes diagnosis and treatment of the underlying disease process. Treatment of the primary condition often results in the improvement of the affected immune components (Chinen & Shearer, 2008). Factors that contribute to immunosuppression are identified and infection is treated. Additional treatment includes HSCT, monoclonal antibody therapy, and anticoagulation therapy as indicated. HSCT may be curative (Brodsky, 2008; Woolhead, Deepak, Patel, et al., 2008).

NURSING MANAGEMENT FOR PATIENTS WITH IMMUNODEFICIENCIES

Nursing management includes assessment, patient teaching, selected interventions, and supportive care. Assessment of the patient for infection and timely initiation of treatment are essential. Nursing care of patients with primary and secondary immunodeficiencies depends on the underlying cause of the immunodeficiency, the type of immunodeficiency, and its severity. Because immunodeficiencies result in a compromised immune system and pose a high risk for infection, careful assessment of the patient's immune status is essential. The assessment focuses on the history of past infections, particularly the type and frequency of infection; methods of and response to past treatments; signs and symptoms of any current skin, respiratory, oral, gastrointestinal, or genitourinary infection; and measures taken by the patient to prevent infection. The nurse assesses and monitors the patient for signs and symptoms of infection (Chart 51-3).

Many patients develop oral manifestations and need education about promoting good dental hygiene to diminish the oral discomfort and complications that frequently result in inadequate nutritional intake. Involving patients in their daily oral assessment and care helps them become proactive in preventing complications. To implement individualized care strategies, it is essential to provide patients with the skills to promote health and limit the incidence of disease.

Because the inflammatory response may be blunted, the patient is observed for subtle and unusual signs and changes in physical status. Vital signs and the development of pain,

CHART
51-3**Assessing for Infection**

Be alert for the following signs and symptoms:

- Fever with or without chills
- Cough with or without sputum
- Shortness of breath
- Difficulty breathing
- Difficulty swallowing
- White patches in the oral cavity
- Swollen lymph nodes
- Nausea with or without vomiting
- Persistent diarrhea
- Frequency, urgency, or pain on urination
- Change in the character of the urine
- Lesions on the face, lips, or perianal area
- Redness, swelling, or drainage from skin lesions
- Persistent vaginal discharge with or without perianal itching
- Persistent abdominal pain

neurologic signs, cough, and skin and oral lesions are monitored and reported immediately. Pulse rate and respiratory rate should be counted for a full minute, because subtle changes can signal deterioration in the patient's clinical status. Auscultation of the breath sounds is important to detect changes in respiratory status that signal an existing or impending infection. Any unusual response to treatment or a significant change in the patient's clinical condition must be promptly reported to the physician (Jarvis, 2008).

The nurse continuously monitors laboratory values for changes indicative of infection. Culture and sensitivity reports from wound drainage, lesions, sputum, stool, urine, and

blood are monitored to identify pathogenic organisms and appropriate antimicrobial therapy. Changes in laboratory results and subtle changes in clinical status must be reported to the physician, because the immunocompromised patient may fail to develop typical signs and symptoms of infection.

Assessment also focuses on nutritional status; stress level and coping skills; use of alcohol, drugs, or tobacco; and general hygiene practices, all of which may affect immune function. Strategies the patient has used to reduce the risk of infection are identified and evaluated for their appropriateness and effectiveness (Dudek, 2006). Other aspects of nursing care are directed toward reducing the patient's risk for infection, assisting with medical measures aimed at improving immune status and treating infection, achieving optimal nutritional status, and maintaining respiratory, bowel, and bladder function. The patient's ability to demonstrate good hand hygiene must be assessed, and the patient is encouraged to cough and perform deep-breathing exercises at regular intervals. Teaching good dental hygiene measures reduces the potential for oral lesions, as do instructions on measures to protect the integrity of the skin. Attention to strict aseptic technique when performing invasive procedures, such as dressing changes, venipunctures, and bladder catheterizations, is essential. Other aspects of nursing care include assisting the patient to manage stress, to incorporate lifelong patterns of physiologic safety, and to adopt behaviors that strengthen immune system function.

Gene defects that cause many of the currently recognized immunodeficiency disorders are being identified, and genetic testing is becoming available for many of these disorders. Although this testing is rarely indicated in the initial workup for immunodeficiency (Lehman, Hernandez-Trujillo & Ballow, 2008), nurses should be aware of it and

CHART
51-4**HOME CARE CHECKLIST****Infection Prevention for the Patient With Immunodeficiency**

At the completion of the home care instruction, the patient or caregiver will be able to:	PATIENT	CAREGIVER
• Identify signs and symptoms of infection to report to the health care provider, such as fever; chills; wet or dry cough; breathing problems; white patches in the mouth; swollen glands; nausea; vomiting; persistent abdominal pain; persistent diarrhea; problems with urination or changes in the character of the urine; red, swollen, or draining wounds; sores or lesions on the body; persistent vaginal discharge with or without itching; and severe fatigue.	✓	✓
• Demonstrate correct handwashing procedure.	✓	✓
• State rationale for thorough handwashing before eating, after using the bathroom, and before and after performing health care procedures.	✓	✓
• State rationale for use of cream and emollients to prevent or manage dry, chafed, or cracked skin.	✓	✓
• Demonstrate recommended personal hygiene in bathing and foot care to prevent bacterial and fungal diseases.	✓	✓
• State rationale for avoiding contact with people who have known illness or who have recently been vaccinated.	✓	✓
• Verbalize understanding of ways to maintain a well-balanced diet and adequate calories.	✓	✓
• State the reason for avoiding the eating of raw fruits and vegetables, cooking all foods thoroughly, and immediately refrigerating all leftover food.	✓	✓
• Identify the rationale for frequent cleaning of kitchen and bathroom surfaces with disinfectant.	✓	✓
• Identify rationale and benefits of avoiding alcohol, tobacco, and unprescribed medications.	✓	✓
• State rationale for taking prescribed medications as directed.	✓	✓
• Verbalize ways to cope with stress successfully, plans for regular exercise, and rationale for obtaining adequate rest.	✓	✓

CHART
51-5

HOME CARE CHECKLIST

Home Infusion of Intravenous Immunoglobulin (IVIg)

At the completion of the home care instruction, the patient or caregiver will be able to:	PATIENT	CAREGIVER
• Identify the benefits and expected outcome of IVIG.	✓	✓
• Demonstrate how to check for patency of the IV access device.	✓	✓
• Demonstrate how to prepare IVIG.	✓	✓
• Demonstrate how to infuse IVIG.	✓	✓
• Demonstrate how to clean and maintain IV equipment.	✓	✓
• Identify side effects and adverse effects of IVIG.	✓	✓
• State rationale for prophylactic use of acetaminophen (Tylenol) and diphenhydramine (Benadryl) before treatment begins.	✓	✓
• Verbalize understanding of emergency measures for anaphylactic shock.	✓	✓

knowledgeable about it. Some deficiencies can be diagnosed by phenotype and functional assays. Genetic testing can establish or confirm a suspected diagnosis of some primary immune deficiencies. In addition, it also may predict future disease risk prior to the onset of clinical signs and symptoms and guide clinicians in selecting the most appropriate therapeutic options (Morra, Geigenmuller, Curran, et al., 2008). Genetic testing is not typically required in CVID because known genetic defects cause only a small number of cases of CVID, and results would not alter treatment. To perform genetic testing, informed consent from the patient or legal guardian is necessary. It can be accomplished using whole blood samples and mouth swab samples.

If the patient is a candidate for any of the newer or experimental therapies (gene therapy, bone marrow transplantation, immunomodulators such as interferon- γ), the patient and family must be informed about the potential risks and benefits of the treatment regimen. A major role of the nurse is to develop and maintain a knowledge base in these evolving treatment modalities, to help the patient and family understand the treatment options and cope with the uncertainties of treatment outcomes.

Promoting Home and Community-Based Care

Teaching Patients Self-Care

The patient and caregivers require instruction about the signs and symptoms that indicate infection and about the potential for occurrence of atypical symptoms secondary to underlying immunosuppression. They must be informed of the need for continuous monitoring for subtle changes in the patient's physical health status and of the importance of seeking immediate health care if changes are detected. Patients should be advised that they know themselves best; therefore, whenever they experience a symptom that is not typical for them, they should contact their health care provider, who will determine and initiate appropriate therapy. Instruction needs to be provided about prophylactic medication regimens, including dosage, indications, times, actions, potential interactions, and side effects. Patients and their families are also instructed about the importance of continuing treatment regimens without interruption and

incorporating these routines into their daily living patterns. The patient is instructed about the importance of avoiding others with infections and avoiding crowds, and about other ways to prevent infection (Chart 51-4).

The patient who is to receive IVIG at home will need information about the expected benefits and outcomes of the treatment as well as expected adverse reactions and their management (Chart 51-5). Patients who can perform self-infusion at home must be instructed in sterile technique, medication dosages, administration rate, and detection and management of adverse reactions (Shelton, Griffin & Goldman, 2006).

Continuing Care

Encouraging the patient and family to be active partners in the management of the immunodeficiency is the key to successful outcomes and a favorable prognosis. The patient must be made aware that all health-related instructions are lifelong, that follow-up with all scheduled appointments is essential, and that it is the patient's responsibility to notify the primary care provider of any early signs or symptoms of infection, however subtle they may be. If the patient's treatment includes IVIG and the patient or family cannot administer treatment, a referral for home care or an infusion service is warranted.

CRITICAL THINKING EXERCISES

EBP 1 You are the charge nurse on a medical critical care unit. A new nurse approaches you for advice on the best infection control practices to use with a patient with cancer who has just been admitted and is immunosuppressed. Identify the infection control measures that are indicated. Describe the evidence base for the infection control measures you identified and the criteria used to evaluate the strength of that evidence.

2 The mother of your 7-year-old neighbor contacts you to discuss his frequent illnesses. She asks whether there may be something serious underlying the nine ear infections he has had in the previous year. Identify the 10 warning signs of primary immune deficiency that you would consider when responding to this mother's dilemma.

3 You are caring for a 20-year-old man who has an immunodeficiency and has been hospitalized multiple times. Describe the assessment parameters and the nursing plan of care for this patient. Identify the laboratory values that are important to monitor and report. Describe the plan for continuing care for this patient.

Management of Patients With HIV Infection and AIDS

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

- 1 Describe the modes of transmission of HIV infection and prevention strategies.
- 2 Describe the host/HIV interaction during primary infection.
- 3 Explain the pathophysiology associated with the clinical manifestations of HIV/AIDS.
- 4 Describe the clinical management of patients with HIV/AIDS.
- 5 Discuss the nursing interventions appropriate for patients with HIV/AIDS.
- 6 Use the nursing process as a framework for care of the patient with HIV/AIDS.

GLOSSARY

alpha-interferon: protein substance that the body produces in response to infection

B-cell lymphoma: common malignancy in patients with HIV/AIDS

candidiasis: yeast infection of skin or mucous membrane

CCR5: along with the CD4+ receptor, this cell surface molecule is used by HIV to fuse with the host's cell membranes

cytomegalovirus: a species-specific herpes virus that may cause retinitis in people with AIDS

EIA (enzyme immunoassay): a blood test that can determine the presence of antibodies to HIV in the blood or saliva; also referred to as **enzyme-linked immunosorbent assay (ELISA)**. Positive results must be validated, usually with Western blot test.

HIV-1: retrovirus isolated and recognized as the etiologic agent of AIDS

HIV-2: retrovirus identified in 1986 in AIDS patients in West Africa

HIV encephalopathy: degenerative neurologic condition characterized by a group of clinical presentations including loss of coordination, mood swings, loss of inhibitions, and widespread cognitive dysfunctions; formerly referred to as AIDS dementia complex (ADC)

human papillomavirus (HPV): viruses that cause various warts, including plantar and genital warts; some strains of HPV can also cause cervical cancer

immune reconstitution inflammatory syndrome: a syndrome that results from rapid restoration of pathogen-specific immune responses to opportunistic infections; most often occurs after starting antiretroviral therapy

Kaposi's sarcoma: malignancy that involves the epithelial layer of blood and lymphatic vessels

latent reservoir: the integrated HIV provirus within the CD4+ T cell during the resting memory state; does not express viral proteins and is invisible to the immune system and antiviral medications.

GLOSSARY (Continued)

macrophage: large immune cell that devours invading pathogens and other intruders; can harbor large quantities of HIV without being killed, acting as a reservoir of the virus

monocyte: large white blood cell that ingests microbes or other cells and foreign particles. When a monocyte enters tissues, it develops into a macrophage.

Mycobacterium avium complex: opportunistic infection caused by mycobacterial organisms that commonly causes a respiratory illness but can also infect other body systems

opportunistic infection: illness caused by various organisms, some of which usually do not cause disease in people with normal immune systems

p24 antigen: blood test that measures viral core protein; accuracy of test is limited because the p24 antibody binds with the antigen and makes it undetectable

peripheral neuropathy: disorder characterized by sensory loss, pain, muscle weakness, and wasting of muscles in the hands or legs and feet

Pneumocystis pneumonia or Pneumocystis jiroveci pneumonia (PCP): common opportunistic lung infection caused by an organism, believed to be a fungus based on its structure

polymerase chain reaction: a sensitive laboratory technique that can detect and quantify HIV in a person's blood or lymph nodes

primary infection: 4- to 7-week period of rapid viral replication immediately following infection; also known as acute HIV infection

progressive multifocal leukoencephalopathy: opportunistic infection that infects brain tissue and causes damage to the brain and spinal cord

protease inhibitor: medication that inhibits the function of protease, an enzyme needed for HIV replication

provirus: viral genetic material in the form of DNA that has been integrated into the host genome. When it is dormant in human cells, HIV is in a proviral form.

retrovirus: a virus that carries genetic material in RNA instead of DNA and contains reverse transcriptase

reverse transcriptase: enzyme that transforms single-stranded RNA into a double-stranded DNA

viral load test: measures the quantity of HIV RNA in the blood

viral set point: amount of virus present in the blood after the initial burst of viremia and the immune response that follows

wasting syndrome: involuntary weight loss of 10% of baseline body weight with chronic diarrhea or chronic weakness and documented fever

Western blot assay: a blood test that identifies antibodies to HIV and is used to confirm the results of an EIA (ELISA) test

window period: time from infection with HIV until seroconversion detected on HIV antibody test

Although advances have been made in treating human immunodeficiency virus (HIV) infection and acquired immunodeficiency syndrome (AIDS), the epidemic remains a critical public health issue in all communities across the country and around the world. Prevention, early detection, and ongoing treatment remain important aspects of care for people with HIV infection and AIDS. Nurses in all settings encounter people who are positive for HIV infection; therefore, nurses need an understanding of the pathophysiology, knowledge of the physical and psychological consequences associated with the diagnosis, and expert assessment and clinical management skills to provide optimal care for people with HIV infection and AIDS.

In 1987, just 6 years after the first cases of AIDS were reported, the U.S. Food and Drug Administration (FDA) approved the first antiretroviral agent. In 1988, the first randomized controlled trial of primary prophylaxis of *Pneumocystis jirovecii* pneumonia (PCP; formerly *Pneumocystis carinii* pneumonia) appeared in the literature. Currently, more than 25 antiviral agents are approved for use in the United States (Eron, 2008); these agents interfere with the life cycle of HIV in variety of ways. HIV/AIDS is a chronic condition that requires daily medication. Although damage to the immune system is significant, survival rates have increased dramatically.

HIV INFECTION AND AIDS

Since AIDS was first identified almost 30 years ago, remarkable progress has been made in improving the quality and duration of life for people living with HIV disease. During the first decade, this progress was associated with the recognition and treatment of opportunistic diseases and introduction of prophylaxis against common **opportunistic infections**. The second decade witnessed progress in the development of highly active antiretroviral therapies (HAARTs) as well as continuing progress in the treatment of opportunistic infections. The third decade has focused on issues of adherence to antiretroviral therapy, development of second-generation medications that affect different stages of the viral life cycle, and continued need for an effective vaccine. The HIV antibody test, an enzyme immunoassay (EIA; formerly enzyme-linked immunosorbent assay [ELISA]), became available in 1984, allowing early diagnosis of the infection before onset of symptoms. Since then, HIV infection has been best managed as a chronic disease, most appropriately in an outpatient care setting, whereas AIDS may involve acute conditions that require hospital treatment.

Epidemiology

In the fall of 1982, after the first 100 cases were reported, the Centers for Disease Control and Prevention (CDC) issued a case definition of AIDS. Since then, the CDC has revised the case definition a number of times (1985, 1987, and 1993). All 50 states, the District of Columbia, U.S. dependencies and possessions, and independent nations in free association with the United States report AIDS cases to the CDC using a uniform surveillance case definition and case report form (CDC, 2005). Starting in the late 1990s, many more states

began to implement HIV case reporting in response to the changing epidemic and the need for information on the numbers and characteristics of people with HIV infection who had not yet developed AIDS. The demographic characteristics of people with HIV and AIDS are changing; increasing numbers of women, non-Hispanic blacks, residents of the southern United States, and adults older than 45 years of age are dying from AIDS (Coates, 2008).

The CDC now uses a new and precise method to identify cases of HIV. In 2008, the CDC reported that approximately 56,300 new HIV infections occurred in the United States in 2006. This figure was roughly 40% higher than their former estimate of 40,000 HIV infections per year, which was based on limited data and less precise methods (CDC, 2008).

Almost 7000 people around the world still contract HIV infection every day (McConnell, 2008). Although the global percentage of people living with HIV has stabilized since 2000, the level remains unacceptably high. An estimated 33 million people are living with HIV/AIDS; however, the number of new infections declined from 3 million in 2001 to 2.7 million in 2007. Globally, the percentage of women among people with HIV/AIDS remains stable at 50% but is increasing in several countries (Joint United Nations Programme on HIV/AIDS [UNAIDS], 2008). Although there has been considerable progress worldwide in providing treatment to people with HIV/AIDS, there are still significant gaps. Sub-Saharan Africa continues to be most heavily affected by HIV/AIDS, with 67% of all people living with the disease. In 2007, 72% of the deaths from HIV/AIDS occurred in this region (UNAIDS, 2008).

HIV Transmission

HIV-1 is transmitted in body fluids that contain free virions and infected CD4+ T cells. These fluids include blood, seminal fluid, vaginal secretions, amniotic fluid, and breast milk. Inflammation and breaks in the skin or mucosa result in the increased probability that an exposure to HIV will lead to infection. The amount of HIV and infected cells in the body fluid is associated with the probability that the exposure will result in infection. Mother-to-child transmission of HIV-1 may occur in utero, at the time of delivery, or through breast-feeding, but most perinatal infections are thought to occur after exposure during delivery. HIV is not transmitted through casual contact (Chart 52-1).

Blood and blood products can transmit HIV to recipients. However, the risk associated with transfusions has been virtually eliminated as a result of voluntary self-deferral, completion of a detailed health history, extensive testing, heat treatment of clotting factor concentrates, and more

CHART 52-1 Risk Behaviors Associated With HIV Infection and AIDS

- Sharing infected injection drug use equipment
- Having sexual relations with infected individuals (both male and female)

Also at risk are people who received HIV-infected blood or blood products (especially before blood screening was instituted in 1985) and infants born to mothers with HIV infection.

effective virus inactivation methods. Donated blood is tested for antibodies to HIV-1, HIV-2, and p24 antigen; in addition, since 1999, nucleic acid amplification testing (NAT) has been performed.

Gerontologic Considerations

The number of people between the ages of 55 and 64 years living with AIDS more than doubled between the years 1998 and 2003 (from 19,258 to 38,997) (CDC, 2005). HIV infection in middle-aged and older populations may be underreported and underdiagnosed because health care professionals erroneously believe that older adults are not at risk for HIV infection. Also, HIV-related dementia in the older adult may mimic Alzheimer's disease and may be misdiagnosed. The characteristics of older people living with HIV infection reflect those of others in their country of origin who have HIV infection (Nokes, Rivero-Mendez, Valencia, et al., 2006).

Several factors put older adults at risk for HIV infection:

- Many older adults are sexually active but do not use condoms, viewing them only as a means of unneeded birth control.
- Many older adults do not consider themselves at risk for HIV infection.
- Older gay men, who grew up and lived in an era when disclosure of their sexual orientation was not acceptable and who have lost long-time partners, may begin new relationships with younger men.
- Older adults may be intravenous (IV)/injection drug users.
- Older adults may have received HIV-infected blood through transfusions before 1985.
- Normal age-related changes include a reduction in immune system function, which puts the older adult at greater risk for infections, cancers, and autoimmune disorders. Many older adults also experience the loss of loved ones, resulting in depression and bereavement, factors that are associated with depressed immune function.

Prevention of HIV Infection

Until an effective vaccine is developed, nurses need to prevent HIV infection by teaching patients how to eliminate or reduce risky behaviors. Although HIV prevention strategies have focused on individual behaviors, political, economic, and social determinants of risk also need to be considered (Horton & Das, 2008). A combination of evidence-based prevention strategies that include behavioral, structural, and biomedical approaches tempered by the wisdom and ownership of communities offers the best hope for prevention (Merson, O'Malley, Serwadda, et al., 2008).

Preventive Education

Evidence-based programs have been used to educate the public regarding safer sexual practices to decrease the risk of transmitting HIV infection to sexual partners (Chart 52-2). The CDC, through the HIV/AIDS Prevention Research Synthesis Project, has identified evidence-based behavioral interventions that can be applied in a number of settings. Other than abstinence, consistent and correct use of condoms (Chart 52-3) is the only effective method to decrease the risk of sexual transmission of HIV infection. When male condoms are used consistently during vaginal or anal intercourse, their effectiveness can be as high as 95% (Padian, Buve, Balkus, et al., 2008). Nonlatex condoms made of natural materials such as lambskin are available for people with latex allergy but will not protect against HIV infection. A male condom should be used for oral contact with the penis, and a dental dam (a flat piece of latex used by dentists to isolate a tooth for treatment) should be used for oral contact with the vagina or rectum. The polyurethane female condom, which is an effective contraceptive, provides a physical barrier that also prevents exposure to genital secretions containing HIV such as semen and vaginal fluid (Padian, et al., 2008). The female condom is the only barrier method that can be controlled by the woman (see Chapter 46).

Microbicides are chemical products such as gels, creams, films, or suppositories that are inserted into the vagina or

CHART
52-2

HEALTH PROMOTION Safer Sexual Behaviors

- Advise patients to abstain from sharing sexual fluids.
- Advise patients to reduce the number of sexual partners to one.
- Advise patients to always use latex condoms. If the patient is allergic to latex, nonlatex condoms should be used.
- Advise patients to avoid reusing condoms.
- Advise patients to avoid using cervical caps or diaphragms without using a condom as well.
- Advise patients to always use dental dams for oral–genital or anal stimulation.
- Advise patients to avoid anal intercourse because this practice may injure tissues.
- Advise patients to avoid manual–anal intercourse (“fisting”).
- Advise patients not to ingest urine or semen.
- Educate patients about nonpenetrative sexual activities, such as body massage, social kissing (dry), mutual masturbation, fantasy, and sex films.
- Advise patients to avoid sharing needles, razors, toothbrushes, sex toys, or blood-contaminated articles.
- Advise HIV-seropositive patients to inform previous, present, and prospective sexual and drug-using partners of their HIV-positive status. If the patient is concerned for his or her safety, advise the patient that many states have established mechanisms through the public health department in which professionals are available to notify exposed people.
- Advise HIV-seropositive patients to avoid having unprotected sex with another HIV-seropositive person. Cross-infection with that person's HIV can increase the severity of infection.
- Advise HIV-seropositive patients to avoid donating blood, plasma, body organs, or sperm.

CHART
52-3

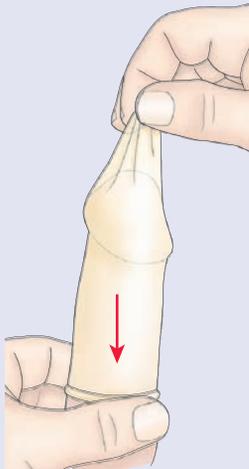

PATIENT EDUCATION

The Right Way to Use a Male Condom

1. Put on a new condom before any kind of sex.
2. Hold the condom by the tip to squeeze out the air.

3. Unroll the condom all the way over the erect penis

4. Have sex.
5. Hold the condom so it cannot come off the penis.
6. Pull out.
7. Use a new condom if you want to have sex again or if you want to have sex in a different place (eg, in the anus and then in the vagina).

Keep condoms cool and dry. Never use skin lotions, baby oil, petroleum jelly, or cold cream with condoms. The oil in these products will cause the condom to break. Products made with water (such as K-Y jelly or glycerin) are safer to use.

rectum before sexual intercourse to prevent HIV transmission (Padian, et al., 2008). Nonoxynol-9 (N-9) was widely advocated to reduce the risk of HIV infection until a clinical trial conducted in almost 1000 female commercial sex workers in African countries revealed that those who used N-9 intravaginally along with condoms were 50% more likely to be infected with HIV than those who did not use the N-9 gel. Microbicide research is moving in three directions: (1) new microbicides that contain antiretroviral agents such as tenofovir gel or dapivirine gel and ring (International Partnership for Microbicides, 2009); (2) long-acting dispersal methods such as vaginal rings that remain

in place or do not require frequent applications; and (3) combination products with different mechanisms of action (Padian, et al., 2008).

In March 2007, based on the results of three clinical trials, the World Health Organization (WHO) and UNAIDS recommended that circumcision be recognized as an effective strategy to reduce the risk of HIV acquisition in men because the presence of the foreskin, which harbors HIV target cells, might facilitate survival and entry of the virus (Padian, et al., 2008). Other topics important in preventive education include the importance of avoiding sexual practices that might cut or tear the lining of the rectum, penis, or vagina and avoiding sexual contact with multiple partners or people who are known to be HIV positive or IV/injection drug users. In addition, people who are HIV positive or who use injection drugs should be instructed not to donate blood or share drug equipment with others.

The Harm Reduction Model recognizes that total abstinence from addictive drugs might not be a realistic short-term goal. This model recommends working with drug users to assist them to increase their healthy behaviors. Needle exchange programs are available in some locations so that IV/injection drug users can obtain sterile drug equipment at no cost. Extensive research has demonstrated that needle exchange programs do not promote increased drug use; on the contrary, they have been found to decrease the incidence of bloodborne infections in people who use IV/injection drugs. Nurses should refer clients to needle exchange programs in their neighborhood whenever available. In the absence of needle exchange programs, IV/injection drug users should be instructed on methods to clean their syringes and advised to avoid sharing cotton and other drug use equipment. Drug users interested in treatment programs should be referred to those programs.

Related Reproductive Education

Because HIV infection in women often occurs during the childbearing years, family planning issues need to be addressed. Attempts to achieve pregnancy by couples in which only one partner has HIV expose the unaffected partner to the virus. Efforts at artificial insemination using processed semen from an HIV-infected partner continue. Studies are needed, because HIV has been found in the spermatozoa of patients with AIDS, and it is possible that HIV can replicate in the male germ cell. Women considering pregnancy need to have accurate information about the risks of transmitting HIV infection to themselves, their partner, and their future children, and about the benefits of taking antiretroviral agents to reduce perinatal HIV transmission. Women who are HIV positive should be instructed not to breast-feed their infants, because HIV is transmitted through breast milk.

Certain contraceptive methods may pose additional health risks for women. Estrogen in oral contraceptives may increase a woman's risk of HIV infection. In addition, HIV-infected women who use estrogen-containing oral contraceptives have shown increased shedding of HIV in vaginal and cervical secretions. The intrauterine contraceptive device (IUD) may also increase the risk of HIV transmission because the string of the IUD may serve as a means to transmit the virus.

Transmission to Health Care Providers

Standard Precautions

To reduce the risk of exposure of health care workers to HIV, the CDC developed standard precautions (Chart 52-4). Specifically, standard precautions are designed to reduce the risk of transmission of bloodborne pathogens and of pathogens from moist body substances. Standard precautions are used when working with all patients in all health care settings, regardless of their diagnosis or presumed infectious status (Siegel, Rhinehart, Jackson, et al., 2007).

Postexposure Prophylaxis for Health Care Providers

Postexposure prophylaxis in response to the exposure of health care personnel to blood or other body fluids reduces the risk of HIV infection. The CDC recommends that all health care providers who have sustained a significant exposure to HIV be counseled and offered anti-HIV postexposure prophylaxis, if appropriate (Chart 52-5). Some clinicians are considering the use of postexposure prophylaxis for patients exposed to HIV as a result of high-risk sexual behavior or IV/injection drug use. This use of postexposure prophylaxis is controversial because of concern that it may be substituted for safer sex practices and safer IV/injection drug use. However, it may be advocated in high-risk situations, especially when the uninfected person has few options because of economic constraints and cultural norms.

Guidelines for treatment of health care workers with possible occupational exposure to HIV are available from the CDC. Treatment should be started as quickly as possible after exposure. Those who choose postexposure prophylaxis must be prepared for the side effects of the medications, as

well as the unknown long-term risks, because HIV often becomes resistant to the medications used to treat it. The cost may be of concern; the cost of a medication regimen ranges from \$500 to more than \$1000, in addition to the costs of testing and counseling. However, the health care institution where the provider is employed usually covers these costs.

Vaccination

Despite enormous international efforts to develop an effective vaccine, the complexity of the science and challenges of HIV are proving formidable obstacles. Hopes were dashed when a vaccine efficacy trial was halted in September 2007, after interim results showed that the vaccine being tested did not protect against HIV and did not reduce viral load after infection (Senior, 2008). Cooperation among all nations continues to grow, and resources are being allocated to develop a vaccine and to create and support the infrastructure needed to facilitate vaccine testing.

Pathophysiology

Because HIV infection is an infectious disease, it is important to understand how HIV-1 integrates itself into a person's immune system and how immunity plays a role in the course of HIV disease. This knowledge is also essential for understanding medication therapy and vaccine development.

Viruses are intracellular parasites. HIV belongs to a group of viruses known as **retroviruses**, which carry their genetic material in the form of ribonucleic acid (RNA) rather than deoxyribonucleic acid (DNA). As shown in Figure 52-1A, HIV consists of a viral core containing the viral RNA, surrounded by an envelope consisting of protruding glycoproteins.

Chart 52-4 • Recommendations for Standard Precautions

- Hand hygiene:** Use after touching blood, body fluids, secretions, excretions, or contaminated items; immediately after removing gloves; and between patient contacts.
- Personal protective equipment (PPE)**
 - **Gloves:** Use for touching blood, body fluids, secretions, excretions, and contaminated items, and for touching mucous membranes and nonintact skin.
 - **Gown:** Use during procedures and patient care activities when contact of clothing/exposed skin with blood or body fluids, secretions, and excretions is anticipated.
 - **Mask, eye protection (goggles), face shield*:** Use during procedures and patient care activities likely to generate splashes or sprays of blood, body fluids, and secretions, especially suctioning or endotracheal intubation.
- Soiled patient care equipment:** Handle in a manner that prevents transfer of microorganisms to others and to the environment; wear gloves if visibly contaminated; and perform hand hygiene.
- Environmental control:** Develop procedures for routine care, cleaning, and disinfection of environmental surfaces, especially frequently touched surfaces in patient care areas.
- Textiles and laundry:** Handle in a manner that prevents transfer of microorganisms to others and to the environment.
- Needles and other sharps:** Do not recap, bend, break, or hand-manipulate used needles; if recapping is required, use a one-handed scoop technique only; use safety features when available; and place used sharps in a puncture-resistant container.
- Patient resuscitation:** Use mouthpiece, resuscitation bag, and other ventilation devices to prevent contact with mouth and oral secretions.
- Patient placement:** Prioritize for single-patient room if patient is at increased risk of transmission, is likely to contaminate the environment, does not maintain appropriate hygiene, or is at increased risk of acquiring infection or developing adverse outcome following infection.
- Respiratory hygiene/cough etiquette** (source containment of infectious respiratory secretions in symptomatic patients, beginning at initial point of encounter, such as triage and reception areas in emergency departments and physician offices): Instruct symptomatic people to cover mouth and nose when sneezing or coughing; use tissues and dispose in no-touch receptacle; observe hand hygiene after soiling of hands with respiratory secretions; and wear surgical mask if tolerated.

*During aerosol-generating procedures on patients with suspected or proven infections transmitted by respiratory aerosols (eg, severe acute respiratory syndrome [SARS]), wear a fit-tested N95 or higher respirator in addition to gloves, gown, and face/eye protection. From the Centers for Disease Control and Prevention. www.cdc.gov/ncidod/dhqp/pdf/guidelines/Isolation2007.pdf

Chart 52-5 • Postexposure Prophylaxis for Health Care Providers

According to the Centers for Disease Control and Prevention (CDC; 2005), the average risk for HIV transmission to health care providers after a percutaneous exposure to HIV-infected blood is estimated to be approximately 0.3% and after a mucous membrane exposure, approximately 0.09%. If you sustain an occupational exposure to HIV, take the following actions immediately:

- Alert your supervisor/nursing faculty and initiate the injury-reporting system used in the setting.
- Identify the source patient, who may need to be tested for HIV, hepatitis B, and hepatitis C. State laws will determine whether written informed consent must be obtained from the source patient before his or her testing. OraQuick rapid testing should be used if possible if the HIV status of the source patient is unknown, because results can be available within 20 minutes.
- Report as quickly as possible to the employee health services, the emergency department, or other designated treatment facility. This visit should be documented in the health care worker's confidential medical record.
- Give consent for baseline testing for HIV, hepatitis B, and hepatitis C. Confidential HIV testing can be performed up

to 72 hours after the exposure but should be performed as soon as the health care worker can give informed consent for baseline testing.

- Get postexposure prophylaxis for HIV in accordance with CDC guidelines. Start the prophylaxis medications within 2 hours after exposure. Make sure that you are being monitored for symptoms of toxicity. Practice safer sex until follow-up testing is complete. Continue the HIV medications for the full 4 weeks after exposure. The majority of HIV exposures will warrant a combination of antiretroviral agents. Combinations that may be prescribed for postexposure prophylaxis include zidovudine (ZDV) and lamivudine (3TC) or emtricitabine (FTC); stavudine (d4T) and 3TC or FTC; and tenofovir (TDF) and 3TC or FTC.
- Follow up with postexposure testing at 1 month, 3 months, and 6 months, and perhaps 1 year.
- Document the exposure in detail for your own records as well as for the employer.

Centers for Disease Control and Prevention. (2005). Updated U.S. Public Health Service guidelines for the management of occupational exposures to HIV and recommendations for postexposure prophylaxis. *MMWR—Morbidity and Mortality Weekly Report*, 54(RR-9), 1–17.

Physiology ■ Pathophysiology

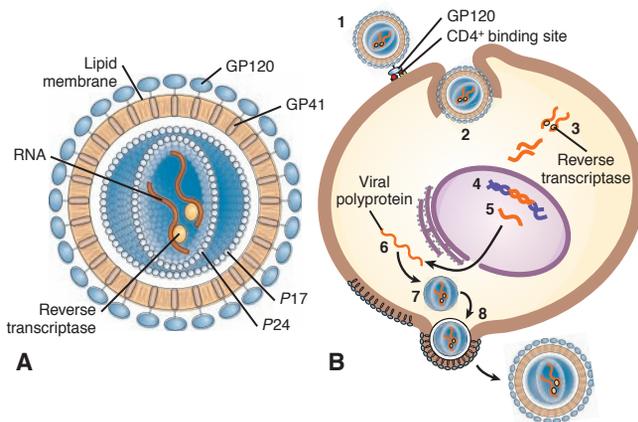

Figure 52-1 **A**, Structure of HIV-1. A glycoprotein envelope surrounds the virus, which carries its genetic material in RNA. Knobs, consisting of proteins GP120 and GP41, protrude from the envelope. These proteins are essential for binding the virus to the CD4+ T lymphocyte. **B**, Life cycle of HIV-1: (1) Attachment of the HIV virus to a CD4+ receptor; (2) internalization and uncoating of the virus with viral RNA and reverse transcriptase; (3) reverse transcription, which produces a mirror image of the viral RNA and double-stranded DNA molecule; (4) integration of viral DNA into host DNA using the integrase enzyme; (5) transcription of the inserted viral DNA to produce viral messenger RNA; (6) translation of viral messenger RNA to create viral polyprotein; (7) cleavage of viral polyprotein into individual viral proteins that make up the new virus; and (8) assembly and release of the new virus from the host cell. Redrawn from Porth, C. & Matfin, G. (2009). *Pathophysiology: Concepts of altered health states* (7th ed.). Philadelphia: Lippincott Williams & Wilkins.

All viruses target specific cells. HIV targets cells with CD4 receptors, which are expressed on the surface of T lymphocytes, monocytes, dendritic cells, and brain microglia. Mature T cells (T lymphocytes) are composed of two major subpopulations that are defined by cell surface receptors of CD4 or CD8. Approximately two thirds of peripheral blood T cells are CD4+, and approximately one third are CD8+. Most people have about 700 to 1000 CD4+ cells/mm³, but a level as low as 500 cells/mm³ can be considered within normal limits. During acute/recent infection, most varieties of HIV-1 use the chemokine receptor CCR5 (R5 virus) for entry to T cells in addition to the CD4+ receptor, which suggests that the R5 variant is preferred to a different variant (CXCR4). Over the course of infection, viruses in the majority of untreated patients eventually exhibit a shift in coreceptor from CCR5 to either CXCR4 or both CCR5 and CXCR4 (dual- or mixed-tropic) receptors (1st International Reference Panel for HIV-1 RNA Genotypes Panel, 2004). The glycoproteins of HIV (GP120 and GP41) must attach to both the CD4+ and the CCR5 binding sites in order to bind to the CD4+ cell membrane, which results in fusion of HIV with the T cell.

Once HIV has attached to the host cell, the virus can replicate. The HIV life cycle is complex (see Fig. 52-1B) and consists of the following steps (Porth & Matfin, 2009):

1. Attachment. In this first step, the GP120 and GP41 glycoproteins of HIV bind with the host's uninfected CD4+ receptor and chemokine coreceptors, usually CCR5, which results in fusion of HIV with the CD4+ T-cell membrane.
2. Uncoating. The contents of HIV's viral core (two single strands of viral RNA and three viral enzymes: reverse transcriptase, integrase, and protease) are emptied into the CD4+ T cell.

3. DNA synthesis. HIV changes its genetic material from RNA to DNA through action of reverse transcriptase, resulting in double-stranded DNA that carries instruction for viral replication.
4. Integration. New viral DNA enters the nucleus of the CD4+ T cell and through action of integrase is blended with the DNA of the CD4+ T cell, resulting in permanent, lifelong infection. Prior to this step, the uninfected person has been only exposed to, not infected with, HIV. With this step, HIV infection is permanent.
5. Transcription. When the CD4+ T cell is activated, the double-stranded DNA forms single-stranded messenger RNA (mRNA), which builds new viruses.
6. Translation. The mRNA creates chains of new proteins and enzymes (polyproteins) that contain the components needed in the construction of new viruses.
7. Cleavage. The HIV enzyme protease cuts the polyprotein chain into the individual proteins that make up the new virus.
8. Budding. New proteins and viral RNA migrate to the membrane of the infected CD4+ T cell, exit from the cell, and start the process all over.

In resting (nondividing) CD4+ cells, HIV can survive in a latent state as an integrated **provirus** that produces few or no viral particles. These resting CD4+ T cells can be stimulated to produce new particles if something activates them. When a T cell that harbors this integrated DNA (also known as provirus) becomes activated against HIV or other microbes, the cell begins to produce new copies of both RNA and viral proteins. Activation of the infected cell may be achieved by antigens, mitogens, certain cytokines (tumor necrosis factor-alpha [TNF- α] or interleukin-1 [IL-1]), or virus gene products of such viruses as **cytomegalovirus (CMV)**, Epstein-Barr virus, herpes simplex virus, and hepatitis viruses. Consequently, whenever the infected CD4+ cell is activated, HIV replication and budding occur, which can destroy the host cell. Newly formed HIV released into the blood can infect other CD4+ cells (see Fig. 52-1B).

HIV-1 mutates quickly, at a relatively constant rate, with about 1% of the virus's genetic material changing annually. HIV-1 exhibits substantial genetic diversity and several different genotypes of HIV-1 exist. There is a major group (group M), which consists of subtypes A through L, and a more diverse collection of outliers, which has been referred to as groups N and O. Many of the early nucleic acid-based tests had a fairly narrow band of specificity targeted mainly at subtype B viruses, because these predominated in the western world (1st International Reference Panel for HIV-1 RNA Genotypes, 2004).

A mutation of CCR5 that is common in Caucasians, but not other ethnic groups, has been identified. About 1% of Caucasians lack functional CCR5 and are highly protected against HIV infection even if exposed (although protection is not absolute); about 18% are not markedly protected against infection but, if infected, demonstrate significantly slower rates of disease progression.

Stages of HIV Disease

The stage of HIV disease is based on clinical history, physical examination, laboratory evidence of immune dysfunction, signs and symptoms, and infections and malignancies. The CDC standard case definition of AIDS categorizes HIV infection and AIDS in adults and adolescents on the basis of clinical conditions associated with HIV infection and CD4+ T-cell counts. The classification system (Table 52-1) groups clinical conditions into one of three categories, denoted A, B, and C.

Primary Infection (Acute/Recent HIV Infection, Acute HIV Syndrome)

The period from infection with HIV to the development of HIV-specific antibodies is known as **primary infection**. Initially, there is a **window period** during which an HIV-positive person tests negative on the HIV antibody blood test, although he or she is infected and highly infectious, because his or her viral load is very high. After 2 to 3 weeks, antibodies to the glycoproteins of the HIV envelope can be detected in the sera of HIV-infected people, but most of these antibodies lack the ability to totally control the virus. By the time neutralizing antibodies can be detected, HIV-1 is firmly established in the host.

Primary infection is characterized by high levels of viral replication, widespread dissemination of HIV throughout the body, and destruction of CD4+ T cells. This leads to dramatic drops in CD4+ T-cell counts, which are normally 500 to 1500 cells/mm³ of blood. The host is responding to the HIV infection through a CD4+ T-cell response that causes other immune cells, such as CD8+ lymphocytes, to increase their killing of infected, virus-producing cells. The body produces antibody molecules in an effort to contain the free HIV particles (outside cells) and assist in their removal. The remaining amount of virus in the body after this initial immune response is referred to as the **viral set point**, which results in a steady state of infection that lasts for years. The final level of the viral set point is inversely correlated with disease prognosis; that is, the higher the viral set point, the poorer the prognosis.

The primary infection stage is part of CDC category A and includes the acute symptomatic and early infection phases. During this stage, the virus is widely disseminated in lymphoid tissue, and a **latent reservoir** within resting memory CD4+ T cells is created (Zack & Park, 2008). An estimated 40% to 90% of patients who are acutely infected with HIV experience symptoms of acute retroviral syndrome characterized by fever, lymphadenopathy, pharyngitis, skin rash, myalgias/arthralgias, and other conditions (Panel on Antiretroviral Guidelines for Adults and Adolescents (Guidelines) (2008)).

HIV Asymptomatic (CDC Category A: More Than 500 CD4+ T Lymphocytes/mm³)

After the viral set point is reached, HIV-positive people enter into a chronic stage in which the immune system cannot eliminate the virus despite its best efforts. This set point varies greatly from patient to patient and dictates the subsequent rate of disease progression; on average, 8 to 10 years pass before a major HIV-related complication develops. In

Table 52-1 CLASSIFICATION SYSTEM FOR HIV INFECTION AND EXPANDED AIDS SURVEILLANCE CASE DEFINITION FOR ADOLESCENTS AND ADULTS

Diagnostic Categories CD4+ T-Cell Category	Clinical Categories		
	A Asymptomatic, Acute (Primary) HIV or PGL	B Symptomatic, Not (A) or (C) Conditions	C AIDS-Indicator Conditions
(1) $\geq 500/\mu\text{L}$	A1	B1	C1
(2) 200–499/ μL	A2	B2	C2
(3) $< 200/\mu\text{L}$ AIDS-indicator T-cell count	A3	B3	C3
People with AIDS-indicator conditions (clinical category C) and those in categories A3 or B3 are considered to have AIDS.		Clinical Category C Examples of conditions in adults and adolescents include the following: <ul style="list-style-type: none"> • Candidiasis of bronchi, trachea, or lungs; esophagus • Cervical cancer, invasive • Coccidioidomycosis, disseminated or extrapulmonary • Cryptococcosis, extrapulmonary • Cryptosporidiosis, chronic intestinal (exceeding 1 mo's duration) • Cytomegalovirus disease (other than liver, spleen, or lymph nodes) • Cytomegalovirus retinitis (with loss of vision) • Encephalopathy, HIV related • Herpes simplex: chronic ulcer(s) (exceeding 1 mo's duration); or bronchitis, pneumonitis, or esophagitis • Histoplasmosis, disseminated or extrapulmonary • Isosporiasis, chronic intestinal (exceeding 1 mo's duration) • Kaposi's sarcoma • Lymphoma, Burkitt's (or equivalent term); immunoblastic (or equivalent term); primary, of brain • <i>Mycobacterium avium</i> complex or <i>M. kansasii</i>, disseminated or extrapulmonary • <i>Mycobacterium tuberculosis</i>, any site (pulmonary or extrapulmonary) • <i>Mycobacterium</i>, other species or unidentified species, disseminated or extrapulmonary • <i>Pneumocystis jiroveci</i> pneumonia • Pneumonia, recurrent • Progressive multifocal leukoencephalopathy • <i>Salmonella</i> septicemia, recurrent • Toxoplasmosis of brain • Wasting syndrome due to HIV 	
Clinical Category A Includes one or more of the following in an adult or adolescent with confirmed HIV infection and without conditions in clinical categories B and C: <ul style="list-style-type: none"> • Asymptomatic HIV infection • Persistent generalized lymphadenopathy (PGL) • Acute (primary) HIV infection with accompanying illness or history of acute HIV infection 			
Clinical Category B Examples of conditions in clinical category B include, but are not limited to, the following: <ul style="list-style-type: none"> • Bacillary angiomatosis • Candidiasis, oropharyngeal (thrush) or vulvovaginal (persistent, frequent, or poorly responsive to therapy) • Cervical dysplasia (moderate or severe)/cervical carcinoma in situ • Constitutional symptoms, such as fever (38.5°C) or diarrhea exceeding 1 mo in duration • Hairy leukoplakia, oral • Herpes zoster (shingles), involving at least two distinct episodes or more than one dermatome • Idiopathic thrombocytopenic purpura • Listeriosis • Pelvic inflammatory disease, particularly if complicated by tubo-ovarian abscess • Peripheral neuropathy 			

Adapted from Centers for Disease Control, U.S. Department of Health and Human Services. (1992). 1993 revised classification system for HIV infection and expanded surveillance case definition for AIDS among adolescents and adults. *MMWR Morbidity and Mortality Weekly Report*, 41(RR-17), 1–19.

this prolonged, chronic stage, patients feel well and have few, if any, symptoms. Apparent good health continues because CD4+ T-cell levels remain high enough to preserve immune defensive responses.

HIV Symptomatic (CDC Category B: 200 to 499 CD4 + T Lymphocytes/mm³)

Over time, the number of CD4+ T cells gradually falls. Category B consists of symptomatic conditions in HIV-infected patients that are not included in the conditions listed in category C. These conditions must also meet one of the following criteria: (1) the condition is caused by HIV infection or a defect in cellular immunity, or (2) the condition is considered to have a clinical course or to require management that is complicated by HIV infection. If a person was once treated for a category B condition and has not developed a category C disease but is now symptom-free, that person's stage of HIV disease is considered category B.

AIDS (CDC Category C: Fewer Than 200 CD4+ T Lymphocytes/mm³)

When the CD4+ T-cell level drops below 200 cells/mm³ of blood, the person is said to have AIDS. As levels decrease

to fewer than 100 cells/mm³, the immune system is significantly impaired. Once a patient has had a category C condition, he or she remains in category C even if CD4+ T cells rebound with treatment. This classification has implications for entitlements (ie, disability benefits, housing, and food stamps), because these programs are often linked to an AIDS diagnosis. Although the 1993 classification emphasizes CD4+ T-cell counts, it allows for CD4+ percentages (percentage of CD4+ T cells compared with total lymphocytes). The CD4+ percentage is less subject to variation on repeated measurements than is the absolute CD4+ T-cell count. A CD4+ percentage of less than 14% of the total lymphocytes is consistent with a diagnosis of AIDS. The percentage, as compared with the absolute number of CD4+ T cells, becomes particularly important when the patient has a heightened immune response to infections in addition to HIV.

Assessment and Diagnostic Findings in HIV Infection

During the first stage of HIV infection, the patient may be asymptomatic or may exhibit various signs and symptoms. The patient's health history should alert the health care

Table 52-2 SELECTED LABORATORY TESTS FOR DIAGNOSING AND TRACKING HIV AND ASSESSING IMMUNE STATUS

Test	Findings in HIV Infection
EIA (enzyme immunoassay)	Antibodies are detected, resulting in positive results and marking the end of the window period
Western blot	Also detects antibodies to HIV; used to confirm EIA
Viral load CD4/CD8	Measures HIV RNA in the plasma These are markers found on lymphocytes. HIV kills CD4+ cells, which results in a significantly impaired immune system.

provider about the need for HIV screening based on the patient's sexual practices, IV/injection drug use, and receipt of blood transfusions. Additionally, exposure to body fluids containing infected blood while providing care to others with HIV infection (eg, through needlesticks) should alert health care providers to possible HIV infection. Patients who are in later stages of HIV infection may have a variety of symptoms related to their immunosuppressed state. Several screening tests are used to diagnose HIV infection. Others are used to assess the stage and severity of the infection. Table 52-2 identifies common blood tests.

HIV Antibody Tests

In 2006, the CDC issued recommendations for HIV testing in public and private health care settings (CDC, 2006), including hospital emergency departments, inpatient facilities, urgent care clinics, primary care settings, public health clinics, community clinics, substance abuse treatment clinics, and correctional health care facilities. The objectives of those recommendations were to increase HIV screening of patients, including pregnant women, in health care settings; foster earlier detection of HIV infection; identify and counsel people with unrecognized HIV infection and refer them to clinical and preventive services; and further reduce perinatal transmission of HIV. The major changes from previously published guidelines are:

1. HIV screening is recommended for patients (18 to 64 years of age) in all health care settings after the patient is notified that testing will be performed unless he or she declines (opt-out screening).
2. People at high risk for HIV infection should be screened for the disease at least annually.
3. Separate written consent for HIV testing should not be required; general consent for medical care should be considered sufficient to encompass consent for HIV testing.
4. Prevention counseling should not be required with HIV diagnostic testing or as part of HIV screening programs in health care settings.

Although these guidelines are already in effect in some states, they have not been implemented in others because they violate the states' existing HIV confidentiality laws.

Before an HIV antibody test is performed, the meaning of the test and possible test results are explained, and informed consent for the test is obtained from the patient. When the result of the HIV antibody test is received, it is

Chart 52-6• HIV Test Results: Implications for Patients

Interpretation of Positive Test Results

- Antibodies to HIV are present in the blood (the patient has been infected with the virus, and the body has produced antibodies).
- HIV is active in the body, and the patient can transmit the virus to others.
- Despite HIV infection, the patient does not necessarily have AIDS.
- The patient is not immune to HIV (the antibodies do not indicate immunity).

Interpretation of Negative Test Results

- Antibodies to HIV are not present in the blood at this time, which can mean that the patient has not been infected with HIV or, if infected, the body has not yet produced antibodies (window period—usually 3 weeks to 6 months).
- The patient should continue taking precautions. The test result does not mean that the patient is immune to the virus, nor does it mean the patient is not infected; it just means that the body may not have produced antibodies yet.

carefully explained to the patient in private (Chart 52-6). All test results are kept confidential. Education and counseling about the test result and about preventing transmission are essential. The patient's psychological response to a positive test result may include feelings of panic, depression, and hopelessness. The social and interpersonal consequences of a positive test result can be devastating. The patient may lose his or her sexual partner, housing, and health insurance because of disclosure. He or she may experience discrimination in employment and housing, as well as social ostracism. For these reasons and others, patients who test positive may need ongoing counseling as well as referrals for social, financial, medical, and psychological support services. Patients whose test results are seronegative may develop a false sense of security, possibly resulting in continued high-risk behaviors or feelings that they are immune to the virus. These patients may need ongoing counseling to help modify high-risk behaviors and to encourage returns for repeated testing. Other patients may experience anxiety regarding the uncertainty of their status.

When a person is infected with HIV, the immune system responds by producing antibodies against the virus, usually within 3 to 12 weeks after infection. In 1985, the FDA licensed an HIV-1 antibody assay that uses approximately 5 to 7 mL of blood. Samples are tested using two different laboratory techniques to determine the presence of antibodies to HIV. The **EIA (enzyme immunoassay)** test, formerly referred to as the **ELISA (enzyme-linked immunosorbent assay)** test, identifies antibodies directed specifically against HIV. The **Western blot assay** is used to confirm seropositivity when the EIA result is positive. Adults whose blood contains antibodies for HIV are seropositive.

In addition to this HIV-1 antibody assay, two additional techniques are now available. The OraSure test uses saliva to perform an EIA antibody test. Using less than a drop of

blood, the OraQuick Rapid HIV-1 Antibody Test quickly (approximately 20 minutes) and reliably (99.6% accuracy) detects antibodies to HIV-1. The OraQuick test is becoming the standard method of testing in settings where a delay would seriously affect treatment, such as in labor and delivery rooms or in emergency departments when the HIV status of a sexual abuser is unknown.

Home-based testing for HIV antibodies using a small amount of blood was first proposed in 1985 and approved by the FDA in 1995. However, use of home testing kits raises concerns because of the lack of counseling and possible inaccurate results, including both false-positive and false-negative results.

Viral Load Tests

Target amplification methods quantify HIV RNA or DNA levels in the plasma and have replaced p24 antigen capture assays. Target amplification methods include reverse transcriptase–polymerase chain reaction (RT-PCR) and nucleic acid sequence–based amplification. A widely used **viral load test** measures plasma HIV RNA levels. Currently, these tests are used to track viral load and response to treatment of HIV infection. RT-PCR is also used to detect HIV in high-risk seronegative people before antibodies are measurable, to confirm a positive EIA result, and to screen neonates. HIV culture or quantitative plasma culture and plasma viremia are additional tests that measure viral burden, but they are used infrequently. Viral load is a better predictor of the risk of HIV disease progression than the CD4+ count. The lower the viral load, the longer the time to AIDS diagnosis and the longer the survival time.

Treatment of HIV Infection

Protocols on how and when to start treatment for HIV disease change relatively often. The U.S. Department of Health and Human Services Panel on Antiretroviral Guidelines for Adults and Adolescents (Guidelines, 2008) is composed of HIV specialists from across the country who meet periodically to review the latest scientific evidence. The CD4+ T-cell count is usually the most important consideration in deciding whether antiretroviral medications should be started. In general, antiretroviral medications should be offered to people with a T-cell count of less than 350 cells/mm³ or plasma HIV RNA levels exceeding 100,000 copies/mL (Guidelines, 2008). Some clinicians and patients, however, are choosing not to start medications until the CD4+ cell count decreases to approximately 200 cells/mm³. Monitoring the National Institutes of Health (NIH) Web site (see Resources at the end of the chapter) for frequent updates of the recommendations is essential before caring for patients with HIV/AIDS (Guidelines, 2008).

Clinicians, in partnership with patients, make treatment decisions based on a number of factors, including CD4+ T-cell count, viral load, severity of HIV/AIDS-related symptoms, and willingness of the patient to adhere to the lifelong treatment regimen. The increasing number of antiretroviral agents (Table 52-3) and the rapid evolution of new information have introduced extraordinary complexity into the treatment of HIV infection. More than 25 agents have been approved in the United States. Drugs from

established classes (nucleoside/nucleotide reverse transcriptase inhibitors [NRTIs], non-nucleoside reverse transcriptase inhibitors [NNRTIs], and **protease inhibitors [PIs]**) continue to serve as the mainstays of antiretroviral therapy (Kuritzkes, 2008). In 2008, the integrase inhibitor (raltegravir [Isentress]) and the CCR5 antagonist (maraviroc [Selzentry]), a novel entry inhibitor, were approved and joined the other fusion inhibitors such as enfuvirtide (T-20), which inhibits entry of HIV into the CD4+ T cell (Moyle, Gatell, Perno, et al., 2008). In patients with resistant HIV disease, these new classes of antiretroviral agents offer considerable potential benefit because of the absence of cross-resistance (Cooper, Steigbigel, Gatell, et al., 2008).

To achieve sustained viral suppression, patients must take more than one antiretroviral medication. Although HAART was defined originally as a regimen that included at least one PI, it has evolved to include any regimen with at least two to three different medications. Some pharmaceutical companies have combined two to three agents into one tablet or capsule, such as Kaletra (lopinavir and ritonavir) and Atripla (efavirenz, emtricitabine, and tenofovir) in a single tablet for once-a-day use. Simplifying treatment regimens and decreasing the number of medications that must be taken each day may increase patients' adherence to therapy.

Adherence to long-term treatment is required to manage HIV infection and many other chronic illnesses; however, overall adherence rates remain low (30% to 50%). Although antiretroviral regimens have become less complex, side effects create barriers to adherence, and this can lead to viral resistance. The goals of treatment include maximal and sustained suppression of viral load to a nondetectable level, restoration or preservation of immunologic function, improved quality of life, and reduction of HIV-related morbidity and mortality. Viral load testing is recommended at the time of diagnosis of HIV disease and every 3 to 4 months thereafter in the untreated person; T-cell counts should be measured at diagnosis and usually every 3 to 6 months thereafter (Guidelines, 2008). In the majority of patients, HAART leads to sustained reductions in HIV replication, a rise in CD4+ T-cell counts with reconstitution of immune function, and significant reductions in morbidity and mortality.

It is difficult to predict patients' adherence to medication regimens, but a positive relationship between the patient and health care provider is associated with better adherence. Individualized plans of care that take into consideration housing and social support issues, in addition to health indicators, are essential. Adherence to the antiretroviral treatment plan involves very complex behavior that can change over the duration of the medication regimen. Self-reported adherence measures can distinguish clinically meaningful patterns of medication-taking behaviors; therefore, nurses should ask patients if they are taking their medications as prescribed. Factors associated with nonadherence include active substance abuse, depression, and lack of social support. Gender, race, pregnancy, and history of past substance use have not been associated with nonadherence (Guidelines, 2008). Chart 52-7 summarizes various strategies that health care providers can encourage to promote

Table 52-3 ANTIRETROVIRAL AGENTS*

Generic Name (Abbreviation) and Trade Names	Food Interactions	Adverse Events
Nucleoside Reverse Transcriptase Inhibitors (NRTIs)		
Abacavir (ABC) <i>Ziagen</i>	Can be taken without regard to meals. Alcohol increases abacavir levels 41%. Abacavir has no effect on alcohol.	Hypersensitivity reaction, which can be fatal; symptoms may include fever, rash, nausea, vomiting, malaise or fatigue, loss of appetite, and respiratory symptoms such as sore throat, cough, shortness of breath.
Trizivir (ABC + ZDV, + 3TC) <i>Epzicom</i> (ABC + 3TC)		
Didanosine (ddl) <i>Videx</i> <i>Videx EC</i>	Levels decrease 55%; take half hour before or 2 h after meals.	Pancreatitis; peripheral neuropathy; nausea; diarrhea. Lactic acidosis with fatty degeneration of the liver (rare but potentially life-threatening toxicity associated with use of NRTIs)
Emtricitabine (FTC) <i>Emtriva</i> <i>Truvada</i> (FTC + TDF)	Can be taken without regard to meals	Minimal toxicity; lactic acidosis with hepatic steatosis (rare but potentially life-threatening toxicity with use of NRTIs)
Lamivudine (3TC) <i>EpiVir</i> <i>Combivir</i> (3TC + ZDV)	Can be taken without regard to meals	Minimal toxicity; lactic acidosis with hepatic steatosis (rare but potentially life-threatening toxicity with use of NRTIs)
Trizivir (3TC + ZDV, + ABC)		
Stavudine (d4T) <i>Zerit</i>	Can be taken without regard to meals	Peripheral neuropathy; lipodystrophy; rapidly progressive ascending neuromuscular weakness (rare); pancreatitis; lactic acidosis with hepatic steatosis (higher incidence with d4T than with other NRTIs); hyperlipidemia
Tenofovir disoproxil fumarate (TDF) <i>Viread</i> <i>Truvada</i> (TDF + FTC)	Can be taken without regard to meals	Asthenia, headache, diarrhea, nausea, vomiting, and flatulence; renal insufficiency; lactic acidosis with hepatic steatosis (rare but potentially life-threatening toxicity with use of NRTIs)
Zalcitabine (ddC) <i>Hivid</i>	Can be taken without regard to meals	Peripheral neuropathy; stomatitis; lactic acidosis with hepatic steatosis (rare but potentially life-threatening toxicity with use of NRTIs); pancreatitis
Zidovudine (AZT or ZDV) <i>Retrovir</i> <i>Combivir</i> (AZT + 3TC) <i>Trizivir</i> (AZT + 3TC, + ABC)	Can be taken without regard to meals	Bone marrow suppression; macrocytic anemia or neutropenia; gastrointestinal intolerance, headache, insomnia, asthenia; lactic acidosis with hepatic steatosis (rare but potentially life-threatening toxicity with use of NRTIs)
Non-Nucleoside Reverse Transcriptase Inhibitors (NNRTIs)		
Delavirdine (DLV) <i>Rescriptor</i>	Can be taken without regard to meals	Rash (rare cases of Stevens-Johnson syndrome have been reported); increased transaminase levels; headaches
Efavirenz (EFV) <i>Sustiva</i>	High-fat/high-caloric meals increase peak plasma concentrations of capsules by 39% and tablets by 79%; take on an empty stomach.	Rash (rare cases of Stevens-Johnson syndrome have been reported); central nervous system symptoms (dizziness, somnolence, insomnia, abnormal dreams, confusion, abnormal thinking, impaired concentration, amnesia, agitation, depersonalization, hallucinations, and euphoria); increased transaminase levels; false-positive cannabinoid test; teratogenic in monkeys
Nevirapine (NVP) <i>Viramune</i>	Take without regard to meals.	Rash including Stevens-Johnson syndrome, symptomatic hepatitis including fatal hepatic necrosis has been reported. Single dose used in developing countries to prevent vertical transmission
Etravirine (TMC 125) <i>Intelence</i>	Take after a meal with water.	Serious side effects of this medication include severe skin rash. Mild to moderate rash occurs in the second week of therapy and generally resolves within 1–2 weeks of continued therapy. Nausea, diarrhea, abdominal pain, vomiting, fatigue, peripheral neuropathy, headache, and high blood pressure
Protease Inhibitors (PIs)		
Amprenavir (APV) <i>Agenerase</i>	High-fat meal decreases blood concentration 21%; can be taken with or without food, but high-fat meal should be avoided	GI intolerance; nausea; vomiting; diarrhea; rash; oral paresthesias; hyperlipidemia; transaminase elevation; hyperglycemia; fat maldistribution; possible increased bleeding episodes in patients with hemophilia
Atazanavir (ATV) <i>Reyataz</i>	Administration with food increases bioavailability. Should be taken with food; avoid taking with antacids.	Indirect hyperbilirubinemia; prolonged PR interval—some patients experience asymptomatic first-degree AV block; use with caution in patients with underlying conduction defects or on concomitant medications that can cause PR prolongation; hyperglycemia; fat maldistribution; possible increased bleeding episodes in patients with hemophilia
Fosamprenavir (FOS-APV) <i>Lexiva</i>	Can be taken without regard to meals	Skin rash (19%); diarrhea; nausea; vomiting; headache; hyperlipidemia; transaminase elevation; hyperglycemia; fat maldistribution; possible increased bleeding episodes in patients with hemophilia
Indinavir (IDV) <i>Crixivan</i>	For unboosted IDV: Should be taken 1 h before or 2 h after meals; may take with skim or low-fat meal For RTV-boosted IDV: Can be taken with or without food	Nephrolithiasis; GI intolerance; nausea; indirect hyperbilirubinemia; hyperlipidemia; headache, asthenia; blurred vision; dizziness; rash; metallic taste; thrombocytopenia; alopecia; hemolytic anemia; hyperglycemia; fat maldistribution; possible increased bleeding episodes in patients with hemophilia

Continued on following page

**Table 52-3 ANTIRETROVIRAL AGENTS* (Continued)**

Generic Name (Abbreviation) and Trade Names	Food Interactions	Adverse Events
Lopinavir + ritonavir (LPV/RTV) <i>Kaletra</i>	Should be taken with food	GI intolerance; nausea; vomiting; diarrhea; asthenia; hyperlipidemia (especially hypertriglyceridemia); elevated serum transaminase; hyperglycemia; fat maldistribution; possible increased bleeding episodes in patients with hemophilia
Nelfinavir (NFV) <i>Viracept</i>	Should be taken with a meal or snack	Diarrhea; hyperlipidemia; hyperglycemia; fat maldistribution; possible increased bleeding episodes in patients with hemophilia; serum transaminase elevation
Ritonavir (RTV) <i>Norvir</i>	Should be taken with food if possible; may improve tolerability	GI intolerance; nausea; vomiting; diarrhea; paresthesias—circumoral and extremities; hyperlipidemia, especially hypertriglyceridemia; hepatitis; asthenia; taste perversion; hyperglycemia; fat maldistribution; possible increased bleeding in patients with hemophilia. Lower doses used as a booster
Saquinavir (SQV) <i>Invirase</i>		GI intolerance; nausea; diarrhea; abdominal pain and dyspepsia; headache; hyperlipidemia; elevated transaminase enzymes; hyperglycemia; fat maldistribution; possible increased bleeding episodes in patients with hemophilia. Take with RTV as booster, if prescribed.
Tipranavir (TPV) <i>Aptivus</i>	Take with food	Serious liver problems, bleeding on the brain, rash, increased cholesterol and triglyceride levels, and changes in body fat; women taking birth control pills that contain estrogen may be more likely to develop a rash. Individuals with hemophilia may have increased bleeding. Take with RTV, if prescribed.
Darunavir <i>Prezista</i>		Diarrhea; nausea; headache; and coldlike symptoms, including runny nose or sore throat; inflammation of the liver; abnormal liver function tests; severe skin rash; fever; and abnormally high cholesterol and triglyceride levels have been reported. Take with RTV.
Fusion Inhibitors		
Enfuvirtide (T-20) <i>Fuzeon</i>	Injected subcutaneously, so meals are not an issue	Local injection site reactions—almost 100% of patients (pain, erythema, induration, nodules and cysts, pruritus, ecchymosis); increased rate of bacterial pneumonia; hypersensitivity reaction—symptoms may include rash, fever, nausea, vomiting, chills, rigors, hypotension, or elevated serum transaminases; may recur on challenge
Maraviroc <i>Selzentry</i>	Taken with or without food; requires CCR5 tropism blood test before starting	Cough, fever, dizziness, headache, lowered blood pressure, nausea, and bladder irritation; possible liver problems and cardiac events; an increased risk for some infections; a slight increase in cholesterol levels
Integrase Strand Transfer Inhibitor		
Raltegravir <i>Isentress</i>	No food restrictions identified	Diarrhea, nausea, headache, and fever have been reported.
Multiclass Combination Products		
Efavirenz, emtricitabine, and tenofovir <i>Atripla</i>		

*This information changes often. Check the U.S. Food and Drug Administration Web site (www.fda.gov/oashi/aids/virals.html) and www.aidsinfo.nih.gov/DrugsNew/Default.aspx?MenuItem=Drugs for current information when caring for people with HIV/AIDS.

treatment regimen adherence. Every health care encounter should be used as an opportunity to briefly review the treatment regimen, identify any new issues, and reinforce successful behaviors.

Results of therapy are evaluated with viral load tests (Guidelines, 2008). Viral load levels should be measured immediately before initiation of antiretroviral therapy and again after 2 to 8 weeks, because in most patients adherence to a regimen of potent antiretroviral agents should result in a large decrease in the viral load by 2 to 8 weeks. The viral load should continue to decline over the following weeks, and in most individuals it will drop below detectable levels (currently defined as less than 50 RNA copies/mL) by 16 to 20 weeks. The rate of viral load decline toward unde-

tectable levels is affected by the baseline T-cell count, the initial viral load, the potency of the medication, adherence to the medication regimen, prior exposure to antiretroviral agents, and the presence of any opportunistic infections. The confirmed absence of a viral load response should prompt the health care team to reevaluate the regimen. The CD4+ count should increase by 100 to 150 cells/mm³ per year, with an accelerated response in the first 3 months of treatment (Guidelines, 2008).

Adverse effects associated with all HIV treatment regimens include hepatotoxicity, nephrotoxicity, and osteopenia, along with increased risk of cardiovascular disease and myocardial infarction (Moyle, et al., 2008) (see Table 52-3). Many of the antiretroviral agents that prolong life may

HOME CARE CHECKLIST

Adhering to Medication Therapy for HIV

At the completion of the home care instruction, the patient or caregiver will be able to:	PATIENT	CAREGIVER
• Verbalize knowledge of each medication name.	✓	✓
• State the action of each medication.	✓	✓
• State the correct times that medications are to be taken.	✓	✓
• Identify special guidelines to follow when taking medications (eg, with meals, on an empty stomach, medications that are not to be taken together).	✓	✓
• Demonstrate methods of keeping track of the medication regimen and storage of the prescribed medications and use reminders such as beepers and/or pill boxes.	✓	✓
• Identify specific laboratory tests such as viral load that are necessary to monitor the effectiveness of the prescribed medication regimen.	✓	✓
• List expected side effects of each medication.	✓	✓
• Identify side effects that should be reported to health care providers.	✓	✓
• Explain the importance of and necessity for adherence with prescribed medication regimen.	✓	✓
• Demonstrate correct administration of IM, SC, or IV medications.	✓	✓
• Demonstrate correct use and safe disposal of needles, syringes, and other IV equipment.	✓	✓
• Discuss with health care providers any problems that he or she is having with side effects and adherence.	✓	✓
• Discuss episodes of nonadherence to the medication regimen.	✓	✓

simultaneously cause fat redistribution syndrome and metabolic alterations such as dyslipidemia and insulin resistance, which put the patient at risk for early-onset heart disease and diabetes (Calza, Manfredi, Pocaterra, et al., 2008). The fat redistribution syndrome consists of lipoatrophy (localized subcutaneous fat loss in the face, arms, legs, and buttocks) and lipohypertrophy (central visceral fat [lipomata] accumulation in the abdomen, although possibly in the breasts, dorsocervical region [buffalo hump], and within the muscle and liver) (Calza, et al., 2008). These changes can be very disturbing to the body image of people living with HIV/AIDS and may be a reason that they decline treatment, especially with regimens that include a PI.

Facial wasting, characterized as a sinking of the cheeks, eyes, and temples caused by the loss of fat tissue under the skin, may be treated by injectable fillers such as poly-L-lactic acid (Sculptra) (Fig. 52-2). Hepatotoxicity associated with certain protease inhibitors may limit the use of these agents, especially in patients with underlying liver dysfunction (Guidelines, 2008).

Drug Resistance

Drug resistance can be broadly defined as the ability of pathogens to withstand the effects of medications that are intended to be toxic to them. There are two major components of antiretroviral drug resistance: (1) transmission of drug-resistant HIV at the time of initial infection and (2) selective drug resistance in patients who are receiving non-suppressive regimens (Kuritzkes, 2008). Factors associated with the development of drug resistance include monother-

apy (taking one medication), difficulty with adherence to complex and toxic regimens, and initiation of therapy late in the course of HIV/AIDS.

Resistance testing has a number of limitations and is more helpful in determining which antiretroviral agents should be eliminated rather than which ones should be used. Genotypic testing determines the sequence of viral RNA encoding relevant genes, which allows detection of amino acid mutations that are either proven or suspected to

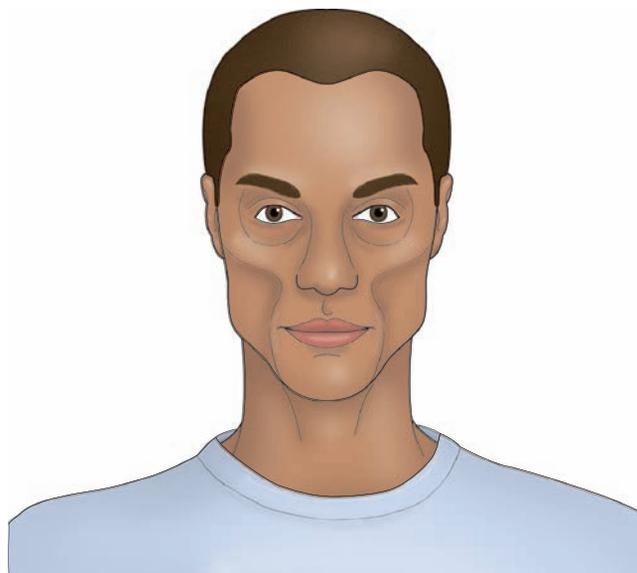

Figure 52-2 Facial lipoatrophy.

be associated with phenotypic resistance. Phenotypic testing determines the drug concentration needed to inhibit replication of a recombinant virus by 50% of a patient's isolate, when compared with a susceptible reference. Resistance testing is of greatest value when it is performed before drugs are discontinued or immediately afterward (within 4 weeks). Drug resistance testing is not advised for patients with a viral load of less than 1000 copies/mL, because the amount of the virus in the blood is too small to ensure reliable results (Guidelines, 2008).

In addition to resistance testing, several factors must be considered in choosing medications for a new regimen, once the prior regimen has failed. These factors include the patient's past treatment history, viral load, and medication tolerance; the likelihood of the patient's adhering to the medication regimen; and concomitant medical conditions or medications.

Treatment Interruption

Discontinuation of antiretroviral therapy may result in viral rebound, immune decompensation, and clinical progression. Unplanned interruption of antiretroviral therapy may become necessary because of severe drug toxicity, intervening illness, surgery that precludes oral therapy, pregnancy, or unavailability of antiretroviral medications. Planned treatment interruption, outside of clinical research trials, is not recommended (Guidelines, 2008).

Immune Reconstitution Inflammatory Syndrome

Immune reconstitution inflammatory syndrome (IRIS) results from rapid restoration of pathogen-specific immune responses to opportunistic infections that cause either the deterioration of a treated infection or new presentation of a subclinical infection. This syndrome typically occurs during the initial months after beginning antiretroviral treatment and is associated with a wide spectrum of pathogens, most commonly mycobacteria, herpes viruses, and deep fungal infections (Meintjes, Lawn, Scano, et al., 2008). IRIS is characterized by fever, respiratory and/or abdominal symptoms, and worsening of the clinical manifestations of an opportunistic infection or the appearance of new manifestations. The nurse should be alert to the possibility of IRIS, especially in the 3-month period after treatment with antiretroviral agents is initiated, because this syndrome is associated with significant morbidity and patients often require hospital admission. Rates of morbidity and mortality attributable to paradoxical tuberculosis-associated IRIS may be higher in settings with limited diagnostic and treatment options (eg, South Africa).

Clinical Manifestations

Patients with HIV/AIDS experience a number of symptoms related to the disease, side effects of treatment, and other illnesses such as hepatitis (Bova, Jaffarian, Himlan, et al., 2008). The clinical manifestations of HIV/AIDS are widespread and may involve virtually any organ system. Diseases associated with HIV infection and AIDS result from infections, malignancies, or the direct effect of HIV on body tissues. Nurses need to understand the causes, signs and symptoms, and interventions, including self-care strategies, that can enhance the quality of life for patients

throughout the illness. Symptom assessment tools can be used to assess patients' symptom intensity and severity. People with HIV/AIDS use a variety of self-care strategies to minimize common symptoms, which can arise from HIV disease, comorbidities, or the effects of medications used to treat HIV and opportunistic infections.

Fatigue is frequently cited by people living with HIV/AIDS as one of the most bothersome symptoms. It has a multifactorial etiology. For more information about fatigue in HIV, see Chart 52-8.

Respiratory Manifestations

Shortness of breath, dyspnea (labored breathing), cough, chest pain, and fever are associated with various opportunistic infections, such as those caused by *P. jiroveci*, *Mycobacterium avium-intracellulare*, CMV, and *Legionella* species.

Pneumocystis Pneumonia

The most common infection in people with AIDS is **Pneumocystis pneumonia (PCP)**, which is caused by *P. jiroveci*. It is the most common opportunistic infection associated with AIDS. Without prophylactic therapy (discussed later), 80% of all people infected with HIV will develop PCP.

The clinical presentation of PCP in HIV infection is generally less acute than in people who are immunosuppressed as a result of other conditions. The time between the onset of symptoms and the actual documentation of disease may be weeks to months. Patients with AIDS initially develop nonspecific signs and symptoms, such as nonproductive cough, fever, chills, shortness of breath, dyspnea, and occasionally chest pain. PCP may be present despite the absence of crackles. Arterial oxygen concentrations in patients who are breathing room air may be mildly decreased, indicating minimal hypoxemia.

If left untreated, PCP eventually progresses and causes significant pulmonary impairment and, ultimately, respiratory failure. A few patients have a dramatic onset and a fulminating course involving severe hypoxemia, cyanosis, tachypnea, and altered mental status. Respiratory failure can develop within 2 to 3 days after the initial appearance of symptoms.

PCP can be diagnosed definitively by identifying the organism in lung tissue or bronchial secretions. This is accomplished by such procedures as sputum induction, bronchial-alveolar lavage, and transbronchial biopsy (by fiberoptic bronchoscopy).

Mycobacterium avium Complex

Mycobacterium avium complex (MAC) disease is a common opportunistic infection in people with AIDS. MAC comprises a group of acid-fast bacilli (mycobacteria) that includes *M. avium*, *M. intracellulare*, and *M. scrofulaceum*. MAC usually causes respiratory infection but is also commonly found in the gastrointestinal tract, lymph nodes, and bone marrow. Most patients with AIDS who have T-cell counts lower than 100 cells/mm³ have widespread disease at diagnosis and are debilitated. MAC infections are associated with rising mortality rates.

Tuberculosis

In HIV-negative people with latent tuberculosis (TB) infection, the *lifetime* risk of developing active TB disease is

CHART
52-8 **NURSING RESEARCH PROFILE**
HIV-Related Fatigue

Barroso, J., Pence, B., Salahuddin, N., et al. (2008). Physiological correlates of HIV-related fatigue. *Clinical Nursing Research*, 17(1), 5–19.

Purpose

Symptom management in people with HIV infection is an increasingly pressing concern. The most frequent and debilitating symptom of HIV is fatigue, which has been defined as “awareness of a decreased capacity for physical and/or mental activity due to an imbalance in the availability, utilization, and/or restoration of resources needed to perform activity” (p. 6).

Design

This study used a longitudinal, repeated-measures design over a 3-year period with a total of seven study visits. The researchers investigated the cross-sectional relationship between fatigue and a wide range of physiologic characteristics in a sample of 128 HIV-positive individuals. Participants completed the HIV-related Fatigue Scale (HRFS), which consists of two subscales: (1) fatigue intensity and (2) impact of fatigue on daily functioning. After completion of the HRFS, blood was drawn to measure hepatic function, thyroid function, HIV viral load, immunologic function, gonadal function, hematologic function, and cellular injury.

Findings

None of the physiologic variables was significantly correlated with the HRFS scales in multivariate linear regression after

controlling for income and years since HIV diagnosis. Income and years of HIV infection were more correlated with fatigue than any of the physiologic measures. Most of the participants had moderate fatigue.

Nursing Implications

Although fatigue is a common symptom that affects daily functioning and quality of life, and it was expected that physiologic variables such as viral load, liver function, and thyroid levels would be associated with fatigue, no statistically significant relationship was found. Fatigue affects the patient’s ability to participate in activities of daily living such as grocery shopping and house cleaning and affects the patient’s ability to maintain social relationships. Less income for people with HIV often means there are fewer choices and more energy is required to meet basic needs. The relationship between the length of time that patients have been HIV positive and have had fatigue might be a result of patients simply growing tired of living with the day-to-day challenges of HIV infection.

Until a better cause of fatigue is identified and treatments are developed, nurses need to help patients cope with this feeling of profound exhaustion. Nurses need to assist patients to create daily schedules around their periods of maximum energy and to assure them that fatigue is not necessarily associated with getting sicker. Nurses can support patients in accessing resources and also provide the emotional support needed to cope with an unpredictable chronic illness.

5% to 10%, whereas in HIV-positive people with latent TB, the *annual* risk is 10%. TB can develop in the lungs as well as in extrapulmonary sites such as the central nervous system (CNS), bone, pericardium, stomach, peritoneum, and scrotum. The CD4 T-cell count influences both the frequency and clinical picture of active TB disease. Important issues in the use of antiretroviral therapy in patients with active TB disease are (1) the sequencing of treatments, (2) the value of directly observed therapy, (3) risk of significant drug interactions with rifamycins, (4) the additive risk of hepatotoxicity and neuropathy associated with agents used to treat HIV and TB, (5) development of IRIS with TB after initiation of antiretroviral therapy, (6) the effect of antiretroviral therapy on results of tuberculin skin testing, and (7) the need for integration of therapy for HIV and TB (Guidelines, 2008).

Gastrointestinal Manifestations

The gastrointestinal manifestations of AIDS include loss of appetite, nausea, vomiting, oral and esophageal candidiasis, and chronic diarrhea. Diarrhea is a problem in 50% to 90% of all AIDS patients. Gastrointestinal symptoms may be related to the direct effect of HIV on the cells lining the intestines. Some of the enteric pathogens that occur most frequently, identified by stool cultures or intestinal biopsy, are *Cryptosporidium muris*, *Salmonella* species, *Isospora belli*, *Giardia lamblia*, CMV, *Clostridium difficile*, and *M. avium-intracellulare*. In patients with AIDS, the effects of diarrhea can be devastating in terms of profound weight loss (more than

10% of body weight), fluid and electrolyte imbalances, perianal skin excoriation, weakness, and inability to perform the usual activities of daily living.

Oral Candidiasis

Candidiasis, a fungal infection, occurs in almost all patients with AIDS and AIDS-related conditions. Commonly preceding other life-threatening infections, it is characterized by creamy-white patches in the oral cavity. If left untreated, oral candidiasis progresses to involve the esophagus and stomach. Associated signs and symptoms include difficult and painful swallowing and retrosternal pain. Some patients also develop ulcerating oral lesions and are particularly susceptible to dissemination of candidiasis to other body systems.

Wasting Syndrome

Wasting syndrome is part of the category C case definition for AIDS. Diagnostic criteria include profound involuntary weight loss exceeding 10% of baseline body weight and either chronic diarrhea for more than 30 days or chronic weakness and documented intermittent or constant fever in the absence of any concurrent illness that could explain these findings. This protein–energy malnutrition is multifactorial. In some AIDS-associated illnesses, patients experience a hypermetabolic state in which excessive calories are burned and lean body mass is lost. This state is similar to that seen in sepsis or trauma and can lead to organ failure. The distinction between cachexia (wasting) and

malnutrition, or between cachexia and simple weight loss, is important, because the metabolic derangement seen in wasting syndrome may not be modified by nutritional support alone.

Anorexia, diarrhea, gastrointestinal malabsorption, and lack of nutrition in chronic disease all contribute to wasting syndrome. Progressive tissue wasting, however, may occur with only modest gastrointestinal involvement and without diarrhea. TNF and IL-1 are cytokines that play important roles in AIDS-related wasting syndrome. Both act directly on the hypothalamus to cause anorexia. Cytokine-induced fever accelerates the body's metabolism by 14% for every 1°F increase in temperature. TNF causes inefficient use of lipids by reducing enzymes that are needed for fat metabolism, whereas IL-1 triggers the release of amino acids from muscle tissue. People with AIDS generally experience increased protein metabolism in relation to fat metabolism, which results in significant decreases in lean body mass due to muscle and protein breakdown.

Hypertriglyceridemia, seen in people with AIDS and attributed to chronically elevated cytokine levels, can persist for months without tissue wasting and loss of lean body mass. It is believed that infections and sepsis lead to transient increases in TNF, IL-1, and other cell mediators above the chronically elevated levels that are often seen with AIDS. These transient increases in TNF and IL-1 trigger muscle wasting.

Oncologic Manifestations

Certain types of cancer occur often in people with AIDS. As a result, these cancers are considered AIDS-defining conditions; that is, their presence in a person infected with HIV is a clear sign that AIDS has developed. These AIDS-related cancers include Kaposi's sarcoma, lymphoma (especially non-Hodgkin lymphoma and primary central nervous system lymphoma), and invasive cervical cancer. With HAART, the incidence of both Kaposi's sarcoma and non-Hodgkin lymphoma has decreased considerably (Levine, 2008). Kaposi's sarcoma and lymphoma are discussed below. Cervical carcinoma is described later in Gynecologic Manifestations.

Kaposi's Sarcoma

Kaposi's sarcoma (KS), the most common HIV-related malignancy, is a disease that involves the endothelial layer of blood and lymphatic vessels. In people with AIDS, epidemic KS is most often seen among male homosexuals and bisexuals. AIDS-related KS exhibits a variable and aggressive course, ranging from localized cutaneous lesions to disseminated disease involving multiple organ systems. Cutaneous signs may be the first manifestation of HIV, appearing in more than 90% of HIV-infected patients as immune functions deteriorate. These skin signs correlate to low CD4+ counts. They can appear anywhere on the body and are usually brownish pink to deep purple. They may be flat or raised and surrounded by ecchymoses (hemorrhagic patches) and edema (Fig. 52-3). Rapid development of lesions involving large areas of skin is associated with extensive disfigurement. The location and size of some lesions can lead to venous stasis, lymphedema, and pain. Ulcerative lesions disrupt skin integrity and increase discomfort and

Figure 52-3 Lesions of the AIDS-related Kaposi's sarcoma. Whereas some patients may have lesions that remain flat, others experience extensively disseminated, raised lesions with edema. From DeVita Jr., V. T., Hellman, S. & Rosenberg, S. (Eds.). (1993). *AIDS: Etiology, diagnosis, treatment, and prevention* (4th ed.). Philadelphia: Lippincott Williams & Wilkins.

susceptibility to infection. The most common sites of visceral involvement are the lymph nodes, gastrointestinal tract, and lungs. Involvement of internal organs may eventually lead to organ failure, hemorrhage, infection, and death.

Diagnosis of KS is confirmed by biopsy of suspected lesions. Prognosis depends on the extent of the tumor, the presence of other symptoms of HIV infection, and the CD4+ count. Death may result from tumor progression. More often, however, it results from other complications of HIV infection.

B-Cell Lymphomas

B-cell lymphomas are the second most common malignancy occurring in people with AIDS. Lymphomas associated with AIDS usually differ from those occurring in the general population. Patients with AIDS are typically much younger than the usual population affected by non-Hodgkin lymphoma. In addition, AIDS-related lymphomas tend to develop outside the lymph nodes, most commonly in the brain, bone marrow, and gastrointestinal tract. These types of lymphomas are characteristically of a higher grade, indicating aggressive growth and resistance to treatment. The course of AIDS-related lymphomas includes multiple sites of organ involvement and complications related to opportunistic infections. Although aggressive combination chemotherapy is frequently successful in the treatment of non-Hodgkin lymphoma that is not associated with HIV infection, treatment is less successful in people with AIDS because of severe hematologic toxicity and complications of opportunistic infections that can occur from treatment.

Neurologic Manifestations

The advent of HAART greatly lowered the incidence of HIV dementia and increased the survival of people with HIV-associated neurocognitive disorders (McArthur, 2008). These disorders consist of cognitive impairment that is often accompanied by motor dysfunction and behavioral change. Neurologic dysfunction results from direct effects of

HIV on nervous system tissue, opportunistic infections, primary or metastatic neoplasms, cerebrovascular changes, metabolic encephalopathies, or complications secondary to therapy. Immune system response to HIV infection in the CNS includes inflammation, atrophy, demyelination, degeneration, and necrosis.

Peripheral Neuropathy

HIV-associated **peripheral neuropathy** is common across the trajectory of HIV disease and may occur in a variety of patterns, with distal sensory polyneuropathy (DSPN) or distal symmetric polyneuropathy the most frequently occurring type. DSPN occurs in advanced HIV disease as a result of immunosuppression, antiretroviral drug toxicity, and/or mitochondrial toxicity. It can lead to significant pain and decreased function (Nicholas, Voss, Corless, et al., 2007).

HIV Encephalopathy

HIV encephalopathy was formerly referred to as AIDS dementia complex (Chart 52-9). It is a clinical syndrome that is characterized by a progressive decline in cognitive, behavioral, and motor functions. Substantial evidence exists that HIV encephalopathy is a direct result of HIV infection. HIV has been found in the brain and cerebrospinal fluid (CSF) of patients with HIV encephalopathy. The brain cells infected by HIV are predominantly the CD4+ cells of

monocyte-**macrophage** lineage. HIV infection is thought to trigger the release of toxins or lymphokines that result in cellular dysfunction or interference with neurotransmitter function rather than cellular damage.

Signs and symptoms may be subtle and difficult to distinguish from fatigue, depression, or the adverse effects of treatment for infections and malignancies. Early manifestations include memory deficits, headache, difficulty concentrating, progressive confusion, psychomotor slowing, apathy, and ataxia. Later stages include global cognitive impairments, delay in verbal responses, a vacant stare, spastic paraparesis, hyperreflexia, psychosis, hallucinations, tremor, incontinence, seizures, mutism, and death.

Confirming the diagnosis of HIV encephalopathy can be difficult. Extensive neurologic evaluation includes a computed tomography scan, which may indicate diffuse cerebral atrophy and ventricular enlargement. Other tests that may detect abnormalities include magnetic resonance imaging, analysis of CSF through lumbar puncture, and brain biopsy.

Cryptococcus neoformans

A fungal infection, *C. neoformans* is another common opportunistic infection among patients with AIDS, and it causes neurologic disease. Cryptococcal meningitis is characterized by symptoms such as fever, headache, malaise, stiff neck, nausea, vomiting, mental status changes, and seizures. Diagnosis is confirmed by CSF analysis.

Chart 52-9 • Care of the Patient With HIV Encephalopathy

Disturbed Thought Processes

- Assess mental status and neurologic functioning.
- Monitor for medication interactions, infections, electrolyte imbalance, and depression.
- Frequently orient the patient to time, place, person, reality, and the environment.
- Use simple explanations.
- Teach the patient to perform tasks in incremental steps.
- Provide memory aids (clocks and calendars).
- Provide memory aids for medication administration.
- Post activity schedule.
- Give positive feedback for appropriate behavior.
- Teach caretakers how to orient patient to time, place, person, reality, and the environment.
- Encourage the patient to designate a responsible person to assume power of attorney.

Disturbed Sensory Perception

- Assess sensory impairment.
- Decrease amount of stimuli in the patient's environment.
- Correct inaccurate perceptions.
- Provide reassurance and safety if the patient displays fear.
- Provide a secure and stable environment.
- Teach caregivers how to recognize inaccurate sensory perceptions.
- Teach caregivers techniques to correct inaccurate perceptions.
- Teach the patient and caregivers to report any changes in the patient's vision to the patient's health care provider.

Risk for Injury

- Assess the patient's level of anxiety, confusion, or disorientation.
- Assess the patient for delusions or hallucinations.
- Remove potentially dangerous objects from the patient's environment.
- Structure the environment for safety (ensure adequate lighting, avoid clutter, provide bed rails if needed).
- Supervise smoking.
- Do not let the patient drive a car if confusion is present.
- Instruct the patient and caregiver in home safety.
- Provide assistance as needed for ambulation and in getting in and out of bed.
- Pad headboard and side rails if the patient has seizures.

Self-Care Deficits

- Encourage activities of daily living within the patient's level of ability.
- Encourage independence but assist if the patient cannot perform an activity.
- Demonstrate any activity that the patient is having difficulty accomplishing.
- Monitor food and fluid intake.
- Weigh patient weekly.
- Encourage the patient to eat, and offer nutritious meals, snacks, and adequate fluids.
- If patient is incontinent, establish a routine toileting schedule.
- Teach caregivers how to meet the patient's self-care needs.

Progressive Multifocal Leukoencephalopathy

Progressive multifocal leukoencephalopathy (PML) is a demyelinating CNS disorder that affects the oligodendroglia. Clinical manifestations often begin with mental confusion and rapidly progress to include blindness, aphasia, muscle weakness, paresis (partial or complete paralysis), and death. Treatments have greatly reduced the threat of mortality associated with this disorder.

Other Neurologic Disorders

Other common infections involving the nervous system include *Toxoplasma gondii*, CMV, and *Mycobacterium tuberculosis* infections. Additional neurologic manifestations include both central and peripheral neuropathies. Vascular myelopathy is a degenerative disorder that affects the lateral and posterior columns of the spinal cord, resulting in progressive spastic paraparesis, ataxia, and incontinence.

Depressive Manifestations

The prevalence of depression among people with HIV infection is unknown. The causes of depression are multifactorial and may include a history of preexisting mental illness, neuropsychiatric disturbances, and psychosocial factors. Depression also occurs in people with HIV infection in response to the physical symptoms, including pain and weight loss, and the lack of someone to talk with about their concerns. People with HIV/AIDS who are depressed may experience irrational guilt and shame, loss of self-esteem, feelings of helplessness and worthlessness, and suicidal ideation.

Integumentary Manifestations

Cutaneous manifestations are associated with HIV infection and the accompanying opportunistic infections and malignancies. KS (described earlier) and opportunistic infections such as herpes zoster and herpes simplex are associated with painful vesicles that disrupt skin integrity. Molluscum contagiosum is a viral infection characterized by deforming plaque formation. Seborrheic dermatitis is associated with an indurated, diffuse, scaly rash involving the scalp and face. Patients with AIDS may also exhibit a generalized folliculitis associated with dry, flaking skin or atopic dermatitis, such as eczema or psoriasis. Up to 60% of patients treated with the antibacterial agent trimethoprim-sulfamethoxazole (TMP-SMZ) develop a drug-related rash that is pruritic with pinkish-red macules and papules. Patients with any of these rashes experience discomfort and are at increased risk for infection from disrupted skin integrity.

Endocrine Manifestations

The endocrine manifestations of HIV infection are not completely understood. At autopsy, endocrine glands show infiltration and destruction from opportunistic infections or neoplasms. Endocrine function may also be affected by therapeutic agents.

Gynecologic Manifestations

Persistent, recurrent vaginal candidiasis may be the first sign of HIV infection in women. Past or present genital ulcers are a risk factor for the transmission of HIV infection. Women with HIV infection are more susceptible to geni-

tal ulcers and venereal warts and have increased rates of incidence and recurrence of these conditions. Ulcerative sexually transmitted diseases (STDs) such as chancroid, syphilis, and herpes are more severe in women with HIV infection. **Human papillomavirus (HPV)** causes venereal warts and is a risk factor for cervical intraepithelial neoplasia, a cellular change that is frequently a precursor to cervical cancer. Women with HIV are 10 times more likely to develop cervical intraepithelial neoplasia than those not infected with HIV. There is a strong association between abnormal Papanicolaou (Pap) smears and HIV seropositivity. HIV-seropositive women with cervical carcinoma present at a more advanced stage of disease and have more persistent and recurrent disease and a shorter interval to recurrence and death than women without HIV infection.

A significant percentage of women who require hospitalization for pelvic inflammatory disease have HIV infection. Women with HIV are at increased risk for pelvic inflammatory disease, and the associated inflammation may potentiate the transmission of HIV infection. Moreover, women with HIV infection appear to have a higher incidence of menstrual abnormalities, including amenorrhea or bleeding between periods, than do women without HIV infection. The failure of health care providers to consider HIV infection in women may lead to a later diagnosis, thereby denying these patients appropriate treatment.

Medical Management

Treatment of Opportunistic Infections

Guidelines for the treatment of opportunistic infections should be consulted for the most current recommendations (Guidelines for Prevention and Treatment of Opportunistic Infections in HIV-Infected Adults and Adolescents [OI Guidelines], 2009). Despite the availability of antiretroviral medications, opportunistic infections (OIs) continue to cause considerable morbidity and mortality for three main reasons: (1) many patients are unaware of their HIV infection and present with an OI as the initial indicator of their disease, (2) some patients are aware of their HIV infection but do not take antiretroviral agents because of psychosocial or economic factors, and (3) others receive prescriptions for antiretroviral medications but fail to attain adequate virologic and immunologic response as a result of issues related to adherence, pharmacokinetics, or unexplained biologic factors (OI Guidelines, 2009).

Immune function should improve with initiation of HAART, resulting in faster resolution of the OI. This has been most clearly shown for OIs for which effective therapy does not exist, such as cryptosporidiosis, microsporidiosis, and PML. These conditions may resolve or at least stabilize after the institution of antiretroviral therapy as well as resolution of lesions of KS (OI Guidelines, 2009).

Pneumocystis Pneumonia

TMP-SMZ is the treatment of choice for PCP; it is as effective as parenteral pentamidine and more effective than other regimens. Oral outpatient therapy using TMP-SMZ is highly effective among patients with mild to moderate PCP. Adjunctive corticosteroids should be started as early as possible and certainly within 72 hours after starting specific

PCP therapy. Alternative therapeutic regimens for patients with mild to moderate disease include (1) dapsone and TMP, (2) primaquine plus clindamycin, and (3) atovaquone suspension. Alternatives for patients with moderate to severe disease include (1) primaquine plus clindamycin or (2) IV pentamidine (generally the drug of second choice for severe disease; it can cause severe hypotension if it is administered too rapidly). Aerosolized pentamidine should not be used for the treatment of PCP because of limited efficacy and more frequent relapse. The recommended duration of therapy for PCP is 21 days (OI Guidelines, 2009). Adverse effects, in addition to hypotension, include impaired glucose metabolism leading to the development of diabetes mellitus from damage to the pancreas, renal damage, hepatic dysfunction, and neutropenia.

Mycobacterium Avium Complex

HIV-infected adults and adolescents should receive chemoprophylaxis against disseminated MAC disease if they have a CD4+ count less than 50 cells/ μ L. Azithromycin (Zithromax) or clarithromycin (Biaxin) are the preferred prophylactic agents. If azithromycin or clarithromycin cannot be tolerated, rifabutin is an alternative prophylactic agent for MAC disease, although drug interactions may make this agent difficult to use (OI Guidelines, 2009). Secondary prophylaxis for disseminated MAC may be discontinued in patients who have sustained increases in CD4 counts (greater than 100 cells/mm³; longer than 3 months) in response to HAART, have completed 12 months of MAC therapy, and have no signs or symptoms attributable to MAC.

Cryptococcal Meningitis

Cryptococcosis among patients with HIV infection most commonly occurs as a subacute meningitis or meningoencephalitis with fever, malaise, and headache. Current primary therapy for cryptococcal meningitis is IV amphotericin B with or without oral flucytosine (5-FC, Ancobon) or fluconazole (Diflucan). Serious potential adverse effects of amphotericin B include anaphylaxis, renal and hepatic impairment, electrolyte imbalances, anemia, fever, and severe chills (OI Guidelines, 2009).

Cytomegalovirus Retinitis

Retinitis caused by CMV is a leading cause of blindness in patients with AIDS. Oral valganciclovir, IV ganciclovir, IV ganciclovir followed by oral valganciclovir, IV foscarnet, IV cidofovir, and the ganciclovir intraocular implant coupled with valganciclovir are all effective treatments for CMV retinitis (OI Guidelines, 2009). A common adverse reaction to ganciclovir is severe neutropenia, which limits the concomitant use of zidovudine (AZT, Compound S, Retrovir). Common adverse reactions to foscarnet are nephrotoxicity, including acute renal failure, and electrolyte imbalances, including hypocalcemia, hyperphosphatemia, and hypomagnesemia, which can be life-threatening. Other common adverse effects include seizures, gastrointestinal disturbances, anemia, phlebitis at the infusion site, and low back pain. Possible bone marrow suppression (producing a decrease in white blood cell and platelet counts), oral candidiasis, and liver and renal impairments require close monitoring.

Other Infections

Oral acyclovir, famciclovir, or valacyclovir may be used to treat infections caused by herpes simplex or herpes zoster. Esophageal or oral candidiasis is treated topically with clotrimazole (Mycelex) oral troches or nystatin suspension. Chronic refractory infection with candidiasis (thrush) or esophageal involvement is treated with ketoconazole (Nizoral) or fluconazole (Diflucan).

Prevention of Opportunistic Infections

TMP-SMZ (Bactrim, Cotrim, Septra) is an antibacterial agent used to treat various organisms causing infection. It also confers cross-protection against toxoplasmosis and some common respiratory bacterial infections. People with HIV infection who have a T-cell count of less than 200 cells/mm³ should receive chemoprophylaxis with TMP-SMZ to prevent PCP. PCP prophylaxis can be safely discontinued in patients who are responding to HAART with a sustained increase in T lymphocytes.

Antidiarrheal Therapy

Although many forms of diarrhea respond to treatment, it is not unusual for this condition to recur and become a chronic problem for the patient with HIV infection. Therapy with octreotide acetate (Sandostatin), a synthetic analogue of somatostatin, has been shown to be effective in managing chronic severe diarrhea. High concentrations of somatostatin receptors have been found in the gastrointestinal tract and in other tissues. Somatostatin inhibits many physiologic functions, including gastrointestinal motility and intestinal secretion of water and electrolytes.

Chemotherapy

Kaposi's Sarcoma

Management of KS is usually difficult because of the variability of symptoms and the organ systems involved. KS is rarely life-threatening except when there is pulmonary or gastrointestinal involvement. The treatment goals are to reduce symptoms by decreasing the size of the skin lesions, to reduce discomfort associated with edema and ulcerations, and to control symptoms associated with mucosal or visceral involvement. No one treatment has been shown to increase survival. Radiation therapy is effective as a palliative measure to relieve localized pain due to tumor mass (especially in the legs) and for KS lesions that are in sites such as the oral mucosa, conjunctiva, face, and soles of the feet.

Interferon is known for its antiviral and antitumor effects. Patients with cutaneous KS treated with **alpha-interferon** have experienced tumor regression and improved immune system function. Alpha-interferon is administered by the IV, intramuscular, or subcutaneous route. Patients may self-administer interferon at home or receive interferon in an outpatient setting.

Lymphoma

Successful treatment of AIDS-related lymphomas has been limited because of the rapid progression of these malignancies. Combination chemotherapy and radiation therapy regimens may produce an initial response, but it is usually short-lived. Because standard regimens for non-AIDS

lymphomas have been ineffective, many clinicians suggest that AIDS-related lymphomas should be studied as a separate group in clinical trials.

Antidepressant Therapy

Treatment for depression in people with HIV infection involves psychotherapy integrated with pharmacotherapy. If depressive symptoms are severe and of sufficient duration, treatment with antidepressants may be initiated. Antidepressants such as imipramine (Tofranil), desipramine (Norpramin), and fluoxetine (Prozac) may be used, because these medications also alleviate the fatigue and lethargy that are associated with depression. A psychostimulant such as methylphenidate (Ritalin) may be used in low doses in patients with neuropsychiatric impairment. Electroconvulsive therapy may be an option for patients with severe depression who do not respond to pharmacologic interventions.

Nutrition Therapy

Malnutrition increases the risk of infection and the incidence of opportunistic infections. Nutrition therapy should be part of the overall management plan and should be tailored to meet the nutritional needs of the patient, whether by oral diet, enteral tube feedings, or parenteral nutritional support, if needed. As with all patients, a healthy diet is essential for the patient with HIV infection. For patients with diarrhea, a diet low in fat, lactose, insoluble fiber, and caffeine and high in soluble fiber is helpful (Anastasi, Capili, Kim, et al., 2006). For all patients with AIDS who experience unexplained weight loss, calorie counts should be obtained to evaluate nutritional status and initiate appropriate therapy. The goal is to maintain the ideal weight and, when necessary, to increase weight.

Appetite stimulants have been successfully used in patients with AIDS-related anorexia. Megestrol acetate (Megace), a synthetic oral progesterone preparation, promotes significant weight gain and inhibits cytokine IL-1 synthesis. In patients with HIV infection, it increases body weight primarily by increasing body fat stores. Dronabinol (Marinol), which is a synthetic tetrahydrocannabinol (THC), the active ingredient in marijuana, has been used to relieve nausea and vomiting associated with cancer chemotherapy. After beginning dronabinol therapy, almost all patients with HIV infection experience a modest weight gain. The effects on body composition are unknown.

Oral supplements may be used to supplement diets that are deficient in calories and protein. Ideally, oral supplements should be lactose-free (many people with HIV infection are intolerant to lactose), high in calories and easily digestible protein, low in fat with the fat easily digestible, palatable, inexpensive, and tolerated without causing diarrhea. Advera is a nutritional supplement that has been developed specifically for people with HIV infection and AIDS. Parenteral nutrition is the final option because of its prohibitive cost and associated risks, including risk of infections.

Complementary and Alternative Modalities

Traditional Western medicine focuses on the treatment of disease. These treatments or interventions are taught in medical schools and are used by physicians in the care of

patients. Complementary and alternative medicine (CAM) is often viewed as consisting of unconventional and unorthodox treatments or interventions that are not traditionally taught in medical schools. These modalities and therapies stress the need to treat the whole person, recognizing the interaction of the body, mind, and spirit. What is considered to be CAM in one culture may actually be a traditional therapy in another. People with HIV infection report substantial use of CAM for symptom management (Andrade & Anderson, 2008). The use of CAM in HIV infection and AIDS often results because of disillusionment with standard medical treatment, which to date has provided no cure. Combined with traditional therapies, CAM may improve the patient's overall well-being. However, there can be adverse drug–drug interactions between certain CAM therapies (eg, St. John's wort) and some antiretroviral medications.

CAM can be divided into four categories:

- Spiritual or psychological therapies may include humor, hypnosis, faith healing, guided imagery, and positive affirmations.
- Nutritional therapies may include vegetarian or macrobiotic diets, vitamin C or beta-carotene supplements, and turmeric, which contains curcumin, a food spice supplement. Chinese herbs, such as traditional herbal mixtures, are also used, in addition to compound Q (a Chinese cucumber extract) and *Momordica charantia* (bitter melon), which is given as an enema.
- Drug and biologic therapies include medications and other substances not approved by the FDA. Examples are *N*-acetylcysteine, pentoxifylline (Trental), and 1-chloro-2, 4-dinitrobenzene. Also included in this category are oxygen therapy, ozone therapy, and urine therapy.
- Treatment with physical forces and devices may include acupuncture, acupressure, massage therapy, reflexology, therapeutic touch, yoga, and crystals.

Although there is insufficient research on the effects of CAM, there is a growing body of literature reporting benefits for modalities involving nutrition, exercise, psychosocial treatment, and Chinese medicine.

Many patients who use these therapies do not report use of CAM to their health care providers. To obtain a complete health history, the nurse should ask about the patient's use of alternative therapies. Patients may need to be encouraged to report their use of CAM to their primary health care provider. Problems may arise, for example, when patients are using CAM while participating in clinical drug trials; alternative therapies can have significant adverse side effects, making it difficult to assess the effects of the medications in the clinical trial. The nurse needs to become familiar with the potential adverse side effects of these therapies. The nurse who suspects that CAM is causing a side effect needs to discuss this with the patient, the alternative therapy provider, and the primary health care provider. It is important for the nurse to view CAM with an open mind and to try to understand the importance of this treatment to the patient. This approach will improve communication with the patient and reduce conflict.

Supportive Care

Patients who are weak and debilitated as a result of chronic illness associated with HIV infection typically require many kinds of supportive care. Nutritional support may be as simple as providing assistance in obtaining or preparing meals. For patients with more advanced nutritional impairment resulting from decreased intake, wasting syndrome, or gastrointestinal malabsorption associated with diarrhea, parenteral feedings may be required. Imbalances that result from nausea, vomiting, and profuse diarrhea often necessitate IV fluid and electrolyte replacement.

Management of skin breakdown associated with KS, perianal skin excoriation, or immobility entails thorough and meticulous skin care that involves regular turning, cleansing, and applications of medicated ointments and dressings. To combat pain associated with skin breakdown, abdominal cramping, peripheral neuropathy, or KS, it is necessary to administer analgesic agents at regular intervals around the clock. Relaxation and guided imagery may be helpful in reducing pain and anxiety.

Pulmonary symptoms, such as dyspnea and shortness of breath, may be related to infection, KS, or fatigue. For patients with these symptoms, oxygen therapy, relaxation training, and energy conservation techniques may be effective. Patients with severe respiratory dysfunction may require mechanical ventilation. Before mechanical ventilation is instituted, the procedure is explained to the patient and the caregiver. If the patient decides to forgo mechanical ventilation, his or her wishes should be followed. Ideally, the patient has prepared an advance directive identifying preferences for treatments and end-of-life care, including hospice care. If the patient has not identified preferences in advance, treatment options are described so that the patient can make informed decisions and have those wishes respected.

NURSING PROCESS

THE PATIENT WITH HIV/AIDS

The nursing care of patients with AIDS is challenging because of the potential for any organ system to be the target of infections or cancer. In addition, this disease is complicated by many emotional, social, and ethical issues. The plan of care for the patient with AIDS (Chart 52-10) is individualized to meet the needs of the patient.

The scope and standards of HIV/AIDS nursing developed by the Association of Nurses in AIDS Care (2007) guide nursing practice. Care includes many of the interventions and concerns cited in the section on supportive care.

Assessment

Nursing assessment includes identification of potential risk factors, including a history of risky sexual practices or IV/injection drug use. The patient's physical status and psychological status are assessed. All factors affecting immune system functioning are thoroughly explored.

Nutritional Status

Nutritional status is assessed by obtaining a dietary history and identifying factors that may interfere with oral

intake, such as anorexia, nausea, vomiting, oral pain, or difficulty swallowing. In addition, the patient's ability to purchase and prepare food is assessed. Weight history (ie, changes over time); anthropometric measurements; and blood urea nitrogen (BUN), serum protein, albumin, and transferrin levels provide objective measurements of nutritional status.

Skin Integrity

The skin and mucous membranes are inspected daily for evidence of breakdown, ulceration, or infection. The oral cavity is monitored for redness, ulcerations, and the presence of creamy-white patches indicative of candidiasis. Assessment of the perianal area for excoriation and infection in patients with profuse diarrhea is important. Wounds are cultured to identify infectious organisms.

Respiratory Status

Respiratory status is assessed by monitoring the patient for cough, sputum production (ie, amount and color), shortness of breath, orthopnea, tachypnea, and chest pain. The presence and quality of breath sounds are investigated. Other measures of pulmonary function include chest x-ray results, arterial blood gas values, pulse oximetry, and pulmonary function test results.

Neurologic Status

Neurologic status is determined by assessing level of consciousness; orientation to person, place, and time; and memory lapses. Mental status is assessed as early as possible to provide a baseline. The patient is also assessed for sensory deficits (visual changes, headache, or numbness and tingling in the extremities), motor involvement (altered gait, paresis, or paralysis), and seizure activity.

Fluid and Electrolyte Balance

Fluid and electrolyte status is assessed by examining the skin and mucous membranes for turgor and dryness. Dehydration may be indicated by increased thirst, decreased urine output, postural hypotension, weak and rapid pulse, and urine specific gravity of 1.025 or more. Electrolyte imbalances, such as decreased serum sodium, potassium, calcium, magnesium, and chloride, typically result from profuse diarrhea. The patient is assessed for signs and symptoms of electrolyte deficits, including decreased mental status, muscle twitching, muscle cramps, irregular pulse, nausea and vomiting, and shallow respirations.

Knowledge Level

The patient's level of knowledge about the disease and the modes of disease transmission is evaluated. In addition, the level of knowledge of family and friends is assessed. The patient's psychological reaction to the diagnosis of HIV infection or AIDS is important to explore. Reactions vary among patients and may include denial, anger, fear, shame, withdrawal from social interactions, and depression. It is often helpful to gain an understanding of how the patient has dealt with illness and major life stresses in the past. The patient's resources for support are also identified.

 CHART
52-10

PLAN OF NURSING CARE
Care of the Patient With AIDS
NURSING DIAGNOSIS: Diarrhea related to enteric pathogens or HIV infection**GOAL:** Resumption of usual bowel habits**Nursing Interventions**

1. Assess patient's normal bowel habits.
2. Assess for diarrhea: frequent, loose stools; abdominal pain or cramping, volume of liquid stools, and exacerbating and alleviating factors.
3. Obtain stool cultures and administer antimicrobial therapy as prescribed.
4. Initiate measures to reduce hyperactivity of bowel:
 - a. Maintain food and fluid restrictions as prescribed. Suggest BRAT diet (*bananas, rice, apple sauce, tea and toast*).
 - b. Discourage smoking.
 - c. Avoid bowel irritants such as fatty or fried foods, raw vegetables, and nuts. Offer small, frequent meals.
5. Administer anticholinergic antispasmodics and opioids or other medications as prescribed.
6. Maintain fluid intake of at least 3 L/day unless contraindicated.

Rationale

1. Provides baseline for evaluation
2. Detects changes in status, quantifies loss of fluid, and provides basis for nursing measures
3. Identifies pathogenic organism; therapy targets specific organism
4. Promotes bowel rest, which may decrease acute episodes
 - a. Reduces stimulation of bowel
 - b. Eliminates nicotine, which acts as bowel stimulant
 - c. Prevents stimulation of bowel and abdominal distention and promotes adequate nutrition
5. Decreases intestinal spasms and motility
6. Prevents hypovolemia

Expected Outcomes

- Exhibits return to normal bowel patterns
- Reports decreasing episodes of diarrhea and abdominal cramping
- Identifies and avoids foods that irritate the gastrointestinal tract
- Appropriate therapy is initiated as prescribed
- Exhibits normal stool cultures
- Maintains adequate fluid intake
- Maintains body weight and reports no additional weight loss
- States rationale for avoiding smoking
- Enrolls in program to stop smoking
- Uses medication as prescribed
- Maintains adequate fluid status
- Exhibits normal skin turgor, moist mucous membranes, adequate urine output, and absence of excessive thirst

NURSING DIAGNOSIS: Risk for infection related to immunodeficiency**GOAL:** Absence of infection**Nursing Interventions**

1. Monitor for infection: fever, chills, and diaphoresis; cough; shortness of breath; oral pain or painful swallowing; creamy-white patches in oral cavity; urinary frequency, urgency, or dysuria; redness, swelling, or drainage from wounds; vesicular lesions on face, lips, or perianal area.
2. Teach patient or caregiver about need to report possible infection.
3. Monitor white blood cell count and differential.
4. Obtain cultures of wound drainage, skin lesions, urine, stool, sputum, mouth, and blood as prescribed. Administer antimicrobial therapy as prescribed.
5. Instruct patient in ways to prevent infection:
 - a. Clean kitchen and bathroom surfaces with disinfectants.
 - b. Clean hands thoroughly after exposure to body fluids.
 - c. Avoid exposure to others' body fluids or sharing eating utensils.
 - d. Turn, cough, and deep breathe, especially when activity is decreased.

Rationale

1. Allows for early detection of infection, essential for prompt initiation of treatment. Repeated and prolonged infections contribute to patient's debilitation.
2. Allows early detection of infection
3. Identifies elevated WBC possibly associated with infection
4. Assists in determining offending organism to initiate appropriate treatment
5. Minimizes exposure to infection and transmission of HIV infection to others

Expected Outcomes

- Identifies reportable signs and symptoms of infection
- Reports signs and symptoms of infection if present
- Exhibits and reports absence of fever, chills, and diaphoresis
- Exhibits normal (clear) breath sounds without adventitious breath sounds
- Maintains weight
- Reports adequate energy level without excessive fatigue
- Reports absence of shortness of breath and cough
- Exhibits pink, moist oral mucous membranes without fissures or lesions
- Takes appropriate therapy as prescribed
- Experiences no infection
- States rationale for strategies to avoid infection
- Modifies activities to reduce exposure to infection or infectious persons
- Practices "safer sex"
- Avoids sharing eating utensils and toothbrush
- Exhibits normal body temperature

CHART
52-10

PLAN OF NURSING CARE
Care of the Patient With AIDS (Continued)

Nursing Interventions	Rationale	Expected Outcomes
<p>d. Do not use IV/injection drugs; if addicted and unable or unwilling to change behavior, use clean needles and syringes.</p> <p>e. Women who may have been exposed to HIV through sexual or drug practices should consult with a physician before becoming pregnant; consider use of antiretroviral agents if pregnant.</p>	<p>d. Clean needles and syringes are the only way to prevent HIV transmission for those who continue to use drugs. Taking precautions is important for those who are antibody positive to prevent transmitting HIV.</p> <p>e. HIV can be transmitted from mother to child in utero; use of antiretroviral agents during pregnancy significantly reduces perinatal transmission of HIV.</p>	

NURSING DIAGNOSIS: Social isolation related to stigma of the disease, withdrawal of support systems, isolation procedures, and fear of infecting others
GOAL: Decreased sense of social isolation

Nursing Interventions	Rationale	Expected Outcomes
<ol style="list-style-type: none"> 1. Assess patient's usual patterns of social interaction. 2. Observe for behaviors indicative of social isolation, such as decreased interaction with others, hostility, non-compliance, sad affect, and stated feelings of rejection or loneliness. 3. Provide instruction concerning modes of transmission of HIV. 4. Assist patient to identify and explore resources for support and positive mechanisms for coping (eg, contact with family, friends, AIDS task force). 5. Allow time to be with patient other than for medications and procedures. 6. Encourage participation in diversional activities such as reading, television, or hand crafts. 	<ol style="list-style-type: none"> 1. Establishes basis for individualized interventions 2. Promotes early detection of social isolation, which may be manifested in several ways 3. Provides accurate information, corrects misconceptions, and alleviates anxiety 4. Enables mobilization of resources and supports 5. Promotes feelings of self-worth and provides social interaction 6. Provides distraction 	<ul style="list-style-type: none"> • Shares with others the need for valued social interaction • Demonstrates interest in events, activities, and communication • Verbalizes feelings and reactions to diagnosis, prognosis, and life changes • Identifies modes of transmission of HIV • States ways of preventing transmission of AIDS virus to others while maintaining contact with valued friends and relatives • Reveals AIDS diagnosis to others when appropriate • Identifies resources (ie, family, friends, and support groups) • Uses resources when appropriate • Accepts offers of assistance and support • Reports decreased sense of isolation • Maintains contacts with those of importance to him or her • Develops or continues hobbies that effectively serve as diversion or distraction

COLLABORATIVE PROBLEMS: Opportunistic infections; impaired breathing; wasting syndrome and fluid and electrolyte imbalances; adverse reaction to medications
GOAL: Absence of complications

Nursing Interventions	Rationale	Expected Outcomes
<p>Opportunistic Infections</p> <ol style="list-style-type: none"> 1. Monitor vital signs. 2. Obtain laboratory specimens and monitor test results. 	<ol style="list-style-type: none"> 1. Changes in vital signs such as increases in pulse rate, respirations, blood pressure, and temperature may indicate infection. 2. Smears and cultures can identify causative agents such as bacteria, fungi, and protozoa, and sensitivity studies can identify antibiotics or other medications effective against the causative agent. 	<ul style="list-style-type: none"> • Exhibits stable vital signs • Experiences control of infection • Identifies signs and symptoms correctly and experiences no complications • Identifies signs and symptoms that are reportable to the physician • Takes medications as prescribed

Continued on following page

 CHART
52-10

PLAN OF NURSING CARE
Care of the Patient With AIDS (Continued)

Nursing Interventions	Rationale	Expected Outcomes
3. Instruct the patient and caregiver about signs and symptoms of infection and the need to report them early.	3. Early recognition of symptoms facilitates prompt treatment and avoids extra complications.	
Impaired Breathing 1. Monitor respiratory rate and pattern. 2. Auscultate the chest for breath sounds and abnormal lung sounds. 3. Monitor pulse rate, blood pressure, and oxygen saturation levels.	1. Rapid shallow breathing, diminished breath sounds, and shortness of breath may indicate respiratory failure resulting in hypoxia. 2. Crackles and wheezes may indicate fluid in the lungs, which disrupts respiratory function and alters the blood's oxygen-carrying capacity. 3. Changes in pulse rate, blood pressure, and oxygen levels may indicate the development of respiratory or cardiac failure.	<ul style="list-style-type: none"> • Maintains stable respiratory rate and pattern within the normal limits • Exhibits no adventitious lung sounds; normal breath sounds • Has stable pulse rate and blood pressure within normal limits, and exhibits no evidence of hypoxia • Oxygen saturation levels within acceptable range
Wasting Syndrome and Fluid and Electrolyte Disturbances 1. Monitor weight and laboratory values for nutritional status. 2. Monitor intake and output and laboratory values for fluid and electrolyte imbalance (potassium, sodium, calcium, phosphorus, magnesium, and zinc). 3. Monitor for and report signs and symptoms of dehydration.	1. Weight loss, malnutrition, and anemia are common in HIV infection and increase risk for superinfection. 2. Chronic diarrhea, inadequate oral intake, vomiting, and profuse sweating deplete electrolytes. Small intestine inflammation may impair the absorption of fluids and electrolytes. 3. Fluid loss results in decreased circulating volume leading to tachycardia, dry skin and mucous membranes, poor skin turgor, elevated urine specific gravity, and thirst. Early detection allows early treatment.	<ul style="list-style-type: none"> • Maintains stable weight • Eats a nutritious diet • Attains and maintains hemoglobin, hematocrit, and ferritin levels within normal limits • Sustains fluid and electrolyte balance within normal limits • Exhibits no signs and symptoms of dehydration
Reactions to Medications 1. Monitor for medication interactions. 2. Monitor for and promptly report side effects from antiretroviral agents. 3. Instruct the patient and caregiver in the medication regimen.	1. People with HIV infection receive many medications for HIV and for disease complications. Early detection of medication interactions is necessary to prevent complications. 2. Side effects from antiretroviral agents can be life-threatening. Serious side effects include anemia, pancreatitis, peripheral neuropathy, mental confusion, and persistent nausea and vomiting. Corrective measures need to be instituted. 3. Knowledge of the medication purpose, correct administration, side effects, and strategies to manage or prevent side effects promote safety and greater compliance with treatment.	<ul style="list-style-type: none"> • Experiences no serious side effects or complications from medications • Correctly describes medication regimen and complies with therapy, including adaptations in eating routines and type of food used with prescribed medications

Diagnosis

Nursing Diagnoses

The list of potential nursing diagnoses is extensive because of the complex nature of this disease. However, based on assessment data, major nursing diagnoses for the patient may include the following:

- Impaired skin integrity related to cutaneous manifestations of HIV infection, excoriation, and diarrhea
- Diarrhea related to enteric pathogens or HIV infection
- Risk for infection related to immunodeficiency
- Activity intolerance related to weakness, fatigue, malnutrition, impaired fluid and electrolyte balance, and hypoxia associated with pulmonary infections

- Disturbed thought processes related to shortened attention span, impaired memory, confusion, and disorientation associated with HIV encephalopathy
- Ineffective airway clearance related to PCP, increased bronchial secretions, and decreased ability to cough related to weakness and fatigue
- Pain related to impaired perianal skin integrity secondary to diarrhea, KS, and peripheral neuropathy
- Imbalanced nutrition, less than body requirements, related to decreased oral intake
- Social isolation related to stigma of the disease, withdrawal of support systems, isolation procedures, and fear of infecting others
- Anticipatory grieving related to changes in lifestyle and roles and unfavorable prognosis
- Deficient knowledge related to HIV infection, means of preventing HIV transmission, and self-care

Collaborative Problems/Potential Complications

Based on the assessment data, possible complications may include the following:

- Opportunistic infections
- Impaired breathing or respiratory failure
- Wasting syndrome and fluid and electrolyte imbalance
- Adverse reaction to medications

Planning and Goals

Goals for the patient may include achievement and maintenance of skin integrity, resumption of usual bowel patterns, absence of infection, improved activity tolerance, improved thought processes, improved airway clearance, increased comfort, improved nutritional status, increased socialization, expression of grief, increased knowledge regarding disease prevention and self-care, and absence of complications.

Nursing Interventions

Promoting Skin Integrity

The skin and oral mucosa are assessed routinely for changes in appearance, location and size of lesions, and evidence of infection and breakdown. The patient is encouraged to maintain a balance between rest and mobility whenever possible. Patients who are immobile are assisted to change position every 2 hours. Devices such as alternating-pressure mattresses and low-air-loss beds are used to prevent skin breakdown. Patients are encouraged to avoid scratching; to use nonabrasive, nondrying soaps; and to apply nonperfumed skin moisturizers to dry skin. Regular oral care is also encouraged.

Medicated lotions, ointments, and dressings are applied to affected skin surfaces as prescribed. Adhesive tape is avoided. Skin surfaces are protected from friction and rubbing by keeping bed linens free of wrinkles and avoiding tight or restrictive clothing. Patients with foot lesions are advised to wear cotton socks and shoes that do not cause the feet to perspire. Antipruritic, antibiotic, and analgesic agents are administered as prescribed.

The perianal region is assessed frequently for impairment of skin integrity and infection. The patient is instructed to keep the area as clean as possible. The perianal area is

cleaned after each bowel movement with nonabrasive soap and water to prevent further excoriation and breakdown of the skin and infection. If the area is very painful, soft cloths or cotton sponges may be less irritating than washcloths. In addition, sitz baths or gentle irrigation may facilitate cleaning and promote comfort. The area is dried thoroughly after cleaning. Topical lotions or ointments may be prescribed to promote healing. Wounds are cultured if infection is suspected, so that the appropriate antimicrobial treatment can be initiated. Debilitated patients may require assistance in maintaining hygienic practices.

Promoting Usual Bowel Patterns

Bowel patterns are assessed for diarrhea. The nurse monitors the frequency and consistency of stools and the patient's reports of abdominal pain or cramping associated with bowel movements. Factors that exacerbate frequent diarrhea are also assessed. The quantity and volume of liquid stools are measured to document fluid volume losses. Stool cultures are obtained to identify pathogenic organisms.

The patient is counseled about ways to decrease diarrhea. The physician may recommend restriction of oral intake to rest the bowel during periods of acute inflammation associated with severe enteric infections. As the patient's dietary intake is increased, foods that act as bowel irritants, such as raw fruits and vegetables, popcorn, carbonated beverages, spicy foods, and foods of extreme temperatures, should be avoided. Small, frequent meals help to prevent abdominal distention. Medications, such as anticholinergic agents, antispasmodic agents, or opioids, can be prescribed to decrease diarrhea by decreasing intestinal spasms and motility. Administering antidiarrheal agents on a regular schedule may be more beneficial than administering them on an as-needed basis. Antibiotics and antifungal agents may also be prescribed to combat pathogens identified by stool cultures. Assessment of self-care strategies being used is essential.

Preventing Infection

The patient and caregivers are instructed to monitor for signs and symptoms of infection: fever; chills; night sweats; cough with or without sputum production; shortness of breath; difficulty breathing; oral pain or difficulty swallowing; creamy-white patches in the oral cavity; unexplained weight loss; swollen lymph nodes; nausea; vomiting; persistent diarrhea; frequency, urgency, or pain on urination; headache; visual changes or memory lapses; redness, swelling, or drainage from skin wounds; and vesicular lesions on the face, lips, or perianal area. The nurse also monitors laboratory test results that indicate infection, such as the white blood cell count and differential. Cultures of specimens from wound drainage, skin lesions, urine, stool, sputum, mouth, and blood are obtained to identify pathogenic organisms and the most appropriate antimicrobial therapy. The patient is instructed to avoid others with active infections such as upper respiratory infections.

Improving Activity Tolerance

Activity tolerance is assessed by monitoring the patient's ability to ambulate and perform activities of daily living. Patients may be unable to maintain their usual levels of

activity because of weakness, fatigue, shortness of breath, dizziness, and neurologic involvement. Assistance in planning daily routines that maintain a balance between activity and rest may be necessary. In addition, patients benefit from instructions about energy conservation techniques, such as sitting while washing or while preparing meals. Personal items that are frequently used should be kept within the patient's reach. Measures such as relaxation and guided imagery may be beneficial because they decrease anxiety, which contributes to weakness and fatigue.

Collaboration with other members of the health care team may uncover other factors associated with increasing fatigue and strategies to address them. For example, if fatigue is related to anemia, administering epoetin alfa (Epogen) as prescribed may relieve fatigue and increase activity tolerance.

Maintaining Thought Processes

The patient is assessed for alterations in mental status that may be related to neurologic involvement, metabolic abnormalities, infection, side effects of treatment, and coping mechanisms. Manifestations of neurologic impairment may be difficult to distinguish from psychological reactions to HIV infection, such as anger and depression.

If the patient experiences altered mental or cognitive status, family and support network members are instructed to speak to the patient in simple, clear language and give the patient sufficient time to respond to questions. The patient's support network is encouraged to orient the patient to the daily routine by talking about what is taking place during daily activities and encouraged to provide the patient with a regular daily schedule for medication administration, grooming, meal times, bedtimes, and awakening times. Posting the schedule in a prominent area (eg, on the refrigerator), providing night lights for the bedroom and bathroom, and planning safe leisure activities allow the patient to maintain a regular routine in a safe manner. Activities that the patient previously enjoyed are encouraged. These should be easy to accomplish and fairly short in duration. The nurse encourages the social support network to remain calm and not to argue with the patient while protecting the patient from injury. Around-the-clock supervision may be necessary, and strategies can be implemented to prevent the patient from engaging in potentially dangerous activities, such as driving, using the stove, or mowing the lawn. Strategies for improving or maintaining functional abilities and for providing a safe environment are used for patients with HIV encephalopathy (see Chart 52-9).

Improving Airway Clearance

Respiratory status, including rate, rhythm, use of accessory muscles, and breath sounds; mental status; and skin color must be assessed at least daily. Any cough and the quantity and characteristics of sputum are documented. Sputum specimens are analyzed for infectious organisms. Pulmonary therapy (coughing, deep breathing, postural drainage, percussion, and vibration) is provided as often as every 2 hours to prevent stasis of secretions and to promote airway clearance. Because of weakness and fatigue, many patients require assistance in attaining a position (such as a high Fowler's or semi-Fowler's position) that facilitates breathing

and airway clearance. Adequate rest is essential to minimize energy expenditure and prevent excessive fatigue. The fluid volume status is evaluated so that adequate hydration can be maintained. Unless contraindicated because of renal or cardiac disease, daily intake of 3 L of fluid is encouraged. Humidified oxygen may be prescribed, and nasopharyngeal or tracheal suctioning, intubation, and mechanical ventilation may be necessary to maintain adequate ventilation.

Relieving Pain and Discomfort

The patient is assessed for the quality and severity of pain associated with impaired perianal skin integrity, the lesions of KS, and peripheral neuropathy. In addition, the effects of pain on elimination, nutrition, sleep, affect, and communication are explored, along with exacerbating and relieving factors. Cleaning the perianal area, as previously described, can promote comfort. Topical anesthetic medications or ointments may be prescribed. Use of soft cushions or foam pads may increase comfort while sitting. The patient is instructed to avoid foods that act as bowel irritants. Antispasmodic and antidiarrheal medications may be prescribed to reduce the discomfort and frequency of bowel movements. If necessary, systemic analgesic agents may also be prescribed. Pain from KS is frequently described as a sharp, throbbing pressure, and heaviness, if lymphedema is present. Pain management may include use of nonsteroidal anti-inflammatory drugs (NSAIDs) and opioids plus non-pharmacologic approaches such as relaxation techniques. When NSAIDs are administered to patients who are receiving zidovudine, hepatic and hematologic status must be monitored.

The patient with pain related to peripheral neuropathy frequently describes it as burning, numbness, and "pins and needles." Pain management approaches may include opioids, tricyclic antidepressants, and anti-embolism stockings to equalize pressure. Tricyclic antidepressants have been found to be helpful in controlling the symptoms of neuropathic pain. They also potentiate the actions of opioids and can be used to relieve pain without increasing the dose of the opioid.

Improving Nutritional Status

Nutritional status is assessed by monitoring weight, dietary intake, and serum albumin, BUN, protein, and transferrin levels. The patient is also assessed for factors that interfere with oral intake, such as anorexia, oral and esophageal candidal infection, nausea, pain, weakness, fatigue, and lactose intolerance (Dudek, 2006). Based on the results of assessment, the nurse can implement specific measures to facilitate oral intake. The dietitian is consulted to determine the patient's nutritional requirements.

Control of nausea and vomiting with antiemetic medications administered on a regular basis may increase the patient's dietary intake. Inadequate food intake resulting from pain caused by oral lesions or a sore throat may be managed by administering prescribed opioids and viscous lidocaine (the patient is instructed to rinse the mouth and swallow). Additionally, the patient is encouraged to eat foods that are easy to swallow and to avoid rough, spicy, or sticky food items and foods that are excessively hot or cold. Oral hygiene before and after meals is encouraged. If fatigue

and weakness interfere with intake, the nurse encourages the patient to rest before meals. If the patient is hospitalized, meals should be scheduled so that they do not occur immediately after painful or unpleasant procedures. The patient with diarrhea and abdominal cramping is encouraged to avoid foods that stimulate intestinal motility and abdominal distention, such as fiber-rich foods or lactose, if the patient is intolerant to lactose. The patient is instructed about ways to enhance the nutritional value of meals. Adding eggs, butter, or fortified milk (milk to which powdered skim milk has been added to increase the caloric content) to gravies, soups, or milkshakes can provide additional calories and protein. Supplements such as puddings, powders, milkshakes, and Advera (previously described) may also be useful (Dudek, 2006). Patients who cannot maintain their nutritional status through oral intake may require enteral feedings or parenteral nutrition.

Decreasing the Sense of Isolation

People with AIDS are at risk for double stigmatization. They have what society refers to as a “dreaded disease,” and they may have a lifestyle that differs from what is considered acceptable by many people. Many people with AIDS are young adults at a developmental stage that is usually associated with establishing intimate relationships, personal goals, and career goals, as well as having and raising children. Their focus changes as they are faced with a disease that threatens their life expectancy with no cure. In addition, they may be forced to reveal hidden lifestyles or behaviors to family, friends, coworkers, and health care providers. As a result, people with HIV infection may be overwhelmed with emotions such as anxiety, guilt, shame, and fear. They also may be faced with multiple losses, such as loss of financial security; normal roles and functions; self-esteem; privacy; ability to control bodily functions; ability to interact meaningfully with the environment; and sexual functioning, as well as rejection by sexual partners, family, and friends. Some patients may harbor feelings of guilt because of their lifestyle or because they may have infected others in current or previous relationships. Other patients may feel anger toward sexual partners who transmitted the virus to them. Infection control measures used in the hospital or at home may further contribute to the patient’s emotional isolation. Any or all of these stressors may cause the patient with AIDS to withdraw both physically and emotionally from social contact.

Nurses are in a key position to provide an atmosphere of acceptance and understanding for people with AIDS and their families and partners. The patient’s usual level of social interaction is assessed as early as possible to provide a baseline for monitoring changes in behaviors that suggest social isolation (eg, decreased interaction with staff or family, hostility, nonadherence). Patients are encouraged to express feelings of isolation and loneliness, with the assurance that these feelings are not unique or abnormal.

Providing information about how to protect themselves and others may help patients avoid social isolation. Patients, family, and friends must be reassured that AIDS is not spread through casual contact. Education of ancillary personnel, nurses, and physicians helps reduce factors that might contribute to patients’ feelings of isolation. Patient

care conferences that address the psychosocial issues associated with AIDS may help sensitize the health care team to patients’ needs.

Coping With Grief

The nurse can help the patient verbalize feelings and explore and identify resources for support and mechanisms for coping, especially when the patient is grieving anticipated losses. The patient is encouraged to maintain contact with family, friends, and coworkers and to use local or national AIDS support groups and hotlines. If possible, losses are identified and addressed. The patient is encouraged to continue usual activities whenever possible. Consultations with mental health counselors are useful for many patients.

Monitoring and Managing Potential Complications

OPPORTUNISTIC INFECTIONS. Patients who are immunosuppressed are at risk for opportunistic infections. Therefore, anti-infective agents may be prescribed and laboratory tests obtained to monitor their effect. Signs and symptoms of opportunistic infections, including fever, malaise, difficulty breathing, nausea or vomiting, diarrhea, difficulty swallowing, and any occurrences of swelling or discharge, should be reported as treated as indicated.

RESPIRATORY FAILURE. Impaired breathing is a major complication that increases the patient’s discomfort and anxiety and may lead to respiratory and cardiac failure. The respiratory rate and pattern are monitored, and the lungs are auscultated for abnormal breath sounds. The patient is instructed to report shortness of breath and increasing difficulty in carrying out usual activities. Pulse rate and rhythm, blood pressure, and oxygen saturation are monitored. Suctioning and oxygen therapy may be prescribed to ensure an adequate airway and to prevent hypoxia. Mechanical ventilation may be necessary for the patient who cannot maintain adequate ventilation as a result of pulmonary infection, fluid and electrolyte imbalance, or respiratory muscle weakness. Arterial blood gas values are used to guide ventilator settings. If the patient is intubated, methods must be established to allow communication with the nurse and others. Attention must be given to assisting the patient receiving mechanical ventilation to cope with the stress associated with intubation and ventilator assistance. The possible need for mechanical ventilation in the future should be discussed early in the course of the disease, when the patient is able to make known his or her preferences about treatment. The use of mechanical ventilation should be consistent with the patient’s decisions about end-of-life treatment. (Further discussion of end-of-life care can be found in Chapter 17.)

CACHEXIA AND WASTING. Wasting syndrome and fluid and electrolyte disturbances, including dehydration, are common complications of HIV infection and AIDS. The patient’s nutritional and electrolyte status is evaluated by monitoring weight gains or losses, skin turgor, ferritin levels, hemoglobin and hematocrit values, and electrolyte levels. Fluid and electrolyte status is monitored on an ongoing basis; fluid intake and output and urine specific gravity may be monitored daily if the patient is hospitalized with complications. The skin is assessed for dryness and adequate

turgor. Vital signs are monitored for decreased systolic blood pressure or increased pulse rate on sitting or standing. Signs and symptoms of electrolyte disturbances, such as muscle cramping, weakness, irregular pulse, decreased mental status, nausea, and vomiting, are documented and reported to the physician. Serum electrolyte values are monitored, and abnormalities are reported.

The nurse helps the patient select foods that will replenish electrolytes, such as oranges and bananas (potassium) and cheese and soups (sodium) (Dudek, 2006). A fluid intake of 3 L or more per day, unless contraindicated, is encouraged to replace fluid lost with diarrhea, and measures to control diarrhea are initiated. If fluid and electrolyte imbalances persist, the nurse administers IV fluids and electrolytes as prescribed. Effects of parenteral therapy are monitored.

SIDE EFFECTS OF MEDICATIONS. Adverse reactions are of concern in patients who receive many medications to treat HIV infection or its complications. Many medications can cause severe toxic effects. Information about the purpose of the medications, their correct administration, side effects, and strategies to manage or prevent side effects is provided. Patients and their caregivers need to know which signs and symptoms of side effects should be reported immediately to their primary health care provider (see Table 52-3).

In addition to medications used to treat HIV infection, other medications that may be required include opioids, tricyclic antidepressants, and NSAIDs for pain relief; medications for treatment of opportunistic infections; antihistamines (diphenhydramine [Benadryl]) for relief of pruritus; acetaminophen (Tylenol) or aspirin for management of fever; and antiemetic agents for control of nausea and vomiting. Concurrent use of these medications can cause many drug interactions, resulting in hepatic and hematologic abnormalities. Therefore, careful monitoring of laboratory test results is essential.

During each contact with the patient, it is important for the nurse to ask not only about side effects but also about how well the patient is managing the medication regimen. The nurse may be able to assist the patient in organizing and planning the medication schedule to promote adherence to the treatment regimen.

Promoting Home and Community-Based Care

TEACHING PATIENTS SELF-CARE. Patients, families, and friends are instructed about the routes of transmission of HIV. As discussed earlier, the nurse discusses precautions the patient can use to avoid transmitting HIV sexually (see Charts 52-2 and 52-3) or through sharing of body fluids. Patients and their families or caregivers must receive instructions about how to prevent disease transmission, including handwashing techniques and methods for safely handling and disposing of items soiled with body fluids. Clear guidelines about avoiding and controlling infection, regular health care appointments, symptom management, nutrition, rest, and exercise are necessary. The importance of personal and environmental hygiene is emphasized. Caregivers are taught many of the guidelines (standard precautions) described in Chart 52-4. Kitchen and bathroom surfaces should be cleaned regularly with disinfectants to prevent growth of fungi and bacteria. Patients with pets are

encouraged to have another person clean areas soiled by animals, such as bird cages and litter boxes. If this is not possible, patients should use gloves and should wash their hands after they clean the area. Patients are advised to avoid exposure to others who are sick or who have been recently vaccinated. The importance of avoiding smoking, excessive alcohol, and over-the-counter and street drugs is emphasized. Patients who are HIV positive or who inject drugs are instructed not to donate blood. IV/injection drug users who are unwilling to stop using drugs are advised to avoid sharing drug equipment with others.

Caregivers in the home are taught how to administer medications, including IV preparations. The medication regimens used for patients with HIV infection and AIDS are often complex and expensive. Patients receiving combination therapies for treatment of HIV infection and its complications require careful teaching about the importance of taking medications as prescribed and explanations and assistance in fitting the medication regimen into their lives (see Chart 52-7). If the patient requires enteral or parenteral nutrition, instruction is provided to the patient and family about how to administer nutritional therapies at home. Home care nurses provide ongoing teaching and support for the patient and family.

CONTINUING CARE. Many people with AIDS remain in their community and continue their usual daily activities, whereas others can no longer work or maintain their independence. Families or caregivers may need assistance in providing supportive care. There are many community-based organizations that provide a variety of services for people living with HIV infection and AIDS; nurses can help identify these services.

Community health nurses, home care nurses, and hospice nurses are in an excellent position to provide the support and guidance so often needed in the home setting. As hospital costs continue to rise and insurance coverage continues to decline, the complexity of home care increases. Home care nurses are key to the safe and effective administration of parenteral antibiotics, chemotherapy, and nutrition in the home.

During home visits, the nurse assesses the patient's physical and emotional status and home environment. The patient's adherence to the therapeutic regimen is assessed, and strategies are suggested to assist with adherence. The patient is assessed for progression of disease and for adverse side effects of medications. Previous teaching is reinforced, and the importance of keeping follow-up appointments is stressed.

Complex wound care or respiratory care may be required in the home. Patients and families are often unable to meet these skilled care needs without assistance. Nurses may refer patients to community programs that offer a range of services for patients, friends, and families, including help with housekeeping, hygiene, and meals; transportation and shopping; individual and group therapy; support for caregivers; telephone networks for the homebound; and legal and financial assistance. These services are typically provided by both professionals and nonprofessional volunteers. A social worker may be consulted to identify sources of financial support, if needed.

Home care and hospice nurses are increasingly called on to provide physical and emotional support to patients and families as patients with AIDS enter the terminal stages of disease. This support takes on special meaning when people with AIDS lose friends and when family members fear the disease or feel anger concerning the patient's lifestyle. The nurse encourages the patient and family to discuss end-of-life decisions and to ensure that care is consistent with those decisions, all comfort measures are employed, and the patient is treated with dignity at all times.

Evaluation

Expected Patient Outcomes

Expected patient outcomes may include:

1. Maintains skin integrity
2. Resumes usual bowel habits
3. Experiences no infections
4. Maintains adequate level of activity tolerance
5. Maintains usual level of thought processes
6. Maintains effective airway clearance
7. Experiences increased sense of comfort and less pain
8. Maintains adequate nutritional status
9. Experiences decreased sense of social isolation
10. Progresses through grieving process
11. Reports increased understanding of AIDS and participates in self-care activities as possible
12. Remains free of complications

Detailed outcomes are included in the plan of nursing care for a patient with AIDS (see Chart 52-10).

EMOTIONAL AND ETHICAL CONCERNS

Nurses in all settings are called on to provide care for patients with HIV infection. In doing so, they encounter not only the physical challenges of this epidemic but also emotional and ethical concerns. The concerns raised by health care professionals involve issues such as fear of infection, responsibility for giving care, values clarification, confidentiality, developmental stages of patients and caregivers, and poor prognostic outcomes.

Many patients with HIV infection have engaged in "stigmatized" behaviors. Because these behaviors challenge some traditional religious and moral values, nurses may feel reluctant to care for these patients. In addition, health care providers may still have fear and anxiety about disease transmission despite education concerning infection control and the low incidence of transmission to health care providers (see Chart 52-5). Nurses are encouraged to examine their personal beliefs and to use the process of values clarification to approach controversial issues. The American Nurses Association's Code of Ethics for Nurses (2008) can also be used to help resolve ethical dilemmas that might affect the quality of care given to patients with HIV infection and AIDS.

Nurses are responsible for protecting the patient's right to privacy by safeguarding confidential information. Inad-

vertent disclosure of confidential patient information may result in personal, financial, and emotional hardships for the patient. The controversy surrounding confidentiality concerns the circumstances in which information may be disclosed to others. Health care team members need accurate patient information to conduct assessment, planning, implementation, and evaluation of patient care. Failure to disclose HIV status could compromise the quality of patient care. Sexual partners of HIV-infected patients should know about the potential for infection and the need to engage in safer sex practices, as well as the possible need for testing and health care. Nurses are advised to discuss concerns about confidentiality with nurse administrators and to consult professional nursing organizations such as the Association of Nurses in AIDS Care and legal experts in their state to identify the most appropriate course of action. Chart 52-11 explores issues related to revealing one's HIV status.

AIDS has had a high mortality rate, but advances in antiretroviral and multidrug therapy have demonstrated promise in slowing or controlling disease progression. It is not known whether current treatment regimens will remain effective, because viral drug resistance has developed with

CHART
52-11

Ethics and Related Issues: Revealing One's HIV Status

Should All People Who Are Infected With HIV Be Required to Reveal This Status to All Their Sexual and Drug-Sharing Contacts?

Situation

The human immunodeficiency virus (HIV) causes HIV infection, which progresses to AIDS. Because sexual contacts and needle-sharing partners are at risk for developing the disease, would a policy that requires notification of contacts infringe on the liberty and privacy of the known HIV-infected person?

Dilemma

The person's right to privacy conflicts with notifying all people who are contacts either through sexual or needle-sharing behavior (autonomy versus justice). The person's right to privacy conflicts with society's need to contain the deadly virus and stem a deadly epidemic (autonomy versus justice).

Discussion

1. What arguments would you offer in favor of notifying all the person's contacts?
2. What arguments would you offer against notifying all or some of the person's contacts?
3. Each state has various laws that pertain to whether contacts can be notified and who is responsible for notifying contacts. Is there a law for contact notification in the state in which you live? If there is such a law in your state, who is responsible for contact notification?
4. What would you do if the person responsible for contact notification refuses to do so based on his or her own beliefs for confidentiality of HIV infection status?
5. How would you respond if the HIV-positive person said that he or she is afraid to notify his or her contact because of fear of a violent response?

most previous medications. Most nurses in the United States have never faced an epidemic in which so many young and middle-aged adults experience serious illness and may die during the usual course of the disease process. Nurses may struggle with the value and meaning of their professional roles as they witness repeated instances of deterioration. Exposure to so many deaths among patients at the same developmental stage as many nurses can create stress. Contributing to this stress are personal fears of contagion or disapproval of the patient's lifestyle and behaviors. Unlike cancer or other diseases, AIDS is associated with controversies challenging our legal and political systems as well as religious and personal beliefs. Nurses who feel stressed and overburdened may experience physical and mental distress in the form of fatigue, headache, changes in appetite and sleep patterns, helplessness, irritability, apathy, negativity, and anger.

Many strategies have been used by nurses to cope with the stress associated with caring for AIDS patients. Education and provision of up-to-date information help to alleviate apprehension and prepare nurses to deliver safe, high-quality patient care. Interdisciplinary meetings allow participants to support one another and provide comprehensive patient care. Staff support groups give nurses an opportunity to solve problems and explore values and feelings about caring for AIDS patients and their families; they also provide a forum for grieving. Other sources of support include nursing administrators, peers, and spiritual advisors.

CRITICAL THINKING EXERCISES

EBP 1 A 43-year-old woman who has been using IV/injection drugs regularly for 20 years says that she is not going to stop using drugs but wants to reduce her risk of HIV infection. How would you counsel her? What is the evidence base on safer sex and strategies to reduce risk from use of IV/injection drugs? Is there evidence about the effectiveness of needle exchange programs? How would you determine the strength of the evidence and how would you present information to her?

2 During a code response in the intensive care unit (ICU), a nursing student is inadvertently stuck with a needle used on a patient with AIDS who has a high viral load. The student is apprehensive. What should the clinical instructor, in consultation with the nurse manager of the ICU, do? What reporting and documentation are needed (be sure to consider the student's health record)? What testing, treatment, and counseling are indicated for the student? Who should pay for the treatment?

EBP 3 During a home visit to a family in which two adolescents are HIV positive through vertical transmission, you are instructing the adolescents, their siblings, and their adult caregivers about strategies to protect the teens from other infections and to protect other family members from HIV transmission. What is the evidence for strategies that you plan to discuss with the adolescents

and their family members? What is the strength of that evidence, and what criteria would you use to evaluate the strength of the evidence?

4 A 48-year-old man who is bleeding from several stab wounds presents to the emergency department. He is intoxicated and combative. An OraQuick Rapid HIV-1 Antibody Test is performed as part of routine health care. What are the implications of this test? How would care in the emergency department be modified because of a positive test result? What are the ethical and legal ramifications of obtaining this test if the patient's ability to consent to testing is questioned?

5 You are making a home visit to a patient with AIDS who is exhibiting early signs of dementia and encephalopathy. Describe the aspects of the home environment that you would assess to ensure safety and adequate care. How would you modify your assessment if the patient lived alone in a third-floor apartment without an elevator? If the patient lived in a rural setting? If the patient had a physical disability that limited his ability to leave his apartment?

Assessment and Management of Patients With Allergic Disorders

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

- 1 Explain the physiologic events involved with allergic reactions.
- 2 Describe the types of hypersensitivity.
- 3 Describe the management of patients with allergic disorders.
- 4 Describe measures to prevent and manage anaphylaxis.
- 5 Use the nursing process as a framework for care of the patient with allergic rhinitis.
- 6 Discuss the different allergic disorders according to type.

GLOSSARY

- allergen:** substance that causes manifestations of allergy
- allergy:** inappropriate and often harmful immune system response to substances that are normally harmless
- anaphylaxis:** clinical response to an immediate immunologic reaction between a specific antigen and antibody
- angioneurotic edema:** condition characterized by urticaria and diffuse swelling of the deeper layers of the skin
- antibody:** protein substance developed by the body in response to and interacting with a specific antigen
- antigen:** substance that induces the production of antibodies
- antihistamine:** medication that opposes the action of histamine
- atopic dermatitis:** type I hypersensitivity involving inflammation of the skin evidenced by itching, redness, and a variety of skin lesions
- atopy:** term often used to describe immunoglobulin E-mediated diseases (ie, atopic dermatitis, asthma, and allergic rhinitis) with a genetic component
- B lymphocytes:** cells that are important in producing circulating antibodies
- bradykinin:** a substance that stimulates nerve fibers and causes pain
- eosinophil:** granular leukocyte
- erythema:** diffuse redness of the skin
- hapten:** incomplete antigen
- histamine:** substance in the body that causes increased gastric secretion, dilation of capillaries, and constriction of the bronchial smooth muscle
- hypersensitivity:** abnormal heightened reaction to a stimulus of any kind
- immunoglobulins:** a family of closely related proteins capable of acting as antibodies
- leukotrienes:** a group of chemical mediators that initiate the inflammatory response
- mast cells:** connective tissue cells that contain heparin and histamine in their granules
- prostaglandins:** unsaturated fatty acids that have a wide assortment of biologic activity
- rhinitis:** inflammation of the nasal mucosa
- serotonin:** chemical mediator that acts as a potent vasoconstrictor and bronchoconstrictor
- T lymphocytes:** cells that can cause graft rejection, kill foreign cells, or suppress production of antibodies
- urticaria:** hives

The human body is menaced by a host of potential invaders—allergens as well as microbial organisms—that constantly threaten its defenses. After penetrating those defenses, these allergens and organisms, if allowed to continue unimpeded, disrupt the body's enzyme systems and destroy its vital tissues. To protect against these agents, the body is equipped with an elaborate defense system.

The epithelial cells that coat the skin and make up the lining of the respiratory, gastrointestinal, and genitourinary tracts provide the first line of defense against microbial invaders. The structure and continuity of these surfaces and their resistance to penetration are initial deterrents to invaders.

One of the most effective defense mechanisms is the body's capacity to equip itself rapidly with weapons (antibodies) individually designed to meet each new invader, namely, specific protein antigens. Antibodies react with antigens in a variety of ways: (1) by coating the antigens' surfaces if they are particular substances, (2) by neutralizing the antigens if they are toxins, and (3) by precipitating the antigens out of solution if they are dissolved. The antibodies prepare the antigens so that the phagocytic cells of the blood and the tissues can dispose of them. However, although this system is normally protective, in some cases the body produces inappropriate or exaggerated responses to specific antigens, and the result is an allergic or hypersensitivity disorder.

ALLERGIC ASSESSMENT

Physiologic Overview

An allergic reaction is a manifestation of tissue injury resulting from interaction between an antigen and an **antibody**. **Allergy** is an inappropriate and often harmful response of the immune system to normally harmless substances, called **allergens** (eg, dust, weeds, pollen, dander). Chemical mediators released in allergic reactions may produce symptoms that range from mild to life-threatening.

In allergic reactions, the body encounters **antigens**, usually proteins that the body's defenses recognize as foreign, and a series of events occurs in an attempt to render the invaders harmless, destroy them, and remove them from the body. When lymphocytes respond to the antigens, **antibodies** (protein substances that protect against antigens) are produced.

Antibodies combine with antigens in a special way, which has been likened to keys fitting into a lock. Antigens (the keys) fit only certain antibodies (the locks). Hence, the term *specificity* refers to the specific reaction of an antibody to an antigen. There are many variations and complexities in these patterns.

Function of Immunoglobulins

Antibodies that are formed by lymphocytes and plasma cells in response to an immunogenic stimulus constitute a group of serum proteins called **immunoglobulins**. Grouped into five classes (IgE, IgD, IgG, IgM, and IgA), immunoglobulins can be found in the lymph nodes, tonsils, appendix, and Peyer's patches of the intestinal tract or circulating in the

blood and lymph. These antibodies are capable of binding with a wide variety of antigens. Immunoglobulins of the IgE class are involved in allergic disorders and some parasitic infections. IgE-producing cells are located in the respiratory and intestinal mucosa. Two or more IgE molecules bind together to an allergen and trigger **mast cells** or basophils to release chemical mediators, such as histamine, serotonin, kinins, slow-reacting substances of anaphylaxis, and the neutrophil factor, which produces allergic skin reactions, asthma, and hay fever. **Atopy** refers to IgE-mediated diseases such as allergic rhinitis that have a genetic component.

Role of B Cells

B cells, or **B lymphocytes**, are programmed to produce one specific antibody. On encountering a specific antigen, B cells stimulate production of plasma cells, the site of antibody production. The result is the outpouring of antibodies for the purpose of destroying and removing the antigens.

Role of T Cells

T cells, or **T lymphocytes**, assist the B cells in producing antibodies. T cells secrete substances that direct the flow of cell activity, destroy target cells, and stimulate the macrophages. The macrophages present the antigens to the T cells and initiate the immune response. They also digest antigens and assist in removing cells and other debris. Unlike a specific antibody, a T cell does not bind free antigens.

Function of Antigens

Antigens are divided into two groups: complete protein antigens and low-molecular-weight substances. Complete protein antigens, such as animal dander, pollen, and horse serum, stimulate a complete humoral response. (See Chapter 50 for a discussion of humoral immunity.) Low-molecular-weight substances, such as medications, function as **haptens** (incomplete antigens), binding to tissue or serum proteins to produce a carrier complex that initiates an antibody response. In an allergic reaction, the production of antibodies requires active communication between cells. When the allergen is absorbed through the respiratory tract, gastrointestinal tract, or skin, allergen sensitization occurs. Macrophages process the antigen and present it to the appropriate cells. These cells mature into allergen-specific secreting plasma cells that synthesize and secrete antigen-specific antibodies.

Function of Chemical Mediators

Mast cells, which are located in the skin and mucous membranes, play a major role in IgE-mediated immediate hypersensitivity. When mast cells are stimulated by antigens, powerful chemical mediators are released, causing a sequence of physiologic events that results in symptoms of immediate hypersensitivity (Fig. 53-1). There are two types of chemical mediators: primary and secondary. Primary mediators are preformed and are found in mast cells or basophils. Secondary mediators are inactive precursors that are formed or released in response to primary mediators. Table 53-1 summarizes the actions of primary and secondary chemical mediators.

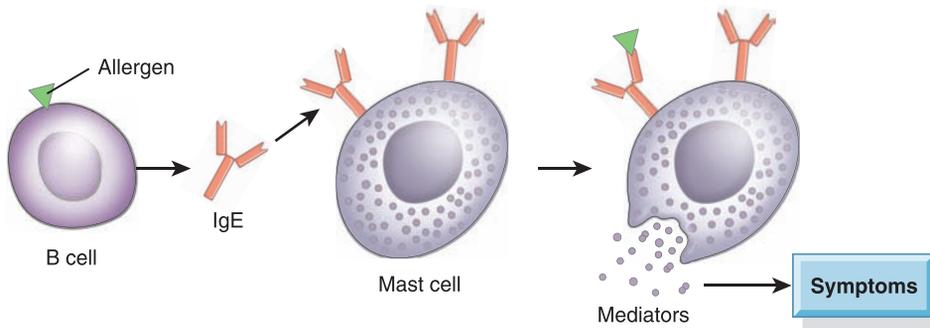

Figure 53-1 Allergen triggers the B cell to make IgE antibody, which attaches to the mast cell. When that allergen reappears, it binds to the IgE and triggers the mast cell to release its chemicals. Courtesy of U.S. Department of Health and Human Services, National Institutes of Health.

Primary Mediators

Histamine

Histamine, which is released by mast cells, plays an important role in the immune response. Its effects, which are greatest within about 15 minutes after antigen contact, include erythema; localized edema in the form of wheals; pruritus; contraction of bronchial smooth muscle, resulting in wheezing and bronchospasm; dilation of small venules and constriction of larger vessels; and increased secretion of gastric and mucosal cells, resulting in diarrhea. Histamine action results from stimulation of histamine-1 (H_1) and histamine-2 (H_2) receptors. H_1 receptors are found predominantly on bronchiolar and vascular smooth muscle cells; H_2 receptors are found on gastric parietal cells.

Certain medications are categorized by their action at these receptors. Diphenhydramine (Benadryl) is an example of an **antihistamine**, a medication that displays an affinity for H_1 receptors. Cimetidine (Tagamet) and ranitidine (Zantac) target H_2 receptors to inhibit gastric secretions in peptic ulcer disease.

Eosinophil Chemotactic Factor of Anaphylaxis

Eosinophil chemotactic factor of anaphylaxis affects movement of **eosinophils** (granular leukocytes) to the site of

allergens. It is preformed in the mast cells and is released from disrupted mast cells.

Platelet-Activating Factor

Platelet-activating factor is responsible for initiating platelet aggregation and leukocyte infiltration at sites of immediate hypersensitivity reactions. It also causes bronchoconstriction and increased vascular permeability (Porth & Matfin, 2009).

Prostaglandins

Prostaglandins produce smooth muscle contraction as well as vasodilation and increased capillary permeability (Porth, 2009). The fever and pain that occur with inflammation in allergic responses are caused in part by the prostaglandins.

Secondary Mediators

Leukotrienes

Leukotrienes are chemical mediators that initiate the inflammatory response. Many manifestations of inflammation can be attributed in part to leukotrienes. In addition, leukotrienes cause smooth muscle contraction, bronchial constriction, mucus secretion in the airways, and the typical wheal-and-flare reactions of the skin. Compared with

Table 53-1 CHEMICAL MEDIATORS OF HYPERSENSITIVITY

Mediators	Action
Primary Mediators	
<i>Preformed and Found in Mast Cells or Basophils</i>	
Histamine (preformed in mast cells)	Vasodilation Smooth muscle contraction, increased vascular permeability, increased mucus secretions Attracts eosinophils
Eosinophil chemotactic factor of anaphylaxis (ECF-A) (preformed in mast cells)	Attracts eosinophils
Platelet-activating factor (PAF) (requires synthesis by mast cells, neutrophils, and macrophages)	Smooth muscle contraction Incites platelets to aggregate and release serotonin and histamine
Prostaglandins (chemically derived from arachidonic acid; require synthesis by cells)	D and F series → bronchoconstriction E series → bronchodilation D, E, and F series → vasodilation
Basophil kallikrein (preformed in mast cells)	Frees bradykinin, which causes bronchoconstriction, vasodilation, and nerve stimulation
Secondary Mediators	
<i>Inactive Precursors Formed or Released in Response to Primary Mediators</i>	
Bradykinin (derived from precursor kininogen)	Smooth muscle contraction, increased vascular permeability, stimulates pain receptors, increased mucus production
Serotonin (preformed in platelets)	Smooth muscle contraction, increased vascular permeability
Heparin (preformed in mast cells)	Anticoagulant
Leukotrienes (derived from arachidonic acid and activated by mast cell degranulation) C, D, and E or slow-reacting substance of anaphylaxis (SRS-A)	Smooth muscle contraction, increased vascular permeability

histamine, leukotrienes are 100 to 1000 times more potent in causing bronchospasm.

Bradykinin

Bradykinin is a substance that has the ability to cause increased vascular permeability, vasodilation, hypotension, and contraction of many types of smooth muscle, such as the bronchi. Increased permeability of the capillaries results in edema. Bradykinin stimulates nerve cell fibers and produces pain.

Serotonin

Serotonin acts as a potent vasoconstrictor and causes contraction of bronchial smooth muscle.

Hypersensitivity

Although the immune system defends the host against infections and foreign antigens, immune responses can themselves cause tissue injury and disease. **Hypersensitivity** is a reflection of excessive or aberrant immune response to any type of stimulus (Abbas & Lichtman, 2008). It usually does not occur with the first exposure to an allergen. Rather, the reaction follows a re-exposure after sensitization, or buildup of antibodies, in a predisposed person. To promote understanding of the immunopathogenesis of disease, hypersensitivity reactions have been classified into four specific types of reactions (Fig. 53-2). Most allergic reactions are either type I or type IV hypersensitivity reactions.

Anaphylactic (Type I) Hypersensitivity

The most severe hypersensitivity reaction is **anaphylaxis**. An unanticipated severe allergic reaction that is often explosive in onset, anaphylaxis is characterized by edema in many tissues, including the larynx, and is often accompanied by hypotension, bronchospasm, and cardiovascular collapse in severe cases. Type I or anaphylactic hypersensitivity is an immediate reaction beginning within minutes of exposure to an antigen. Primary chemical mediators are responsible for the symptoms of type I hypersensitivity because of their effects on the skin, lungs, and gastrointestinal tract. If chemical mediators continue to be released, a delayed reaction may occur and may last for up to 24 hours.

Clinical symptoms are determined by the amount of the allergen, the amount of mediator released, the sensitivity of the target organ, and the route of allergen entry. Type I hypersensitivity reactions may include both local and systemic anaphylaxis. Examples include allergic rhinitis, asthma, and severe allergic response in people sensitized to penicillin or latex.

Cytotoxic (Type II) Hypersensitivity

Type II, or cytotoxic, hypersensitivity occurs when the system mistakenly identifies a normal constituent of the body as foreign. This reaction may be the result of a cross-reacting antibody, possibly leading to cell and tissue damage.

Type II hypersensitivity reactions are associated with several disorders. For example, in myasthenia gravis, the body mistakenly generates antibodies against normal nerve ending receptors. In Goodpasture syndrome, it generates antibodies against lung and renal tissue, producing lung damage and renal failure. A type II hypersensitivity reaction

resulting in red blood cell destruction is associated with drug-induced immune hemolytic anemia, Rh-hemolytic disease of the newborn, and incompatibility reactions in blood transfusions (see Chapter 33).

Immune Complex (Type III) Hypersensitivity

Type III, or immune complex, hypersensitivity involves immune complexes that are formed when antigens bind to antibodies. These complexes are cleared from the circulation by phagocytic action. If these type III complexes are deposited in tissues or vascular endothelium, two factors contribute to injury: the increased amount of circulating complexes and the presence of vasoactive amines. As a result, there is an increase in vascular permeability and tissue injury.

The joints and kidneys are particularly susceptible to this type of injury. Type III hypersensitivity is associated with systemic lupus erythematosus, rheumatoid arthritis, certain types of nephritis, and some types of bacterial endocarditis. These are discussed elsewhere in this text.

Delayed-Type (Type IV) Hypersensitivity

Type IV, or delayed-type, hypersensitivity, also known as cellular hypersensitivity, occurs 24 to 72 hours after exposure to an allergen. It is mediated by sensitized T cells and macrophages rather than antibodies.

An example of a type IV hypersensitivity reaction is contact dermatitis resulting from exposure to allergens such as cosmetics, adhesive tape, topical agents (eg, povidone-iodine), medication additives, and plant toxins. Symptoms include itching, erythema, and raised lesions.

Assessment

Health History

A comprehensive allergy history and a thorough physical examination provide useful data for the diagnosis and management of allergic disorders. An assessment form is useful for obtaining and organizing this information (Chart 53-1).

The degree of difficulty and discomfort experienced by the patient because of allergic symptoms and the degree of improvement in those symptoms with and without treatment are assessed and documented. The relationship of symptoms to exposure to possible allergens is noted.

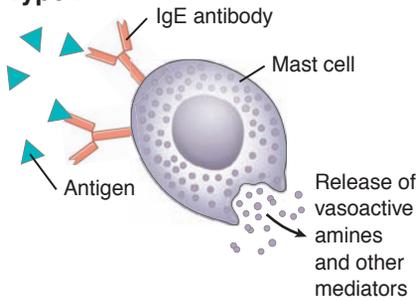

Diagnostic Evaluation

Diagnostic evaluation of the patient with allergic disorders commonly includes blood tests, smears of body secretions, skin tests, and the radioallergosorbent test (RAST). Results of laboratory blood studies provide supportive data for various diagnostic possibilities; however, they are not the major criteria for the diagnosis of allergic disease.

Complete Blood Count With Differential

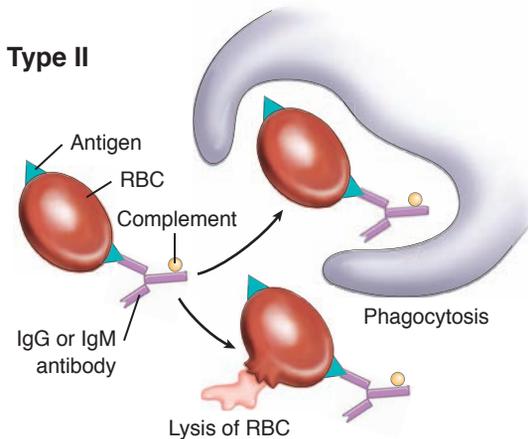

The white blood cell (WBC) count is usually normal except with infection. Eosinophils, which are granular leukocytes, normally make up 1% to 3% of the total number of

Type I

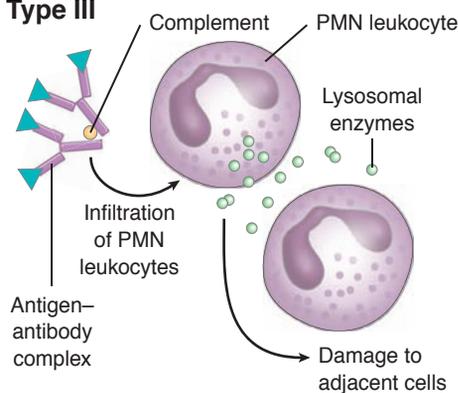

Type I. An anaphylactic reaction is characterized by vasodilation, increased capillary permeability, smooth muscle contraction, and eosinophilia. Systemic reactions may involve laryngeal stridor, angioedema, hypotension, and bronchial, GI, or uterine spasm; local reactions are characterized by hives. Examples of type I reactions include extrinsic asthma, allergic rhinitis, systemic anaphylaxis, and reactions to insect stings.

Type II

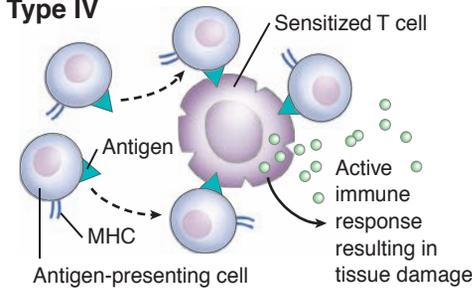

Type II. A cytotoxic reaction, which involves binding either the IgG or IgM antibody to a cell-bound antigen, may lead to eventual cell and tissue damage. The reaction is the result of mistaken identity when the system identifies a normal constituent of the body as foreign and activates the complement cascade. Examples of type II reactions are myasthenia gravis, Goodpasture's syndrome, pernicious anemia, hemolytic disease of the newborn, transfusion reaction, and thrombocytopenia.

Type III

Type III. An immune complex reaction is marked by acute inflammation resulting from formation and deposition of immune complexes. The joints and kidneys are particularly susceptible to this kind of reaction, which is associated with systemic lupus erythematosus, serum sickness, nephritis, and rheumatoid arthritis. Some signs and symptoms include urticaria, joint pain, fever, rash, and adenopathy (swollen glands).

Type IV

Type IV. A delayed, or cellular, reaction occurs 1 to 3 days after exposure to an antigen. The reaction, which results in tissue damage, involves activity by lymphokines, macrophages, and lysozymes. Erythema and itching are common; a few examples include contact dermatitis, graft-versus-host disease, Hashimoto's thyroiditis, and sarcoidosis.

Figure 53-2 Four types of hypersensitivity reactions. (Ig, immunoglobulin; PMN, polymorphonuclear; RBC, red blood cell.)

WBCs. A level between 5% and 15% is nonspecific but does suggest allergic reaction. Higher percentages of eosinophils are considered to represent moderate to severe eosinophilia. Moderate eosinophilia is defined as 15% to 40% eosinophils and may be found in patients with allergic disorders.

Eosinophil Count

An actual count of eosinophils can be obtained from blood samples or smears of secretions. During symptomatic episodes, smears obtained from nasal secretions, conjunctival secretions, and sputum of allergic patients usually reveal eosinophils, indicating an active allergic response.

CHART
53-1

Allergy Assessment Form

Name _____ Age _____ Sex _____ Date _____

I. Chief complaint: _____

II. Present illness: _____

III. Collateral allergic symptoms: _____

Eyes: Pruritus _____ Burning _____ Lacrimation _____

Swelling _____ Injection _____ Discharge _____

Ears: Pruritus _____ Fullness _____ Popping _____

Frequent infections _____

Nose: Sneezing _____ Rhinorrhea _____ Obstruction _____

Pruritus _____ Mouth-breathing _____

Purulent discharge _____

Throat: Soreness _____ Postnasal discharge _____

Palatal pruritus _____ Mucus in the morning _____

Chest: Cough _____ Pain _____ Wheezing _____

Sputum _____ Dyspnea _____

Color _____ Rest _____

Amount _____ Exertion _____

Skin: Dermatitis _____ Eczema _____ Urticaria _____

IV. Family allergies _____

V. Previous allergic treatment or testing: _____

Prior skin testing: _____

Anywhere in home symptoms are worse: _____

IX. What does patient think makes symptoms worse? _____

X. Under what circumstances is patient free of symptoms? _____

XI. Summary and additional comments: _____

Total Serum Immunoglobulin E Levels

High total serum IgE levels support the diagnosis of allergic disease. However, a normal IgE level does not exclude the diagnosis of an allergic disorder. IgE levels are not as sensitive as the paper radioimmunosorbent test (PRIST) or the enzyme-linked immunosorbent assay (ELISA), also referred to as enzyme immunoassay (EIA).

Skin Tests

Skin testing entails the intradermal injection or superficial application (epicutaneous) of solutions at several sites. Depending on the suspected cause of allergic signs and symptoms, several different solutions may be applied at separate sites. These solutions contain individual antigens representing an assortment of allergens most likely to be implicated in the patient's disease. Positive (wheal-and-flare) reactions are clinically significant when correlated with the history, physical findings, and results of other laboratory tests.

The results of skin tests complement the data obtained from the history. They indicate which of several antigens are most likely to provoke symptoms and provide some clue to the intensity of the patient's sensitization. The dosage of the antigen (allergen) injected is also important. Most patients are hypersensitive to more than one allergen. Under testing conditions, they may not react (although they usually do) to the specific allergens that induce their attacks.

In cases of doubt about the validity of the skin tests, a RAST or a provocative challenge test may be performed. If a skin test is indicated, there is a reasonable suspicion that a specific allergen is producing symptoms in an allergic patient. However, several precautionary steps must be observed before skin testing with allergens is performed:

- Testing is not performed during periods of bronchospasm.

- Epicutaneous tests (scratch or prick tests) are performed before other testing methods, in an effort to minimize the risk of systemic reaction.
- Emergency equipment must be readily available to treat anaphylaxis.

Types of Skin Tests

The methods of skin testing include prick skin tests, scratch tests, and intradermal skin testing (Fig. 53-3). After negative prick or scratch tests, intradermal skin testing is

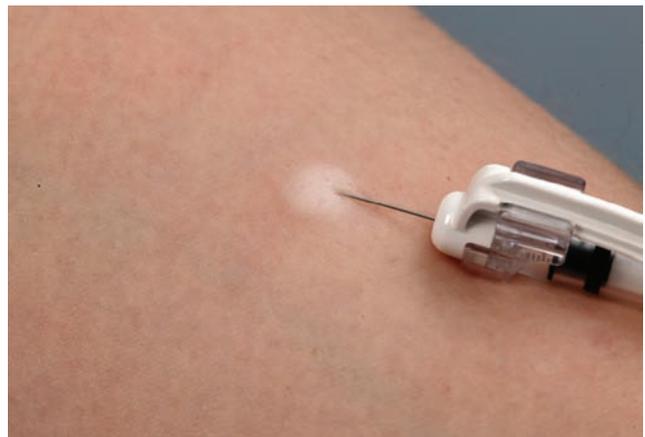

Figure 53-3 Intradermal testing. A 0.5-mL or 1-mL sterile syringe with a 26/27-gauge intradermal needle is used to inject 0.02 to 0.03 mL of intradermal allergen. The needle is inserted with the bevel facing upward and the syringe parallel to the skin. The skin is penetrated superficially, and a small amount of the allergen solution is injected to create a bleb (raised area) approximately 5 mm in diameter. A separate sterile syringe and needle are used for each injection. From Taylor, C., Lillis C. & LeMone, P. (2005). *Fundamentals of nursing: The art and science of nursing care* (5th ed.). Philadelphia: Lippincott Williams & Wilkins.

performed with allergens that are suggested by the patient's history to be problematic. The back is the most suitable area of the body for skin testing because it permits the performance of many tests. A multitest applicator with multiple test heads is commercially available for simultaneous administration of antigens by multiple punctures at different sites. A negative response on a skin test cannot be interpreted as an absence of sensitivity to an allergen. Such a response may occur with insufficient sensitivity of the test or with use of an inappropriate allergen in testing. Therefore, it is essential to observe the patient undergoing skin testing for an allergic reaction even if the previous response was negative.

Interpretation of Skin Test Results

Familiarity with and consistent use of a grading system are essential. The grading system used should be identified on a skin test record for later interpretation. A positive reaction, evidenced by the appearance of an urticarial wheal (round, reddened skin elevation) (Fig. 53-4), localized erythema (diffuse redness) in the area of inoculation or contact, or pseudopodia (irregular projection at the end of a wheal) with associated erythema is considered indicative of sensitivity to the corresponding antigen. False-positive results may occur because of improper preparation or administration of allergen solutions.

NURSING ALERT

Corticosteroids and antihistamines, including over-the-counter allergy medications, suppress skin test reactivity and should be stopped 48 to 96 hours before testing, depending on the duration of their activity. False-positive results may occur because of improper preparation or administration of allergen solutions.

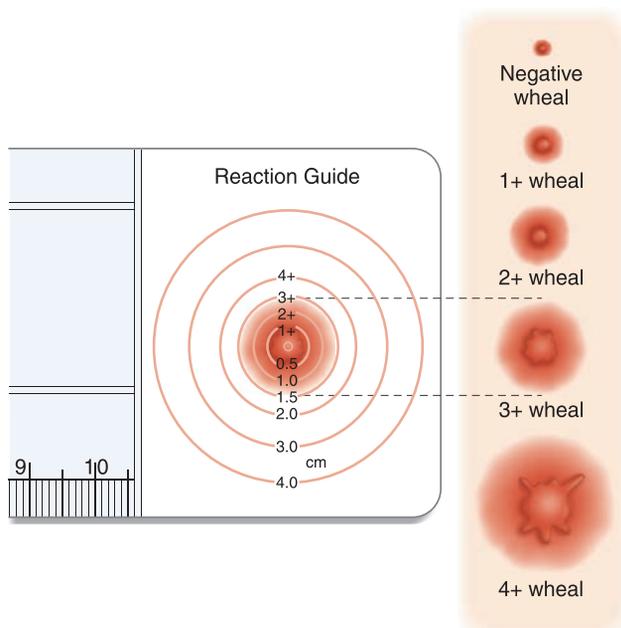

Figure 53-4 Interpretation of reactions: Negative = wheal soft with minimal erythema. 1+ = wheal present (5 to 8 mm) with associated erythema. 2+ = wheal (7 to 10 mm) with associated erythema. 3+ = wheal (9 to 15 mm), slight pseudopodia possible with associated erythema. 4+ = wheal (12 mm+) with pseudopodia and diffuse erythema.

Interpretation of positive or negative skin tests must be based on the history, physical examination, and other laboratory test results. The following guidelines are used for the interpretation of skin test results:

- Skin tests are more reliable for diagnosing atopic sensitivity in patients with allergic rhinoconjunctivitis than in patients with asthma.
- Positive skin tests correlate highly with food allergy.
- The use of skin tests to diagnose immediate hypersensitivity to medications is limited, because metabolites of medications, not the medications themselves, are usually responsible for causing hypersensitivity.

Provocative Testing

Provocative testing involves the direct administration of the suspected allergen to the sensitive tissue, such as the conjunctiva, nasal or bronchial mucosa, or gastrointestinal tract (by ingestion of the allergen), with observation of target organ response. This type of testing is helpful in identifying clinically significant allergens in patients who have a large number of positive tests. Major disadvantages of this type of testing are the limitation of one antigen per session and the risk of producing severe symptoms, particularly bronchospasm, in patients with asthma.

Radioallergosorbent Test

RAST is a radioimmunoassay that measures allergen-specific IgE. A sample of the patient's serum is exposed to a variety of suspected allergen particle complexes. If antibodies are present, they will combine with radiolabeled allergens. Test results are then compared with control values. In addition to detecting an allergen, RAST indicates the quantity of allergen necessary to evoke an allergic reaction. Values are reported on a scale from 0 to 5. Values of 2 or greater are considered significant. The major advantages of RAST over other tests include decreased risk of systemic reaction, stability of antigens, and lack of dependence on skin reactivity modified by medications. The major disadvantages include limited allergen selection and reduced sensitivity compared with intradermal skin tests, lack of immediate results, and higher cost.

ALLERGIC DISORDERS

There are two types of IgE-mediated allergic reactions: atopic and nonatopic disorders. Although the underlying immunologic reactions of the two types of disorders are the same, the predisposing factors and manifestations are different. The atopic disorders are characterized by a hereditary predisposition and production of a local reaction to IgE antibodies, which manifests in one or more of the following three atopic disorders: allergic rhinitis, asthma, and atopic dermatitis/eczema. The nonatopic disorders lack the genetic component and organ specificity of the atopic disorders (Porth & Matfin, 2009). Latex allergy (see later discussion) may be a type I or type IV hypersensitivity reaction, although

true latex allergy is considered to be a type I hypersensitivity reaction (Rolland & O'Hehir, 2008). Contact dermatitis is considered to be a type IV hypersensitivity reaction.

Anaphylaxis

Anaphylaxis is a clinical response to an immediate (type I hypersensitivity) immunologic reaction between a specific antigen and an antibody. The reaction results from a rapid release of IgE-mediated chemicals, which can induce a severe, life-threatening allergic reaction. It is estimated that between 3.3 and 43 million people in the United States are at risk for anaphylaxis (Lieberman, 2006; Porth & Matfin, 2009).

Pathophysiology

Anaphylaxis is caused by the interaction of a foreign antigen with specific IgE antibodies found on the surface membrane of mast cells and peripheral blood basophils. The subsequent release of histamine and other bioactive mediators causes activation of platelets, eosinophils, and neutrophils. Histamine, prostaglandins, and inflammatory leukotrienes are potent vasoactive mediators that are implicated in the vascular permeability changes, flushing, urticaria, angioedema, hypotension, and bronchoconstriction that characterize anaphylaxis. Smooth muscle spasm, bronchospasm, mucosal edema and inflammation, and increased capillary permeability result. These systemic changes characteristically produce clinical manifestations within seconds or minutes after antigen exposure (Lieberman, 2006; Porth & Matfin, 2009). Closely related to anaphylaxis is a nonallergenic anaphylaxis (anaphylactoid) reaction, which is described in Chart 53-2.

Substances that most commonly cause anaphylaxis include foods, medications, insect stings, and latex (Chart 53-3). Foods that are common causes of anaphylaxis include peanuts, tree nuts, shellfish, fish, milk, eggs, soy, and wheat. Many medications have been implicated in anaphylaxis. Those that are most frequently reported include antibiotics (eg, penicillin), radiocontrast agents, intravenous (IV)

Chart 53-2 • Nonallergenic Anaphylaxis (Anaphylactoid Reaction)

Closely resembling anaphylaxis is an anaphylactoid reaction, which is caused by the release of mast cell and basophil mediators triggered by non-IgE-mediated events. This non-allergenic anaphylaxis reaction may occur with medications, food, exercise, or cytotoxic antibody transfusions. The reaction may be local or systemic. Local reactions usually involve urticaria and angioedema at the site of the antigen exposure. Although possibly severe, nonallergenic anaphylaxis reactions are rarely fatal. Systemic reactions occur within about 30 minutes after exposure and involve cardiovascular, respiratory, gastrointestinal, and integumentary organ systems. For the most part, the treatment of nonallergenic anaphylaxis reaction is identical to that of anaphylaxis (Johansson, Hourihane, Bousquet, et al., 2005).

Chart 53-3 • Common Causes of Anaphylaxis

Foods

Peanuts, tree nuts (eg, walnuts, pecans, cashews, almonds), shellfish (eg, shrimp, lobster, crab), fish, milk, eggs, soy, wheat

Medications

Antibiotics, especially penicillin and sulfa antibiotics, allopurinol, radiocontrast agents, anesthetic agents (lidocaine, procaine), vaccines, hormones (insulin, vasopressin, adrenocorticotrophic hormone [ACTH]), aspirin, nonsteroidal anti-inflammatory drugs (NSAIDs)

Other Pharmaceutical/Biologic Agents

Animal serums (tetanus antitoxin, snake venom antitoxin, rabies antitoxin), antigens used in skin testing

Insect Stings

Bees, wasps, hornets, yellow jackets, ants, including fire ants

Latex

Medical and nonmedical products containing latex

anesthetic agents, aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs), and opioids. Antibiotics and radiocontrast agents cause the most serious anaphylactic reactions, producing reactions in about 1 of every 5000 exposures. Penicillin is the most common cause of anaphylaxis and accounts for about 75% of fatal anaphylactic reactions in the United States each year. The actual prevalence of penicillin allergy in the general population is unknown; however, the incidence of self-reported penicillin allergy ranges from 1% to 10%. It has been reported that 80% to 90% of those patients with self-reported penicillin allergy have no evidence of IgE antibodies to penicillin on skin testing (Adkinson, Busse, Bochner, et al., 2009; Walker, 2007).

The diagnosis of risk of anaphylaxis is determined by prick and intradermal skin testing. Skin testing of patients who have clinical symptoms consistent with a type I, IgE-mediated reaction has been recommended (Adkinson, et al., 2009).

Clinical Manifestations

Anaphylactic reactions produce a clinical syndrome that affects multiple organ systems. Reactions may be categorized as mild, moderate, or severe. The time from exposure to the antigen to onset of symptoms is a good indicator of the severity of the reaction: the faster the onset, the more severe the reaction. The severity of previous reactions does not determine the severity of subsequent reactions, which could be the same or more or less severe. The severity depends on the degree of allergy and the dose of allergen (Virella, 2007).

Mild systemic reactions consist of peripheral tingling and a sensation of warmth, possibly accompanied by a sensation of fullness in the mouth and throat. Nasal congestion, periorbital swelling, pruritus, sneezing, and tearing of

the eyes can also be expected. Onset of symptoms begins within the first 2 hours after exposure.

Moderate systemic reactions may include flushing, warmth, anxiety, and itching in addition to any of the milder symptoms. More serious reactions include bronchospasm and edema of the airways or larynx with dyspnea, cough, and wheezing. The onset of symptoms is the same as for a mild reaction.

Severe systemic reactions have an abrupt onset with the same signs and symptoms described previously. These symptoms progress rapidly to bronchospasm, laryngeal edema, severe dyspnea, cyanosis, and hypotension. Dysphagia (difficulty swallowing), abdominal cramping, vomiting, diarrhea, and seizures can also occur. Cardiac arrest and coma may follow.

Prevention

Strict avoidance of potential allergens is an important preventive measure for the patient at risk for anaphylaxis. Patients at risk for anaphylaxis from insect stings should avoid areas populated by insects and should use appropriate clothing, insect repellent, and caution to avoid further stings.

If avoidance of exposure to allergens is impossible, the patient should be instructed to carry and administer epinephrine to prevent an anaphylactic reaction in the event of exposure to the allergen. People who are sensitive to insect bites and stings, those who have experienced food or medication reactions, and those who have experienced idiopathic or exercise-induced anaphylactic reactions should always carry an emergency kit that contains epinephrine. The EpiPen from Dey Pharmaceuticals (Napa, CA) is a commercially available first-aid device that delivers premeasured doses of 0.3 mg (EpiPen) or 0.15 mg (EpiPen Jr.) of epinephrine (Fig. 53-5). The autoinjection system requires no preparation, and the self-administration technique is not complicated. The patient must be given an opportunity to demonstrate the correct technique for use; an EpiPen training device can be used for teaching correct technique. Verbal and written information about the emergency kit, as well as strategies to avoid exposure to threatening allergens, must also be provided.

Screening for allergies before a medication is prescribed or first administered is an important preventive measure. A careful history of any sensitivity to suspected antigens must be obtained before administering any medication, particularly in parenteral form, because this route is associated with the most severe anaphylaxis. Nurses caring for patients in any setting (hospital, home, outpatient diagnostic testing sites, long-term care facilities) must assess patients' risks for anaphylactic reactions. Patients are asked about previous exposure to contrast agents used for diagnostic tests and any allergic reactions, as well as reactions to any medications, foods, insect stings, and latex. People who are predisposed

to anaphylaxis should wear some form of identification, such as a MedicAlert bracelet, which names allergies to medications, food, and other substances.

People who are allergic to insect venom may require venom immunotherapy, which is used as a control measure and not a cure. Immunotherapy administered after an insect sting is very effective in reducing the risk of anaphylaxis from future stings (Douglass & O'Hehir, 2006; Walker, 2007). Insulin-allergic patients with diabetes and those who are allergic to penicillin may require desensitization. Desensitization is based on controlled anaphylaxis, with a gradual release of mediators. Patients who undergo desensitization are cautioned that there should be no lapses in therapy, because this may lead to the reappearance of the allergic reaction when the use of the medication is resumed.

Medical Management

Management depends on the severity of the reaction. Initially, respiratory and cardiovascular functions are evaluated. If the patient is in cardiac arrest, cardiopulmonary resuscitation is instituted. Oxygen is provided in high concentrations during cardiopulmonary resuscitation or if the patient is cyanotic, dyspneic, or wheezing. Epinephrine, in a 1:1000 dilution, is administered subcutaneously in the upper extremity or thigh and may be followed by a continuous IV infusion. Most adverse events associated with administration of epinephrine (ie, adrenaline) occur when the dose is excessive or it is given intravenously. Patients at risk for adverse effects include elderly patients and those with hypertension, arteriopathies, or known ischemic heart disease.

Antihistamines and corticosteroids may also be administered to prevent recurrences of the reaction (Goroll & Mulley, 2006) and to treat urticaria and angioedema. IV fluids (eg, normal saline solution), volume expanders, and vasopressor agents are administered to maintain blood pressure and normal hemodynamic status. In patients with episodes of bronchospasm or a history of bronchial asthma or chronic obstructive pulmonary disease, aminophylline and corticosteroids may also be administered to improve airway patency and function. If hypotension is unresponsive to vasopressors, glucagon may be administered intravenously for its acute inotropic and chronotropic effects.

Patients who have experienced anaphylactic reactions and received epinephrine should be transported to the local emergency department for observation and monitoring because of the risk for a "rebound" reaction 4 to 10 hours after the initial allergic reaction. Patients with severe reactions are monitored closely for 12 to 14 hours in a facility that can provide emergency care, if needed. Because of the potential for recurrence, patients with even mild reactions must be informed about this risk (Goroll & Mulley, 2006; Lieberman, 2006).

Nursing Management

If a patient is experiencing an allergic response, the nurse's initial action is to assess the patient for signs and symptoms of anaphylaxis. The nurse assesses the airway, breathing pattern, and vital signs. The patient is observed for signs of increasing edema and respiratory distress. Prompt notification of the physician and preparation for initiation of emergency measures (intubation, administration of emergency medications, insertion of IV lines, fluid administration, oxygen

Figure 53-5 The EpiPen. Autoinjectors are commercially available first-aid devices that administer premeasured doses of epinephrine. An EpiPen training device is available for patients to practice correct self-injection technique. Courtesy of Dey, L. P., Napa, CA.

administration) are important to reduce the severity of the reaction and to restore cardiovascular function. The nurse documents the interventions used and the patient's vital signs and response to treatment.

The patient who has recovered from anaphylaxis needs an explanation of what occurred and instruction about avoiding future exposure to antigens and how to administer emergency medications to treat anaphylaxis. The patient must be instructed about antigens that should be avoided and about other strategies to prevent recurrence of anaphylaxis. All patients who have experienced an anaphylactic reaction should receive a prescription for preloaded syringes of epinephrine. The nurse instructs the patient and family in their use and has the patient and family demonstrate correct administration (Chart 53-4).

Allergic Rhinitis

Allergic **rhinitis** (hay fever, seasonal allergic rhinitis) is the most common form of respiratory allergy presumed to be mediated by an immediate (type I hypersensitivity) immunologic reaction, and it is among the top 10 reasons for visits to primary care physicians (Ferguson, 2008; Quillen & Feller, 2006). It affects about 10% to 25% of the U.S. population

(Nathan, 2008). The symptoms are similar to those of viral rhinitis (see Chapter 22) but are usually more persistent and demonstrate seasonal variation; rhinitis is considered to be the allergic form if the symptoms are caused by an allergen-specific IgE-mediated immunologic response. However, a sizable proportion of patients with rhinitis have mixed rhinitis, or coexisting allergic and nonallergic rhinitis (Nathan, 2008). The proportion of patients with the allergic form of rhinitis increases with age. It often occurs with other conditions, such as allergic conjunctivitis, sinusitis, and asthma. If symptoms are severe, allergic rhinitis may interfere with sleep, leisure, and school or work activities (Quillen & Feller, 2006). If left untreated, many complications may result, such as allergic asthma, chronic nasal obstruction, chronic otitis media with hearing loss, anosmia (absence of the sense of smell), and, in children, orofacial dental deformities. Early diagnosis and adequate treatment are essential to reduce complications and relieve symptoms.

Because allergic rhinitis is induced by airborne pollens or molds, it is characterized by the following seasonal occurrences:

- Early spring—tree pollen (oak, elm, poplar)
- Early summer—rose pollen (rose fever), grass pollen (Timothy, red-top)
- Early fall—weed pollen (ragweed)

CHART

53-4

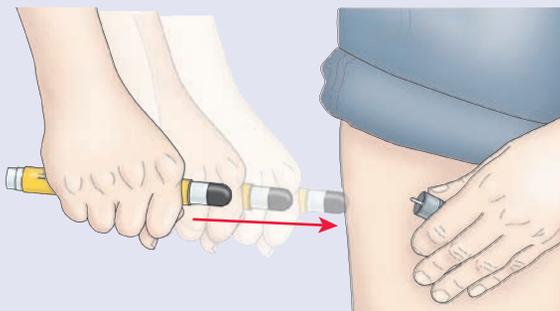

PATIENT EDUCATION

Self-Administration of Epinephrine

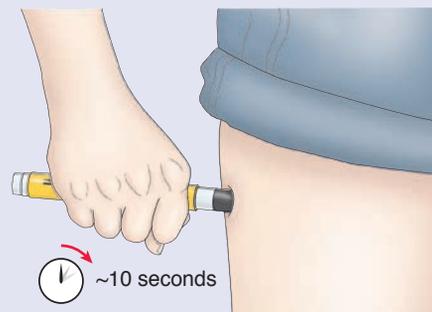

1. After removing the EpiPen autoinjector from its carrying tube, grasp the unit with the black tip (injecting end) pointing downward. Form fist around the unit with the black tip down and with your other hand, remove the gray safety release cap.

2. Hold black tip near outer thigh. Swing and **jab firmly** into outer thigh until a click is heard with the device perpendicular (90-degree angle) to the thigh.

3. Hold firmly against the thigh for approximately 10 seconds. Remove the unit from the thigh and massage injection area for 10 seconds. Call 911 and seek immediate medical attention. Carefully place the used EpiPen, needle-end first, into the device storage tube without bending the needle. Screw on the storage tube completely, and take with you to the hospital emergency room.

Each year attacks begin and end at about the same time. Airborne mold spores require warm, damp weather. Although there is no rigid seasonal pattern, these spores appear in early spring, are rampant during the summer, then taper off and disappear by the first frost in areas that experience dramatic seasonal temperature variation. In temperate areas that do not experience freezing temperatures, these allergens, especially mold, can persist throughout the year.

Pathophysiology

Sensitization begins by ingestion or inhalation of an antigen. On re-exposure, the nasal mucosa reacts by the slowing of ciliary action, edema formation, and leukocyte (primarily eosinophil) infiltration. Histamine is the major mediator of allergic reactions in the nasal mucosa. Tissue edema results from vasodilation and increased capillary permeability.

Clinical Manifestations

Typical signs and symptoms of allergic rhinitis include sneezing and nasal congestion; clear, watery nasal discharge; and nasal itching. Itching of the throat and soft palate is common. Drainage of nasal mucus into the pharynx results in multiple attempts to clear the throat and results in a dry cough or hoarseness. Headache, pain over the paranasal sinuses, and epistaxis can accompany allergic rhinitis. The symptoms of this chronic condition depend on environmental exposure and intrinsic host responsiveness. Allergic rhinitis can affect quality of life by also producing fatigue, loss of sleep, and poor concentration (Nathan, 2008).

Assessment and Diagnostic Findings

Diagnosis of seasonal allergic rhinitis is based on history, physical examination, and diagnostic test results. Diagnostic tests include nasal smears, peripheral blood counts, total serum IgE, epicutaneous and intradermal testing, RAST, food elimination and challenge, and nasal provocation tests. Results indicative of allergy as the cause of rhinitis include increased IgE and eosinophil levels and positive reactions on allergen testing. False-positive and false-negative responses to these tests, particularly skin testing and provocation tests, may occur.

Medical Management

The goal of therapy is to provide relief from symptoms. Therapy may include one or all of the following interventions: avoidance therapy, pharmacotherapy, and immunotherapy. Verbal instructions must be reinforced by written information. Knowledge of general concepts regarding assessment and therapy in allergic diseases is important so that the patient can learn to manage certain conditions as well as prevent severe reactions and illnesses.

Avoidance Therapy

In avoidance therapy, every attempt is made to remove the allergens that act as precipitating factors. Simple measures and environmental controls are often effective in decreasing symptoms. Examples include use of air conditioners, air cleaners, humidifiers, and dehumidifiers; removal of dust-catching furnishings, carpets, and window coverings; removal of pets from the home or bedroom; use of pillow and mattress covers that are impermeable to dust mites; and a

smoke-free environment (Nathan, 2008; Quillen & Feller, 2006). Because multiple allergens are often implicated, multiple measures to avoid exposure to allergens are often necessary (Nathan, 2008; Platts-Mills, Leung & Schatz, 2007). High-efficiency particulate air (HEPA) purifiers and vacuum cleaner filters may also be used to reduce allergens in the environment. Research has shown that multiple avoidance strategies tailored to a person's risk factors can reduce the severity of symptoms, the number of work or school days missed because of symptoms, and the number of unscheduled health care visits for treatment (Ferguson, 2008). In many cases, it is impossible to avoid exposure to all environmental allergens, so pharmacologic therapy or immunotherapy is needed.

Pharmacologic Therapy

Antihistamines

Antihistamines, now classified as H₁ receptor antagonists (or H₁-blockers), are used in the management of mild allergic disorders. H₁ blockers bind selectively to H₁ receptors, preventing the actions of histamines at these sites. They do not prevent the release of histamine from mast cells or basophils. The H₁ antagonists have no effect on H₂ receptors, but they do have the ability to bind to nonhistaminic receptors. The ability of certain antihistamines to bind to and block muscarinic receptors underlies several of the prominent anticholinergic side effects of these medications.

Oral antihistamines, which are readily absorbed, are most effective when given at the first occurrence of symptoms, because they prevent the development of new symptoms. The effectiveness of these medications is limited to certain patients with hay fever, vasomotor rhinitis, **urticaria** (hives), and mild asthma. They are rarely effective in other conditions or in any severe conditions.

Antihistamines are the major class of medications prescribed for the symptomatic relief of allergic rhinitis. The major side effect is sedation, although H₁ antagonists are less sedating than earlier antihistamines (Arcangelo & Peterson, 2005; Karch, 2008). Additional side effects include nervousness, tremors, dizziness, dry mouth, palpitations, anorexia, nausea, and vomiting. Antihistamines are contraindicated during the third trimester of pregnancy; in nursing mothers and newborns; in children and elderly people; and in patients whose conditions may be aggravated by muscarinic blockade (eg, asthma, urinary retention, open-angle glaucoma, hypertension, prostatic hyperplasia).

Newer antihistamines are called second-generation or nonsedating H₁ receptor antagonists. Unlike first-generation H₁ receptor antagonists, they do not cross the blood-brain barrier and do not bind to cholinergic, serotonergic, or alpha-adrenergic receptors (Karch, 2008). They bind to peripheral rather than central nervous system H₁ receptors, causing less sedation. Examples of these medications are loratadine (Claritin), cetirizine (Zyrtec), and fexofenadine (Allegra). These are summarized in Table 53-2.

Antihistamines may also be combined with decongestants to reduce the nasal congestion associated with allergies. Some of these combination products are available as over-the-counter (nonprescription) medications; examples are desloratadine/pseudoephedrine (Claritin-D) and

Table 53-2 SELECTED H ₁ ANTIHISTAMINES			
H ₁ Antihistamine	Contraindications	Major Side Effects	Nursing Implications and Patient Teaching
First-Generation H₁ Antihistamines (Sedating)			
Diphenhydramine (Benadryl)	Allergy to any antihistamines Third trimester of pregnancy Lactation Use cautiously with narrow-angle glaucoma, asthma, stenosing peptic ulcer, BPH or bladder neck obstruction, pregnancy, elderly patients, hypertension	Drowsiness, confusion, dizziness, dry mouth, nausea, vomiting, photosensitivity, urinary retention	Administer with food if gastrointestinal upset occurs. Caution patients to avoid alcohol, driving, or engaging in any hazardous activities until CNS response to medication is stabilized. Suggest sucking on sugarless lozenges or ice chips for relief of dry mouth. Encourage use of sunscreen and hat while outdoors. Assess for urinary retention; monitor urinary output.
Chlorpheniramine (Chlor-Trimeton)	Allergy to any antihistamines Third trimester of pregnancy Lactation Use cautiously with narrow-angle glaucoma, asthma, stenosing peptic ulcer, BPH or bladder neck obstruction, pregnancy, elderly patients, hypertension	Drowsiness, sedation, and dizziness, although less than other sedating agents; confusion, dry mouth, nausea, vomiting, urinary retention, epigastric distress, thickening of bronchial secretions	Caution patients to avoid alcohol, driving, or engaging in any hazardous activities until CNS response to medication is stabilized. Suggest sucking on sugarless lozenges or ice chips for relief of dry mouth. Recommend use of humidifier.
Hydroxyzine (Atarax)	Allergy to hydroxyzine or cetirizine (Zyrtec), pregnancy, lactation, hypertension	Drowsiness, dry mouth, involuntary motor activity, including tremor and seizures	Caution patients to avoid alcohol, driving, or engaging in any hazardous activities until CNS response to medication is stabilized. Suggest sucking on sugarless lozenges or ice chips for relief of dry mouth. Instruct patients to report tremors.
Second-Generation H₁ Antihistamines (Nonsedating)			
Cetirizine (Zyrtec)	Allergy to any antihistamines Narrow-angle glaucoma Asthma Stenosing peptic ulcer BPH or bladder neck obstruction Lactation Hypertension	Dry nasal mucosa, thickening of bronchial secretions	Can be taken without regard to meals. Instruct patients to use caution if driving or performing tasks that require alertness. Recommend use of humidifier.
Desloratadine (Clarinet)	Allergy to loratadine (Alavert, Claritin) Lactation Use cautiously with renal or hepatic impairment pregnancy, hypertension	Somnolence, nervousness, dizziness, fatigue, dry mouth	Can be taken without regard to meals. Suggest sucking on sugarless lozenges or ice chips for relief of dry mouth. Recommend use of humidifier.
Loratadine (Alavert, Claritin)	Allergy to any antihistamines Narrow-angle glaucoma Asthma Stenosing peptic ulcer BPH or bladder neck obstruction, hypertension	Headache, nervousness, dizziness, depression, edema, increased appetite	Instruct patients to take on empty stomach (1 h before or 2 h after meals or food). Instruct patients to avoid alcohol and to use caution if driving or performing tasks that require alertness. Suggest sucking on sugarless lozenges or ice chips for relief of dry mouth. Recommend use of humidifier.
Fexofenadine (Allegra)	Allergy to any antihistamines Pregnancy Lactation Use with caution with hepatic or renal impairment, in elderly patients, and with hypertension	Fatigue, drowsiness, GI upset	Should not be administered within 15 min of ingestion of antacids. Instruct patients to use caution if driving or performing tasks that require alertness. Recommend use of humidifier.

BPH = benign prostatic hyperplasia; CNS = central nervous system.

cetirizine/pseudoephedrine (Zyrtec-D). Decongestants can cause an increase in blood pressure; therefore, patients with a history of hypertension should be cautioned about long-term use of any medication containing decongestants.

Adrenergic Agents

Adrenergic agents, vasoconstrictors of mucosal vessels, are used topically (nasal and ophthalmic formulations) in addition to the oral route. The topical route (drops and sprays) causes fewer side effects than oral administration; however, the use of drops and sprays should be limited to a few days to avoid rebound congestion. Adrenergic nasal decongestants are applied topically to the nasal mucosa for the relief of nasal congestion. They activate the alpha-adrenergic receptor sites

on the smooth muscle of the nasal mucosal blood vessels, reducing local blood flow, fluid exudation, and mucosal edema. Topical ophthalmic drops are used for symptomatic relief of eye irritations caused by allergies. Potential side effects include hypertension, dysrhythmias, palpitations, central nervous system stimulation, irritability, tremor, and tachyphylaxis (acceleration of hemodynamic status).

Mast Cell Stabilizers

Intranasal cromolyn sodium (NasalCrom) is a spray that acts by stabilizing the mast cell membrane, thus reducing the release of histamine and other mediators of the allergic response. In addition, it inhibits macrophages, eosinophils, monocytes, and platelets involved in the immune response

(Arcangelo & Peterson, 2005). Cromolyn interrupts the physiologic response to nasal antigens, and it is used prophylactically (before exposure to allergens) to prevent the onset of symptoms and to treat symptoms once they occur. It is also used therapeutically in chronic allergic rhinitis. This spray is as effective as antihistamines but is less effective than intranasal corticosteroids in the treatment of seasonal allergic rhinitis. The patient must be informed that the beneficial effects of the medication may take a week or so to manifest. The medication is of no benefit in the treatment of nonallergic rhinitis. Adverse effects (eg, sneezing, local stinging and burning sensations) are usually mild.

Corticosteroids

Intranasal corticosteroids are indicated in more severe cases of allergic and perennial rhinitis that cannot be controlled by more conventional medications such as decongestants, antihistamines, and intranasal cromolyn. Examples of these medications include beclomethasone (Beconase, Vancenase), budesonide (Rhinocort), dexamethasone (Decadron Phosphate Turbinaire), flunisolide (Nasalide), fluticasone (Cutivate, Flonase), and triamcinolone (Nasacort).

Because of their anti-inflammatory actions, corticosteroids are equally effective in preventing or suppressing the major symptoms of allergic rhinitis. These medications are administered by metered-spray devices. If the nasal passages are blocked, a topical decongestant may be used to clear the passages before the administration of the intranasal corticosteroid. Patients must be aware that full benefit may not be achieved for several days to 2 weeks. Adverse effects of intranasal corticosteroids are mild and include drying of the nasal mucosa and burning and itching sensations caused by the vehicle used to administer the medication. Systemic effects are more likely with dexamethasone. Recommended use of this medication is limited to 30 days. Beclomethasone, budesonide, flunisolide, fluticasone, and triamcinolone are deactivated rapidly after absorption, so they do not achieve significant blood levels. Because corticosteroids suppress host defenses, they must be used with caution in patients with tuberculosis or untreated bacterial infections of the lungs. Patients taking corticosteroids are at risk for infection and suppression of typical manifestations of inflammation, because host defenses are compromised. Inhaled corticosteroids do not affect the immune system to the same degree as systemic corticosteroids (ie, oral corticosteroids). Because corticosteroids are inhaled into the upper respiratory tract, tuberculosis or untreated bacterial infections of the lungs may become apparent and progress. Whenever possible,

patients with tuberculosis or other bacterial infections of the lungs should avoid inhaled corticosteroids.

Oral and parenteral corticosteroids are used when conventional therapy has failed and symptoms are severe and of short duration. They can control symptoms of allergic reactions such as hay fever, medication-induced allergies, and allergic reactions to insect stings. Because the response to corticosteroids is delayed, these agents have little or no value in acute therapy for severe reactions such as anaphylaxis. Patients who receive corticosteroids must be cautioned not to stop taking the medication suddenly or without specific instructions from the physician. The patient is also instructed about side effects, which include fluid retention, weight gain, hypertension, gastric irritation, glucose intolerance, and adrenal suppression. Further discussion of corticosteroids is provided in Chapter 42.

Leukotriene Modifiers

As previously discussed, leukotrienes have many effects on the inflammatory cycle. Leukotriene modifiers, such as zileuton (Zyflo), zafirlukast (Accolate), and montelukast (Singulair), block the synthesis or action of leukotrienes and prevent the signs and symptoms associated with asthma (Table 53-3).

Leukotriene modifiers are for long-term use, and patients should be advised to take their medication daily. Patients take appropriate “rescue” medications for symptom exacerbation but continue to take the leukotriene modifier on a daily basis. The 2007 National Asthma Education and Prevention Program (NAEPP) suggests using a leukotriene modifier in conjunction with an inhaled corticosteroid for mild persistent asthma.

Immunotherapy

Allergen desensitization (allergen immunotherapy, hyposensitization) is primarily used to treat IgE-mediated diseases by injections of allergen extracts. Immunotherapy, also referred to as allergy vaccine therapy, involves the administration of gradually increasing quantities of specific allergens to the patient until a dose is reached that is effective in reducing disease severity from natural exposure (Stokes, 2008). This type of therapy provides an adjunct to symptomatic pharmacologic therapy and can be used when avoidance of allergens is not possible. Specific immunotherapy has been used in the treatment of allergic disorders for about 100 years. Goals of immunotherapy include reducing the level of circulating IgE, increasing the level of blocking antibody IgG, and reducing mediator cell sensitivity. Immunotherapy has been most effective for ragweed pollen;

Table 53-3 LEUKOTRIENE MODIFIERS

Leukotriene Modifier	Available Formulations	Frequency of Dosing
Leukotriene-Receptor Antagonists (LTRAs)		
Zafirlukast (Accolate)	Tablets: 10 mg; 20 mg	Taken twice a day
Montelukast (Singulair)	Tablets: 10 mg Chewable tablets: 4 mg; 5 mg Granules: 4 mg/packet	Taken once a day in PM
Leukotriene-Receptor Inhibitors (LTRIs)		
Zileuton (Zyflo CR)	Tables: 600 mg extended release	Taken twice a day within 1 h after morning and evening meals

Chart 53-5 • Immunotherapy: Indications and Contraindications

Indications

- Allergic rhinitis, conjunctivitis, or allergic asthma
- History of a systemic reaction to Hymenoptera and specific IgE antibodies to Hymenoptera venom
- Desire to avoid the long-term use, potential adverse effects, or costs of medications
- Lack of control of symptoms by avoidance measures or use of medications

Contraindications

- Use of beta-blocker or angiotensin-converting enzyme (ACE) inhibitor therapy, which may mask early signs of anaphylaxis
- Presence of significant pulmonary or cardiac disease or organ failure
- Inability of the patient to recognize or report signs and symptoms of a systemic reaction
- Nonadherence of the patient to other therapeutic regimens and nonlikelihood that the patient will adhere to the immunization schedule (often weekly for an indefinite period)
- Inability to monitor the patient for at least 30 minutes after administration of immunotherapy
- Absence of equipment or adequate personnel to respond to allergic reaction if one occurs

however, treatment for grass, tree pollen, cat dander, and house dust mite allergens has also been effective. Indications and contraindications for immunotherapy are presented in Chart 53-5.

Correlation of a positive skin test with a positive allergy history is an indication for immunotherapy if the allergen cannot be avoided. The benefit of immunotherapy has been fairly well established in instances of allergic rhinitis and bronchial asthma that are clearly due to sensitivity to one of the common pollens, molds, or household dust. Unlike antiallergy medication, allergen immunotherapy has the potential to alter the allergic disease course after 3 to 5 years of therapy. Because it may prevent progression or development of asthma or multiple or additional allergies, it is also considered to be a potential preventive measure (Stokes, 2008). The patient must understand what to expect and the importance of continuing therapy for several years before immunotherapy is accomplished. When skin tests are performed, the results are correlated with symptoms; treatment is based on the patient's needs rather than on the results of skin tests.

The most common method of treatment is the serial injection of one or more antigens that are selected in each particular case on the basis of skin testing. This method provides a simple and efficient technique for identifying IgE antibodies to specific antigens. Specific treatment consists of injecting extracts of the allergens that cause symptoms in a particular patient. Injections begin with very small amounts and are gradually increased, usually at weekly intervals, until a maximum tolerated dose is attained. Maintenance booster injections are administered at 2- to 4-week intervals, frequently for a period of several years, before maximum benefit is achieved, although some patients will

note early improvement in their symptoms. Long-term benefit seems to be related to the cumulative dose of vaccine given over time (Stokes, 2008). Immunotherapy should not be initiated during pregnancy; for patients who have been receiving immunotherapy before pregnancy, the dosage should not be increased during pregnancy.

Although severe systemic reactions are rare, the risk of systemic and potentially fatal anaphylaxis exists. It tends to occur most frequently at the induction or "up-dosing" phase. Therefore, the patient must be monitored after administration of immunotherapy. Because of the risk of anaphylaxis, injections should not be administered by a lay person or by the patient. The patient must remain in the office or clinic for at least 30 minutes after the injection and is observed for possible systemic symptoms. If a large, local swelling develops at the injection site, the next dose should not be increased, because this may be a warning sign of a possible systemic reaction.

NURSING ALERT

Because the injection of an allergen may induce systemic reactions, such injections are administered only in a setting (ie, physician's office, clinic) where epinephrine is immediately available.

Therapeutic failure is evident when a patient does not experience a decrease of symptoms within 12 to 24 months, fails to develop increased tolerance to known allergens, and cannot decrease the use of medications to reduce symptoms. Potential causes of treatment failure include misdiagnosis of allergies, inadequate doses of allergen, newly developed allergies, and inadequate environmental controls.

NURSING PROCESS

THE PATIENT WITH ALLERGIC RHINITIS

Assessment

The examination and history of the patient reveal sneezing, often in paroxysms; thin and watery nasal discharge; itching eyes and nose; lacrimation; and occasionally headache. The health history includes a personal or family history of allergy. The allergy assessment identifies the nature of antigens, seasonal changes in symptoms, and medication history. The nurse also obtains subjective data about how the patient feels just before symptoms become obvious, such as the occurrence of pruritus, breathing problems, and tingling sensations. In addition to these symptoms, hoarseness, wheezing, hives, rash, erythema, and edema are noted. Any relationship between emotional problems or stress and the triggering of allergy symptoms is assessed.

Diagnosis

Nursing Diagnoses

Based on the assessment data, the patient's major nursing diagnoses may include the following:

- Ineffective breathing pattern related to allergic reaction

- Deficient knowledge about allergy and the recommended modifications in lifestyle and self-care practices
- Ineffective individual coping with chronicity of condition and need for environmental modifications

Collaborative Problems/Potential Complications

Based on assessment data, potential complications may include the following:

- Anaphylaxis
- Impaired breathing
- Nonadherence to the therapeutic regimen

Planning and Goals

The goals for the patient may include restoration of normal breathing pattern, increased knowledge about the causes and control of allergic symptoms, improved coping with alterations and modifications, and absence of complications.

Nursing Interventions

Improving Breathing Pattern

The patient is instructed and assisted to modify the environment to reduce the severity of allergic symptoms or to prevent their occurrence. The patient is instructed to reduce exposure to people with upper respiratory tract infections. If an upper respiratory infection occurs, the patient is encouraged to take deep breaths and to cough frequently to ensure adequate gas exchange and prevent atelectasis. The patient is instructed to seek medical attention, because the presence of allergy symptoms along with an upper respiratory tract infection may compromise adequate lung function. Adherence to medication schedules and other treatment regimens is encouraged and reinforced.

Promoting Understanding of Allergy and Allergy Control

Instruction includes strategies to minimize exposure to allergens and explanation about desensitization procedures and correct use of medications. The nurse informs and reminds the patient of the importance of keeping appointments for desensitization procedures, because dosages are usually adjusted on a weekly basis, and missed appointments may interfere with the dosage adjustment.

Patients also need to understand that medications for allergy control should be used only when the allergy is apparent. This is usually on a seasonal basis. Continued use of medications when not required can cause an increased tolerance to the medication, with the result that the medication will not be effective when needed.

Coping With a Chronic Disorder

Although allergic reactions are infrequently life-threatening, they require constant vigilance to avoid allergens and modification of the lifestyle or environment to prevent recurrence of symptoms. Allergic symptoms are often present year-round and create discomfort and inconvenience for the patient. Although patients may not feel ill during allergy seasons, they often do not feel well, either. The need to be alert for possible allergens in the environment may be tiresome, placing a burden on the patient's ability to lead a normal life. Stress related to these difficulties may in turn increase the frequency or severity of symptoms.

To assist the patient in adjusting to these modifications, the nurse must have an appreciation of the difficulties encountered by the patient. The patient is encouraged to verbalize feelings and concerns in a supportive environment and to identify strategies to deal with them effectively.

Monitoring and Managing Potential Complications

ANAPHYLAXIS AND IMPAIRED BREATHING. Respiratory and cardiovascular functioning can be significantly altered during allergic reactions by the reaction itself or by the medications used to treat reactions. The respiratory status is evaluated by monitoring the respiratory rate and pattern and by assessing for breathing difficulties or abnormal lung sounds. The pulse rate and rhythm and blood pressure are monitored to assess cardiovascular status regularly or any time the patient reports symptoms such as itching or difficulty breathing. In the event of signs and symptoms suggestive of anaphylaxis, emergency medications and equipment must be available for immediate use.

NONADHERENCE TO THE THERAPEUTIC REGIMEN. Knowing about the treatment regimen does not ensure adherence. Having the patient identify potential barriers and explore acceptable solutions for effective management of the condition (eg, installing tile floors rather than carpet, not gardening in the spring) can increase adherence to the treatment regimen.

Promoting Home and Community-Based Care

TEACHING PATIENTS SELF-CARE. The patient is instructed about strategies to minimize exposure to allergens, the actions and adverse effects of medications, and the correct use of medications. The patient should know the name, dose, frequency, actions, and side effects of all medications taken.

Instruction about strategies to control allergic symptoms is based on the needs of the patient as determined by the results of tests, the severity of symptoms, and the motivation of the patient and family to deal with the condition. Suggestions for patients who are sensitive to dust and mold in the home are given in Chart 53-6. Additional nursing interventions for allergy management are presented in Chart 53-7.

If the patient is to undergo immunotherapy, the nurse reinforces the physician's explanation regarding the purpose and procedure. Instructions are given regarding the series of injections, which usually are administered initially every week and then at 2- to 4-week intervals. These instructions include remaining in the physician's office or the clinic for at least 30 minutes after the injection so that emergency treatment can be given if the patient has a reaction; avoiding rubbing or scratching the injection site; and continuing with the series for the period of time required. In addition, the patient and family are instructed about emergency treatment of severe allergic symptoms.

Because antihistamines may produce drowsiness, the patient is cautioned about this and other side effects of the particular medication. Operating machinery, driving a car, and performing activities that require intense concentration should be postponed. The patient is also informed about the dangers of drinking alcohol when taking these medications, because they tend to exaggerate the effects of alcohol.

CHART
53-6HOME CARE CHECKLIST
Allergy Management

At the completion of the home care instruction, the patient or caregiver will be able to:	PATIENT	CAREGIVER
• Verbalize how to maintain a dust-free environment by removing drapes, curtains, and venetian blinds and replacing them with pull shades; covering the mattress with a hypoallergenic cover that can be zipped; and removing rugs and replacing them with wood flooring or linoleum.	✓	✓
• Identify rationale for washing the floor and dusting and vacuuming daily.	✓	✓
• Identify rationale for replacing stuffed furniture with wood pieces that can easily be dusted.	✓	✓
• State rationale for wearing a mask whenever cleaning is being done.	✓	✓
• Identify rationale for avoiding use of tufted bedspreads, stuffed toys, and feather pillows and replacing them with washable cotton material.	✓	✓
• State rationale for avoiding the use of any clothing that causes itching.	✓	✓
• Verbalize ways to reduce dust in the house as a whole by using steam or hot water for heating rather than air and using air filters or air conditioning.	✓	✓
• Verbalize ways to reduce exposure to pollens or molds by identifying seasons of the year when pollen counts are high; wearing a mask at times of increased exposure (windy days and when grass is being cut); and avoiding contact with weeds, dry leaves, and freshly cut grass.	✓	✓
• State rationale for seeking air-conditioned areas at the height of the allergy season.	✓	✓
• State rationale for avoiding sprays and perfumes.	✓	✓
• State rationale for use of hypoallergenic cosmetics.	✓	✓
• State rationale for taking prescribed medications as ordered.	✓	✓
• Identify specific foods that may cause allergic symptoms. (Examples of foods that can cause allergic reactions are fish, nuts, eggs, and chocolate.)	✓	✓
• Develop a list of foods to avoid.	✓	✓

Chart 53-7 • Selected Nursing Strategies for Allergy Management

- Identify the patient's known allergens (eg, medications, foods, insects, environmental allergens).
- Describe the patient's typical allergic reaction and its severity.
- Document the patient's allergies (eg, medications, foods, insects, environmental allergens) in the patient's medical record.
- Post allergy alerts appropriately.
- Encourage the patient to wear a medical alert band and to carry information about allergies at all times.
- Monitor the patient closely after administration of new medications and exposure to new foods, contrast agents, latex, and other allergens.
- Investigate potential for allergic reactions with all new medications through consultation with the pharmacist.
- Instruct the patient to question all medications and new foods.
- Identify early manifestations of allergic reactions.
- Administer emergency treatment for allergic reactions.
- Monitor the patient's response and status for 12–14 hours after a severe allergic reaction.
- Instruct the patient and family about emergency home management of allergic reaction.
- Instruct the patient and family about avoidance measures to reduce risk of exposure to allergens.

The patient must be aware of the effects caused by overuse of the sympathomimetic agents in nose drops or sprays. A condition referred to as rhinitis medicamentosa may result (Fig. 53-6). After topical application of the medication, a rebound period occurs in which the nasal mucous membranes become more edematous and congested than they were before the medication was used. Such a reaction encourages the use of more medication, and a cyclic pattern results. The topical agent must be discontinued immediately and completely to correct this problem.

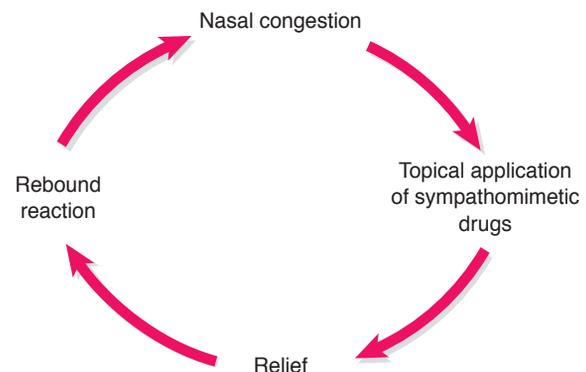

Figure 53-6 Rhinitis medicamentosa. This cyclic pattern results from overuse of sympathomimetic nose drops or sprays.

CONTINUING CARE. Follow-up telephone calls to the patient are often reassuring to the patient and family and provide an opportunity for the nurse to answer any questions. The patient is reminded to keep follow-up appointments and is informed about the importance of continuing with treatment. The importance of participating in health promotion activities and health screening is also emphasized.

Evaluation

Expected Patient Outcomes

Expected patient outcomes may include the following:

1. Exhibits normal breathing patterns
 - a. Demonstrates lungs clear on auscultation
 - b. Exhibits absence of adventitious breath sounds (crackles, rhonchi, wheezing)
 - c. Has a normal respiratory rate and pattern
 - d. Reports no complaints of respiratory distress (shortness of breath, difficulty on inspiration or expiration)
2. Demonstrates knowledge about allergy and strategies to control symptoms
 - a. Identifies causative allergens, if known
 - b. States methods of avoiding allergens and controlling indoor and outdoor precipitating factors
 - c. Removes from the environment items that retain dust
 - d. Wears a dampened mask if dust or mold may be a problem
 - e. Avoids smoke-filled rooms and dust-filled or freshly sprayed areas
 - f. Uses air conditioning for a major part of the day when allergens are high
 - g. Takes antihistamines as prescribed; participates in hyposensitization program, if applicable
 - h. Describes name, purpose, side effects, and method of administration of prescribed medications
 - i. Identifies when to seek immediate medical attention for severe allergic responses
 - j. Describes activities that are possible, including ways to participate in activities without activating the allergies
3. Experiences relief of discomfort while adapting to the inconveniences of an allergy
 - a. Relates the emotional aspects of the allergic response
 - b. Demonstrates use of measures to cope positively with allergy
4. Demonstrates absence of complications
 - a. Exhibits vital signs within normal limits
 - b. Reports no symptoms or episodes of anaphylaxis (urticaria, itching, peripheral tingling, fullness in the mouth and throat, flushing, difficulty swallowing, coughing, wheezing, or difficulty breathing)
 - c. Demonstrates correct procedure to self-administer emergency medications to treat severe allergic reaction
 - d. Correctly states medication names, dose and frequency of administration, and medication actions

- e. Correctly identifies side effects and untoward signs and symptoms to report to physician
- f. Discusses acceptable lifestyle changes and solutions for identified potential barriers to adherence to treatment and medication regimen

Contact Dermatitis

Contact dermatitis, a type IV delayed hypersensitivity reaction, is an acute or chronic skin inflammation that results from direct skin contact with chemicals or allergens. There are four basic types: allergic, irritant, phototoxic, and photoallergic (Table 53-4). Eighty percent of cases are caused by excessive exposure to or additive effects of irritants (eg, soaps, detergents, organic solvents). Skin sensitivity may develop after brief or prolonged periods of exposure, and the clinical picture may appear hours or weeks after the sensitized skin has been exposed.

Clinical Manifestations

Symptoms include itching, burning, erythema, skin lesions (vesicles), and edema, followed by weeping, crusting, and finally drying and peeling of the skin. In severe responses, hemorrhagic bullae may develop. Repeated reactions may be accompanied by thickening of the skin and pigmentary changes. Secondary invasion by bacteria may develop in skin that is abraded by rubbing or scratching. Usually, there are no systemic symptoms unless the eruption is widespread.

Assessment and Diagnostic Findings

The location of the skin eruption and the history of exposure aid in determining the condition. However, in cases of obscure irritants or an unobservant patient, the diagnosis can be extremely difficult, often involving many trial-and-error procedures before the cause is determined. Patch tests on the skin with suspected offending agents may clarify the diagnosis. The patch test most commonly used is the Thin-layer Rapid Use Epicutaneous (TRUE) test.

Atopic Dermatitis

Atopic dermatitis is a type I immediate hypersensitivity disorder characterized by inflammation and hyperreactivity of the skin. Other terms used to describe this skin disorder include atopic eczema, atopic dermatitis/eczema, and atopic dermatitis/eczema syndrome (AEDS). In a revised classification system developed to clarify terminology, AEDS includes both allergic and nonallergic disorders. The term *atopic dermatitis* is currently the most commonly used of these terms and is used in the following discussion.

Atopic dermatitis affects 15% to 20% of children and 1% to 3% of adults in developed countries (Bieber, 2008). Most patients have significant elevations of serum IgE and peripheral eosinophilia. Pruritus and hyperirritability of the skin are the most consistent features of atopic dermatitis and are related to large amounts of histamine in the skin. Excessive dryness of the skin with resultant itching is related to changes

Table 53-4 TYPES, TESTING, AND TREATMENT OF CONTACT DERMATITIS

Type	Etiology	Clinical Presentation	Diagnostic Testing	Treatment
Allergic	Results from contact of skin and allergenic substance. Has a sensitization period of 10–14 days.	Vasodilation and perivascular infiltrates on the dermis Intracellular edema Usually seen on dorsal aspects of hand	Patch testing (contraindicated in acute, widespread dermatitis)	Avoidance of offending material Burow's solution or cool water compress Systemic corticosteroids (prednisone) for 7–10 days Topical corticosteroids for mild cases Oral antihistamines to relieve pruritus
Irritant	Results from contact with a substance that chemically or physically damages the skin on a nonimmunologic basis. Occurs after first exposure to irritant or repeated exposures to milder irritants over an extended time.	Dryness lasting days to months Vesiculation, fissures, cracks Hands and lower arms most common areas	Clinical picture Appropriate negative patch tests	Identification and removal of source of irritation Application of hydrophilic cream or petrolatum to soothe and protect Topical corticosteroids and compresses for weeping lesions Antibiotics for infection and oral antihistamines for pruritus
Phototoxic	Resembles the irritant type but requires sun and a chemical in combination to damage the epidermis.	Similar to irritant dermatitis	Photopatch test	Same as for allergic and irritant dermatitis
Photoallergic	Resembles allergic dermatitis but requires light exposure in addition to allergen contact to produce immunologic reactivity.	Similar to allergic dermatitis	Photopatch test	Same as for allergic and irritant dermatitis

in lipid content, sebaceous gland activity, and sweating. In response to stroking of the skin, immediate redness appears on the skin. Pallor follows in 15 to 30 seconds and persists for 1 to 3 minutes. Lesions develop secondary to the trauma of scratching and appear in areas of increased sweating and hypervascularity. Atopic dermatitis is chronic, with remissions and exacerbations. This condition has a tendency to recur, with remission from adolescence to 20 years of age.

It is important to note that atopic dermatitis is often the first step in a process that leads to asthma and allergic rhinitis. It is the result of interactions between susceptibility genes, the environment, defective function of the skin barrier, and immunologic responses.

Medical Management

Treatment of patients with atopic dermatitis must be individualized. Guidelines for treatment include decreasing itching and scratching by wearing cotton fabrics, washing with a mild detergent, humidifying dry heat in winter, maintaining room temperature at 20°C to 22.2°C (68°F to 72°F), using antihistamines such as diphenhydramine (Benadryl), and avoiding animals, dust, sprays, and perfumes. Keeping the skin moisturized with daily baths to hydrate the skin and the use of topical skin moisturizers is encouraged. Topical corticosteroids are used to prevent inflammation, and any infection is treated with antibiotics to eliminate *Staphylococcus aureus* when indicated. Use of immunosuppressive agents, such as cyclosporine (Neoral, Sandimmune), tacrolimus (Prograf, Protopic), and pimecrolimus (Elidel), may be effective in inhibiting T cells and mast cells involved in atopic dermatitis (Novak, 2007). Research to assess the effectiveness and the adverse side effects of medications used to treat atopic dermatitis is needed.

Nursing Management

Patients who experience atopic dermatitis and their families require assistance and support from the nurse to cope with the disorder. The symptoms are often disturbing to the patient and disruptive to the family. The appearance of the skin may affect the patient's self-esteem and his or her willingness to interact with others. Instructions and counseling about strategies to incorporate preventive measures and treatments into the lifestyle of the family may be helpful.

The patient and family need to be aware of signs of secondary infection and of the need to seek treatment if infection occurs. The nurse also teaches the patient and family about the side effects of medications used in treatment.

Dermatitis Medicamentosa (Drug Reactions)

Dermatitis medicamentosa, a type I hypersensitivity disorder, is the term applied to skin rashes associated with certain medications. Although people react differently to each medication, certain medications tend to induce eruptions of similar types. Rashes are among the most common adverse reactions to medications and occur in approximately 2% to 3% of hospitalized patients.

In general, drug reactions appear suddenly, have a particularly vivid color, manifest with characteristics that are more intense than the somewhat similar eruptions of infectious origin, and, with the exception of bromide and the iodide rashes, disappear rapidly after the medication is withdrawn. Rashes may be accompanied by systemic or generalized symptoms. On discovery of a medication allergy, patients are warned that they have a hypersensitivity to a

particular medication and are advised not to take it again. Patients should carry information identifying the hypersensitivity with them at all times.

Skin eruptions related to medication therapy suggest more serious hypersensitivities. Frequent assessment and prompt reporting of the appearance of any eruptions are important so that early treatment can be initiated. Some cutaneous drug reactions may be associated with a clinical complex that involves other organs. These are known as complex drug reactions. Patients who suspect that a new rash may be caused by a drug allergy (newly prescribed medications, especially antibiotics such as penicillin or sulfa medications) should stop taking the medication immediately and contact their prescribing clinician, who will determine whether the medication and the rash are related.

Urticaria and Angioneurotic Edema

Urticaria (hives) is a type I hypersensitive allergic reaction of the skin characterized by the sudden appearance of pinkish, edematous elevations that vary in size and shape, itch, and cause local discomfort. They may involve any part of the body, including the mucous membranes (especially those of the mouth), the larynx (occasionally with serious respiratory complications), and the gastrointestinal tract.

Each hive remains for a few minutes to several hours before disappearing. For hours or days, clusters of these lesions may come, go, and return episodically. If this sequence continues for longer than 6 weeks, the condition is called chronic urticaria.

Angioneurotic edema involves the deeper layers of the skin, resulting in more diffuse swelling rather than the discrete lesions characteristic of hives. On occasion, this reaction covers the entire back. The skin over the reaction may appear normal but often has a reddish hue. The skin does not pit on pressure, as ordinary edema does. The regions most often involved are the lips, eyelids, cheeks, hands, feet, genitalia, and tongue; the mucous membranes of the larynx, the bronchi, and the gastrointestinal canal may also be affected, particularly in the hereditary type (see discussion in the following section). Swellings may appear suddenly, in a few seconds or minutes, or slowly, in 1 or 2 hours. In the latter case, their appearance is often preceded by itching or burning sensations. Seldom does more than a single swelling appear at one time, although one may develop while another is disappearing. Infrequently, swelling recurs in the same region. Individual lesions usually last 24 to 36 hours. On rare occasions, swelling may recur with remarkable regularity at intervals of 3 to 4 weeks.

Several frequently prescribed medications, such as angiotensin-converting enzyme (ACE) inhibitors and penicillin, may cause angioedema. The nurse needs to be aware of all medications the patient is taking and be alert to the potential of angioedema as a side effect.

Hereditary Angioedema

Hereditary angioedema, although not an immunologic disorder in the usual sense, is included because of its resemblance to allergic angioedema and because of the potential

seriousness of the condition. Symptoms are caused by edema of the skin, the respiratory tract, or the digestive tract. Attacks may be precipitated by trauma, or they may seem to occur spontaneously.

Clinical Manifestations

When skin is involved, the swelling usually is diffuse, does not itch, and usually is not accompanied by urticaria. Gastrointestinal edema may cause abdominal pain severe enough to suggest the need for surgery. Typically, attacks last 1 to 4 days and are harmless; however, attacks can occasionally affect the subcutaneous and submucosal tissues in the region of the upper airway and can be associated with respiratory obstruction and asphyxiation. This disorder is inherited as an autosomal dominant trait. Approximately 85% of patients with this disorder have one nonproductive gene, and the remaining 15% have a gene mutation (Virella, 2007).

Medical Management

Attacks usually subside within 3 to 4 days, but during this time the patient should be observed carefully for signs of laryngeal obstruction, which may necessitate tracheostomy as a life-saving measure. Epinephrine, antihistamines, and corticosteroids are usually used in treatment, but their success is limited.

Food Allergy

IgE-mediated food allergy, a type I hypersensitivity reaction, occurs in 6% to 8% of children and about 2% of the adult population; it is thought to occur in people who have a genetic predisposition combined with exposure to allergens early in life through the gastrointestinal or respiratory tract or nasal mucosa (Bush, 2008). Researchers have also identified a second type of food allergy, a non-IgE-mediated food allergy syndrome in which T cells play a major role (Cappellano, 2008).

Almost any food can cause allergic symptoms. Any food can contain an allergen that results in anaphylaxis. The most common offenders are seafood (lobster, shrimp, crab, clams, fish), legumes (peanuts, peas, beans, licorice), seeds (sesame, cottonseed, caraway, mustard, flaxseed, sunflower seeds), tree nuts, berries, egg white, buckwheat, milk, and chocolate. Peanut and tree nut (eg, cashew, walnut) allergies are responsible for most severe food allergy reactions. In more than 70% of children with peanut allergy, symptoms develop at their first known exposure, suggesting unknown exposure through breast milk or another source (Burks, 2008; Bush, 2008). Pregnant and breast-feeding women who are aware of a family history of allergy (mother, father, or a sibling of the unborn infant with asthma, eczema, hay fever, or other allergy) should avoid peanuts and peanut-containing foods during pregnancy as a precaution (Burks, 2008; Cappellano, 2008).

One of the dangers of food allergens is that they may be hidden in other foods and not apparent to people who are susceptible to the allergen. For example, peanuts and peanut butter are often used in salad dressings and Asian, African, and Mexican cooking and may result in severe allergic reactions,

including anaphylaxis. Previous contamination of equipment with allergens (eg, peanuts) during preparation of another food product (eg, chocolate cake) is enough to produce anaphylaxis in people with severe allergy.

Clinical Manifestations

The clinical symptoms are classic allergic symptoms (urticaria, dermatitis, wheezing, cough, laryngeal edema, angioedema) and gastrointestinal symptoms (itching; swelling of lips, tongue, and palate; abdominal pain; nausea; cramps; vomiting; and diarrhea).

Assessment and Diagnostic Findings

A careful diagnostic workup is required in any patient with a suspected food hypersensitivity. Included are a detailed allergy history, a physical examination, and pertinent diagnostic tests. Skin testing is used to identify the source of symptoms and is useful in identifying specific foods as causative agents.

Medical Management

Therapy for food hypersensitivity includes elimination of the food responsible for the hypersensitivity (Chart 53-8). Pharmacologic therapy is necessary for patients who cannot avoid exposure to offending foods and for patients with multiple food sensitivities not responsive to avoidance measures. Medication therapy involves the use of H₁ blockers, antihistamines, adrenergic agents, corticosteroids, and cromolyn sodium. Another essential aspect of management is teaching patients and family members how to recognize and manage the early stages of an acute anaphylactic reaction. Many food allergies disappear with time, particularly in children. About one third of proven allergies disappear in 1 to 2 years if the patient carefully avoids the offending food. However, peanut allergy has been reported to persist throughout adulthood in some people (Burks, 2008).

Nursing Management

In addition to participating in management of the allergic reaction, the nurse focuses on preventing future exposure of the patient to the food allergen. If a severe allergic or anaphylactic reaction to food allergens has occurred, the nurse must instruct the patient and family about strategies to prevent its recurrence. The patient is instructed about the im-

portance of carefully assessing foods prepared by others for obvious as well as hidden sources of food allergens and of avoiding locations and facilities where those allergens are likely to be present. This includes careful reading of food labels and monitoring the preparation of food by others to be sure that exposure to even minute amounts of allergenic foods is avoided. The patient and family must be knowledgeable about early signs and symptoms of allergic reactions and must be proficient in emergency administration of epinephrine if a reaction occurs. The nurse also advises the patient to wear a medical alert bracelet or to carry identification and emergency equipment at all times. Patients' food allergies should be noted on their medical records, because there may be risk of allergic reactions not only to food but also to some medications containing similar substances (Bush, 2008). Pregnant women and those who are breastfeeding are instructed to avoid eating peanuts or food containing peanuts to minimize the risk of peanut allergy in their children.

Latex Allergy

Latex allergy, the allergic reaction to natural rubber proteins, has been implicated in rhinitis, conjunctivitis, contact dermatitis, urticaria, asthma, and anaphylaxis. Shortly after 1987, when hospitals and outpatient facilities mandated the use of powdered latex gloves to prevent transmission of infections, some health care workers began to experience numerous adverse reactions (Bernstein, 2006). From 1989 until the mid-1990s, the number of cases steadily increased. However, since that time, the prevalence has been steadily declining, possibly because of the use of nonpowdered latex and latex-free gloves (Rolland & O'Hehir, 2008).

Natural rubber latex is derived from the sap of the rubber tree (*Hevea brasiliensis*). The conversion of the liquid rubber latex into a finished product entails the addition of more than 200 chemicals. The proteins in the natural rubber latex (Hevea proteins) or the various chemicals that are used in the manufacturing process are thought to be the source of the allergic reactions. Not all objects composed of latex have the same ability to stimulate an allergic response. For example, the antigenicity of latex gloves can vary widely depending on the manufacturing method used.

CHART
53-8

HOME CARE CHECKLIST Managing Food Allergies

At the completion of the home care instruction, the patient or caregiver will be able to:	PATIENT	CAREGIVER
• Verbalize understanding of the need to maintain an allergen-free diet.	✓	✓
• Demonstrate reading of food labels to identify hidden allergens in food.	✓	✓
• Identify ways to manage an allergen-free diet when eating away from home.	✓	✓
• State the need to wear a medical alert medallion or bracelet.	✓	✓
• List symptoms of food allergy.	✓	✓
• Demonstrate emergency administration of epinephrine.	✓	✓
• State the importance of replacing epinephrine when outdated.	✓	✓
• State the importance of prompt treatment of allergic reactions and health care follow-up.	✓	✓

Table 53-5 SELECTED PRODUCTS CONTAINING NATURAL RUBBER LATEX AND LATEX-FREE ALTERNATIVES

Products Containing Latex	Examples of Latex-Safe Alternatives*
Hospital Environment	
Ace bandage (brown)	Ace bandage, white all cotton
Adhesive bandages, Band-Aid dressing, Telfa	Cotton pads and plastic or silk tape, Active Strip (3M), Duoderm
Anesthesia equipment	Neoprene anesthesia kit (King)
Blood pressure cuff, tubing, and bladder	Clean Cuff, single-use nylon or vinyl blood pressure cuffs or wrap with stockinette or apply over clothing
Catheters	All-silicone or vinyl catheters
Catheter leg bag straps	Velcro straps
Crutch axillary pads and hand grips, tips	Cover with cloth, tape
ECG pads	Baxter, Red Dot 3M ECG pads
Elastic compression stockings	Kendall SCD stockings with stockinette
Gloves	Dermaprene, Neoprene, polymer, or vinyl gloves
IV catheters	Jelco, Deseret IV catheters
IV rubber injection ports	Cover Y-sites and ports; do not puncture. Use three-way stopcocks on plastic tubing
Levin tube	Salem sump tube
Medication vials	Remove rubber stopper
Penrose drains	Jackson-Pratt, Zimmer hemovac drains
Prepackaged enema kits	Theravac, Fleet Ready-to-use
Pulse oximeters	Nonin oximeters
Resuscitation bags	Laerdal, Puritan Bennett, <i>certain</i> Ambu
Stethoscope tubing	PVC tubing; cover with latex-free stockinette
Syringes—single use (Monoject, B & D)	Terumo syringes, Abbott PCA Abboject
Suction tubing	PVC (Davol, Laerdal)
Tapes	Dermicel, Micropore
Thermometer probes	Diatec probe covers
Tourniquets	X-Tourn straps (Avcor)
Theraband	New Thera-band Exercisers, plastic tubing
Home Environment	
Balloons	Mylar balloons
Diapers, incontinence pads	Huggies, Always, <i>some</i> Attends
Condoms, diaphragms	Polyurethane products, Durex/Avanti and Reality products (female condom)
Feminine hygiene pad	Kimberly-Clark products
Wheelchair cushions	ROHO cushions, Sof Care bed/chair cushions

*Confirmation is essential to verify that all items are latex-free before using, especially if risk of latex allergy is present.

Populations at risk include health care workers, patients with atopic allergies or multiple surgeries, people working in factories that manufacture latex products, females, and patients with spina bifida. Because more food handlers, hairdressers, automobile mechanics, and police often wear latex gloves, they may also be at risk for latex allergy. It is estimated that 1% to 3% of the general population have an allergy to latex and that as many as 10% to 20% of health care workers are sensitized (Rolland & O'Hehir, 2008). Patients are at risk for anaphylactic reactions as a result of contact with latex during medical treatments, especially surgical procedures.

Food that has been handled by people wearing latex gloves may stimulate an allergic response. Cross-reactions have been reported in people who are allergic to certain food products, such as kiwis, bananas, pineapples, mangos, passion fruit, avocados, and chestnuts (Bernstein, 2006).

Routes of exposure to latex products can be cutaneous, percutaneous, mucosal, parenteral, or aerosol. Allergic reactions are more likely with parenteral or mucous membrane exposure but can also occur with cutaneous contact or inhalation (Rolland & O'Hehir, 2008). The most frequent source of exposure is cutaneous, which usually involves the wearing of natural latex gloves. The powder used to facilitate putting on latex gloves can become a carrier of latex proteins from the gloves; when the gloves are put on or removed, the particles become airborne and can be inhaled or settle on skin, mucous membranes, or clothing. Mucosal ex-

posure can occur from the use of latex condoms, catheters, airways, and nipples. Parenteral exposure can occur from IV lines or hemodialysis equipment. In addition to latex-derived medical devices, many household items also contain latex. Examples of medical and household items containing latex and a list of alternative products are found in Table 53-5. It is estimated that more than 40,000 medical devices and nonmedical products contain latex. Even chemical additives used in the manufacture of nonlatex gloves and other items have been associated with allergic symptoms, although these items otherwise have a low potential to stimulate an allergic response (Bernstein, 2006).

Clinical Manifestations

Several different types of reactions to latex are possible (Table 53-6). Irritant contact dermatitis, a nonimmunologic response, may be caused by mechanical skin irritation or an alkaline pH associated with latex gloves. Common symptoms of irritant dermatitis include erythema and pruritus. These symptoms can be eliminated by changing glove brands or by using powder-free gloves. Use of hand lotion before donning latex gloves can worsen the symptoms, because lotions may leach latex proteins from the gloves, increasing skin exposure and the risk of developing true allergic reactions (Bernstein, 2006).

Delayed hypersensitivity to latex, a type IV reaction mediated by T cells in the immune system, is localized to the area of exposure and is characterized by symptoms of

Table 53-6 TYPES OF REACTIONS TO LATEX

Type of Reaction	Cause	Signs/Symptoms	Treatment
Irritant contact dermatitis	Damage to skin because of irritation and loss of epidermoid skin layer; not an allergic reaction. Can be caused by excessive use of soaps and cleansers, multiple handwashings, inadequate hand drying, mechanical irritation (eg, sweating, rubbing inside powdered gloves), exposure to chemicals added during the manufacturing of gloves, and alkaline pH of powdered gloves. Reaction may occur with first exposure, is usually benign, and is not life-threatening.	Acute: redness, edema, burning, discomfort, itching Chronic: dry, thickened, cracked skin	Referral for diagnostic testing Avoidance of exposure to irritant Thorough washing and drying of hands Use of powder-free gloves with more frequent changes of gloves Changing glove types Use of water- or silicone-based moisturizing creams, lotions, or topical barrier agents Avoidance of oil- or petroleum-based skin agents with latex products, because they cause breakdown of the latex product
Allergic contact dermatitis	Delayed hypersensitivity (type IV) reaction. Usually affects only area in contact with latex; reaction is usually to chemical additives used in the manufacturing process rather than to latex itself. Cause of reaction is T cell–mediated sensitization to additives of latex. Reaction is not life-threatening and is far more common than a type I reaction. Slow onset; occurs 18–24 h after exposure. Resolves within 3–4 days after exposure. More severe reactions may occur with subsequent exposures.	Pruritus, erythema, swelling, crusty thickened skin, blisters, other skin lesions	Referral for diagnosis (patch tests) and treatment Thorough washing and drying of hands Use of water- or silicone-based moisturizing creams, lotions, or topical barrier agents Avoidance of oil- or petroleum-based products unless they are latex compatible Avoidance of identified causative agent, because continued exposure to latex products in presence of breaks in skin may contribute to latex protein sensitization
Latex allergy	Type I IgE-mediated immediate hypersensitivity to plant proteins in natural rubber latex. In sensitized people, antilatax IgE antibody stimulates mast cell proliferation and basophil histamine release. Exposure can be through contact with the skin, mucous membranes, or internal tissues, or through inhalation of traces of powder from latex gloves. Severe reactions usually occur shortly after parenteral or mucous membrane exposure. People with any type I reaction to latex are at high risk for anaphylaxis. Local swelling, redness, edema, itching, and systemic reactions, including anaphylaxis, occur within minutes after exposure.	Rhinitis, flushing, conjunctivitis, urticaria, laryngeal edema, bronchospasm, asthma, severe vasodilation, angioedema, anaphylaxis, cardiovascular collapse, death	Immediate treatment of reaction with epinephrine, fluids, vasopressors, and corticosteroids, and airway and ventilator support, with close monitoring for recurrence for next 12–14 h Prompt referral for diagnostic evaluation Treatment and diagnostic evaluation in latex-free environment Assessment of all patients for symptoms of latex allergy Teaching of patients and family members about the disorder and about the importance of preventing future reactions by avoiding latex (eg, wearing medical alert bracelet, carrying EpiPen)

contact dermatitis, including vesicular skin lesions, papules, pruritus, edema, erythema, and crusting and thickening of the skin. These symptoms usually appear on the back of the hands. This reaction is thought to be caused by chemicals that are used in the manufacturing of latex products. It is the most common allergic reaction to latex. Although not usually life-threatening, delayed hypersensitivity reactions often require major changes in the patient's home and work environment to avoid further exposure. People who are sensitized to latex are at increased risk for development of type I allergic reactions (Bernstein, 2006).

Immediate hypersensitivity, a type I allergic reaction, is mediated by the IgE mast cell system. Symptoms can include rhinitis, conjunctivitis, asthma, and anaphylaxis. The term *latex allergy* is usually used to describe the type I reaction. Clinical manifestations have a rapid onset and can include urticaria, wheezing, dyspnea, laryngeal edema, bronchospasm, tachycardia, angioedema, hypotension, and cardiac arrest.

Localized itching, erythema, or local urticaria within minutes after exposure to latex is often the initial symptom. Symptoms of subsequent reactions can include generalized urticaria, angioedema, rhinitis, conjunctivitis, asthma, and anaphylactic shock minutes after dermal or mucosal exposure to latex. An increasing number of people who are allergic to latex experience severe reactions characterized by generalized urticaria, bronchospasm, and hypotension.

Assessment and Diagnostic Findings

The diagnosis of latex allergy is based on the history and diagnostic test results (Rolland & O'Hehir, 2008). Sensitization is detected by skin testing, RAST, ELISA or level of Hevea latex-specific IgE antibody in the serum. Testing for the chemicals found in the rubber production that makes latex is performed using the patch test. Skin patch testing is the preferred method for patients with contact allergies. The TRUE test and other skin tests should be performed only by clinicians who have expertise in their administration

and interpretation and who have the necessary equipment available to treat local or systemic allergic reactions to the reagent. Nasal challenge and dipstick tests may be useful in the future as screening tests for latex allergy.

Medical Management

The best treatment available for latex allergy is the avoidance of latex-based products, but this is often difficult because of their widespread use. Patients who have experienced an anaphylactic reaction to latex should be instructed to wear medical identification. Antihistamines and an emergency kit containing epinephrine should be provided to these patients, along with instructions about emergency management of latex allergy symptoms. Patients should be counseled to notify all health care workers as well as local paramedic and ambulance companies about their allergy. Warning labels can be attached to car windows to alert police and paramedics about the driver's or passenger's latex allergy in case of a motor vehicle crash. People with latex allergy should be provided with a list of alternative products and referred to local support groups; they are also urged to carry their own supply of nonlatex gloves.

People with type I latex sensitivity may be unable to continue to work if a latex-free work environment is not possible. This may occur with surgeons, dentists, operating room personnel, or intensive care nurses. Occupational implications for employees with type IV latex sensitivity are usually easier to manage by changing to nonlatex gloves and avoiding direct contact with latex-based medical equipment. Although latex-specific immunotherapy has been attempted, this method of treatment remains experimental.

Nursing Management

The nurse can assume a pivotal role in the management of latex allergies in both patients and staff. All patients should be asked about latex allergy, although special attention should be given to those at particularly high risk (eg, patients with spina bifida, patients who have undergone multiple surgical procedures). Every time an invasive procedure must be performed, the nurse should consider the possibility of latex allergies. Nurses working in operating rooms, intensive care units, short procedure units, and emergency departments need to pay particular attention to latex allergy. See Chapter 18 for a latex allergy screening form.

Although the type I reaction is the most significant of the reactions to latex, care must be taken in the presence of irritant contact dermatitis and delayed hypersensitivity reaction to avoid further exposure of the person to latex. Patients with latex allergy are advised to notify their health care providers and to wear a medical information bracelet. Patients must become knowledgeable about what products contain latex and what products are safe, nonlatex alternatives. They must also become knowledgeable about signs and symptoms of latex allergy and emergency treatment and self-injection of epinephrine in case of allergic reaction.

Nurses can be instrumental in establishing and participating in multidisciplinary committees to address latex allergy and to promote a latex-free environment. Latex allergy protocols and education of staff about latex allergy and precautions are important strategies to reduce this growing problem and to ensure assessment and prompt treatment of affected people.

CRITICAL THINKING EXERCISES

1 A 23-year-old college student has developed symptoms of severe seafood allergy. She is to receive instructions about self-administration of epinephrine if she experiences anaphylaxis. Develop a teaching plan for her and identify outcomes to measure the effectiveness of your teaching. Given her allergy to seafood, what other teaching or counseling is needed?

EBP 2 A 35-year-old woman has developed symptoms of asthma thought to be an allergic response to the two dogs and two cats her new roommate has brought with her into the apartment. Develop an evidence-based plan for strategies to reduce or eliminate the patient's allergen exposure. Describe the strength of the evidence and criteria used to assess its strength. What instructional strategies and outcome measures will you use to educate her about avoidance strategies and to assess the effectiveness of their use?

3 An 18-year-old man is scheduled for removal of his wisdom teeth in the dentist's office. He reports that he has severe seasonal and bee sting allergies. He also experienced an episode of hives and itching during a dental procedure in the past. He reports that he has had to use emergency epinephrine on several occasions in the past because of severe allergic reactions caused by bee stings. What precautions are needed preprocedure, during the procedure, and postprocedure for this patient to prevent the potential occurrence of a severe allergic reaction? What interventions and nursing management would be indicated if he developed a severe allergic reaction?

chapter 54

Assessment and Management of Patients With Rheumatic Disorders

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

- 1 Explain the pathophysiology of rheumatic diseases.
- 2 Describe the assessment and diagnostic findings seen in patients with a suspected diagnosis of rheumatic disease or disorder.
- 3 Discuss appropriate nursing interventions based on nursing diagnoses and collaborative problems that commonly occur with rheumatic disorders.
- 4 Describe the systemic effects of a connective tissue disease.
- 5 Devise a teaching plan for the patient with newly diagnosed rheumatic disease.
- 6 Identify modifications in interventions to accommodate changes in patients' functional ability that may occur with disease progression.

GLOSSARY

ankylosis: fixation or immobility of a joint

arthritis: inflammation of a joint

arthroplasty: replacement of a joint

osteoarthritis: degenerative joint disease

osteophyte: a bony outgrowth or protuberance; bone spur

pannus: proliferation of newly formed synovial tissue infiltrated with inflammatory cells

rheumatic diseases: numerous disorders affecting skeletal muscles, bones, cartilage, ligaments, tendons, and joints

rheumatoid arthritis: autoimmune disease of unknown origin

subchondral bone: bony plate that supports the articular cartilage

tophi: accumulation of crystalline deposits in articular surfaces, bones, soft tissue, and cartilage

Rheumatic diseases include common disorders such as osteoarthritis (OA) and less common conditions such as systemic lupus erythematosus (SLE) and scleroderma. These conditions can be life-threatening, or they can be minor illnesses. The problems caused by the rheumatic diseases include not only the obvious limitations in mobility and activities of daily living but also the more subtle systemic effects that can lead to organ failure and death or result in problems such as pain, fatigue, altered self-image, and sleep disturbances. The rheumatic disease may be the patient's primary health problem or a secondary diagnosis. An understanding of rheumatic diseases and their effects on a patient's function and well-being is essential to developing an appropriate plan of nursing care.

Rheumatic Diseases

Commonly called **arthritis** (inflammation of a joint) and thought of as one condition, the **rheumatic diseases** are more than 100 different types of disorders that primarily affect skeletal muscles, bones, cartilage, ligaments, tendons, and joints in males and females of all ages (Porth & Matfin, 2009). Some disorders are more likely to occur at a particular time of life or to affect one gender more than the other. The onset of these conditions may be acute or insidious, with a course possibly marked by periods of remission (a period when disease symptoms are reduced or absent) and exacerbation (a period when symptoms occur or increase). Treatment can be simple, aimed at localized relief, or it can be complex, directed toward relief of systemic effects. Permanent changes and disability may result from these disorders.

Nurses need to understand the classification of rheumatic diseases. One basic system is to classify disease as

either monoarticular (affecting a single joint) or polyarticular (affecting multiple joints), and then to further classify it as either inflammatory or noninflammatory. Conditions that may secondarily affect the musculoskeletal structure are also included, illustrating the diversity of the rheumatic diseases.

Pathophysiology

The joint is the area most commonly affected in rheumatic diseases. Despite the diversity of rheumatic diseases, from localized involvement of one joint to systemic, multisystem disorders, they all involve some degree of inflammation and degeneration, which may occur simultaneously. Inflammation is manifested in the joints as synovitis. In inflammatory rheumatic diseases, the primary process is inflammation caused by the immune response. Degeneration occurs as a secondary process, resulting from the effect of **pannus** (proliferation of newly formed synovial tissue infiltrated with inflammatory cells). Conversely, in degenerative rheumatic diseases, inflammation occurs as a secondary process. This synovitis is usually milder, is more likely to be seen in advanced disease, and represents a reactive process.

Inflammation

Inflammation is a series of related steps. In response to the triggering event, (eg, trauma, increased stress), the antigen stimulus activates monocytes and T lymphocytes (also called T cells). Next, the immunoglobulin antibodies form immune complexes with antigens. Phagocytosis of the immune complexes is initiated, generating an inflammatory reaction (joint effusion, pain, and edema) (Fig. 54-1). During the next step, the immune response deviates from normal. Phagocytosis produces chemicals such as leukotrienes and prostaglandins. Leukotrienes contribute to the inflam-

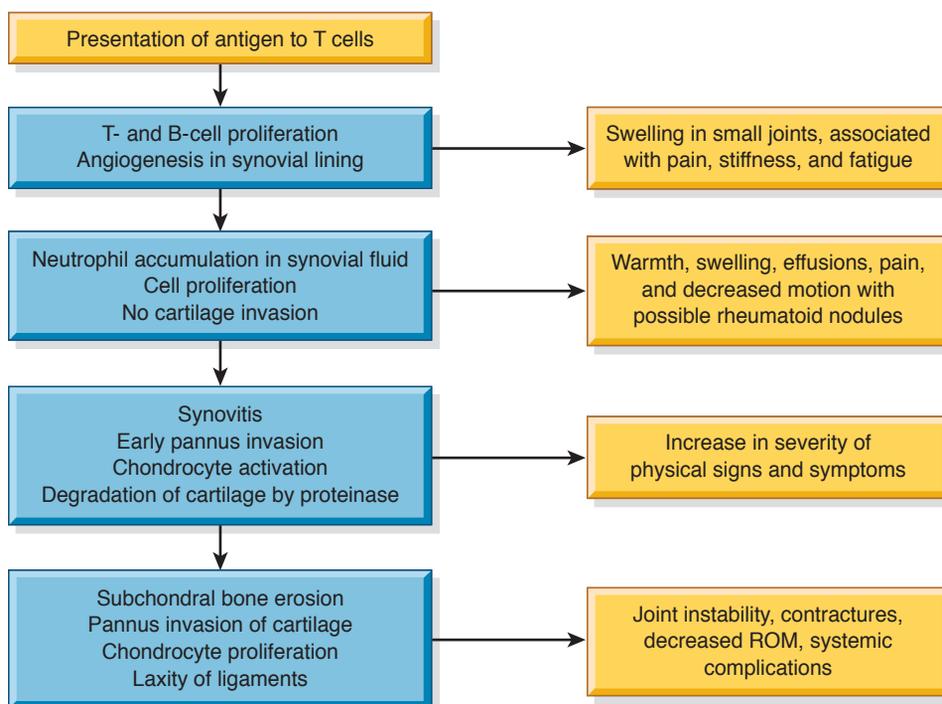

Figure 54-1 Pathophysiology and associated physical signs of rheumatoid arthritis. ROM, range of motion.

matory process by attracting other white blood cells to the area. Prostaglandins act as modifiers to inflammation. In some cases, they increase inflammation; in other cases, they decrease it. Leukotrienes and prostaglandins produce enzymes such as collagenase that break down collagen, a vital part of a normal joint. The release of these enzymes in the joint causes edema, proliferation of synovial membrane and pannus formation, destruction of cartilage, and erosion of bone.

The immunologic inflammatory process begins when antigens are presented to T lymphocytes, leading to a proliferation of T and B cells. B cells are a source of antibody-forming cells, or plasma cells. In response to specific antigens, plasma cells produce and release antibodies. Antibodies combine with corresponding antigens to form pairs, or immune complexes. The immune complexes build up and are deposited in synovial tissue or other organs in the body, triggering the inflammatory reaction that can ultimately damage the involved tissue.

The systemic nature of the rheumatic diseases is reflected in the resultant widespread inflammatory process. Although focused in the joints, inflammation also involves other areas. The blood vessels (vasculitis and arteritis), lungs, heart, and kidneys may also be affected by the inflammation. In the joints, this inflammatory response is manifested as pannus extending throughout the joint space and, if persistent, eroding the articular cartilage, causing secondary degenerative changes to the joint.

Degeneration

Although the cause of degeneration of the articular cartilage is poorly understood, the process is known to be metabolically active and therefore is more accurately called “degradation.” One theory of degradation is that genetic or hormonal influences, mechanical factors, and prior joint damage cause cartilage failure. Degradation of cartilage ensues, and increased mechanical stress on bone ends causes stiffening of bone tissue. Another theory is that bone stiffening occurs and results in increased mechanical stress on cartilage, which in turn initiates the processes of degradation. (See Chapter 66 for more information on the structure and function of the articular system.)

Clinical Manifestations

The most common symptom in the rheumatic diseases that causes a person to seek medical attention is pain. Other common symptoms include joint swelling, limited movement, stiffness, weakness, and fatigue.

Assessment and Diagnostic Findings

Assessment begins with a general health history, which includes the onset of symptoms and how they evolved, family history, past health history, and any other contributing factors. Because many of the rheumatic diseases are chronic conditions, the health history should also include information about the patient’s perception of the problem, previous treatments and their effectiveness, the patient’s support systems, and the patient’s current knowledge base and the source of that information. A complete health history is followed by a complete physical assessment (see Chapter 5).

Assessment for rheumatic diseases combines the physical examination with a functional assessment. Inspection of the patient’s general appearance occurs during initial contact. Gait, posture, and general musculoskeletal size and structure are observed. Gross deformities and abnormalities in movement are noted. The symmetry, size, and contour of other connective tissues, such as the skin and adipose tissue, are also noted and recorded. Chart 54-1 outlines the important areas for consideration during the physical assessment. The functional assessment is a combination of history (what the patient reports that he or she can and cannot do) and examination (observation of activities: the patient demonstrates what he or she can and cannot do, such as dressing and getting in and out of a chair). Observation also includes the adaptations and adjustments the patient may have made (sometimes without awareness); for example, with shoulder or elbow involvement, the person may bend over to reach a fork, rather than raising the fork to the mouth.

The history and physical assessment data are supplemented by supportive or confirming diagnostic test findings. In some instances, tests are used to monitor the course of the disease. For example, the erythrocyte sedimentation rate (ESR) reflects inflammatory activity and, indirectly, the progression or remission of disease.

Laboratory Studies

Some of the most common laboratory studies are listed with their corresponding normal ranges and primary indications in Table 54-1. Many of the tests require special laboratory techniques and may not be performed in every health care facility. The primary health care provider determines which tests are necessary based on symptoms, stage of disease, cost, and likely benefit.

Other Diagnostic Studies

Imaging studies commonly used for patients with rheumatic diseases include x-ray studies, computed tomography (CT) scans and magnetic resonance imaging (MRI) scans, and arthrography. See Chapter 66 for further information about these and other diagnostic studies.

Gerontologic Considerations

Although people of all ages, from infancy through childhood, adolescence, and adulthood, may be affected, rheumatic disease is commonly thought of by the patient, family, and society as a whole as an inevitable consequence of aging. Many older people expect and accept the immobility and self-care problems related to the rheumatic diseases and do not seek help, thinking that nothing can be done. Careful diagnosis and appropriate treatment can improve the quality of life for older people (Schmajuk, Schneeweiss, Katz, et al., 2007).

In elderly patients, other medical conditions may take precedence over the rheumatic disease, which commonly becomes a secondary diagnosis and concern. Identifying the effects of the rheumatic disease on the patient’s lifestyle, independence, and other chronic or acute conditions is important.

The frequency, pattern of onset, clinical features, severity, and effects on function of the rheumatic disease in

Assessing for Rheumatic Disorders

In addition to the head-to-toe assessment or systems review, the following are important areas of consideration to be noted when performing the complete physical assessment of a patient with a known or suspected rheumatic disorder.

Manifestation

Skin (inquire and inspect)

Rash, lesions

Increased bruising

Erythema

Thinning

Warmth

Photosensitivity

Hair (inquire and inspect)

Alopecia or thinning

Eye (inquire and inspect)

Dryness, grittiness

Decreased acuity or blindness

Cataracts

Decreased peripheral vision

Conjunctivitis, uveitis

Ear (inquire)

Tinnitus

Decreased acuity

Mouth (inquire and inspect)

Buccal, sublingual lesions

Altered sense of taste

Dryness

Dysphagia

Difficulty chewing

Chest (inspect and inquire)

Pleuritic pain

Decreased chest expansion

Activity intolerance (dyspnea)

Cardiovascular system (inquire, inspect, palpate)

Blanching of fingers on exposure to cold

Peripheral pulses

Abdomen (inquire and palpate)

Altered bowel habits

Nausea, vomiting, bloating, and pain

Weight change (measure)

Genitalia (inquire and inspect)

Dryness, itching

Abnormal menses

Altered sexual performance

Hygiene

Urethritis, dysuria

Lesions

Significance

Associated with lupus erythematosus (LE), vasculitis, adverse effect of medication

Associated with several rheumatic diseases and adverse effect of medication

Sign of inflammation

Adverse effect of medication

Sign of inflammation

Associated with systemic lupus erythematosus (SLE), dermatomyositis, adverse effect of medication

Associated with rheumatic diseases or adverse effect of medication

Associated with Sjögren's syndrome (commonly occurring with rheumatoid arthritis [RA] and LE)

Associated with temporal arteritis, medication complications

Adverse effect of medication

Adverse effect of medication

Associated with ankylosing spondylitis and Reiter's syndrome

Adverse effect of medication

Adverse effect of medication

Associated with vasculitis, dermatomyositis, adverse effect of medication

Adverse effect of medication

Associated with Sjögren's syndrome

Associated with myositis

Associated with decreased range of motion of jaw

Associated with RA and SLE

Associated with ankylosing spondylitis

Associated with pulmonary hypertension in scleroderma

Associated with Raynaud's phenomenon

Deficit may indicate vascular involvement or edema associated with medication effect or rheumatic diseases, especially SLE or scleroderma

Associated with scleroderma, spondylosis, ulcerative colitis, decreased physical mobility, medication effect

Adverse effect of medication

Associated with RA (decreased), adverse effect of medication (increased or decreased)

Associated with Sjögren's syndrome

Adverse effect of medication

Fear of pain (or of pain caused by partner) and limitation of motion may affect sexual mobility.

Poor hygiene may be related to limitations in activities of daily living.

Associated with ankylosing spondylitis and Reiter's syndrome

Associated with vasculitis

CHART
54-1

Assessing for Rheumatic Disorders (Continued)

Manifestation

Neurologic (inquire and inspect)
Paresthesias of extremities; abnormal reflex pattern

Headaches

Musculoskeletal (inspect and palpate)
Joint redness, warmth, swelling, tenderness, deformity—
location of first joint involved, pattern of progression,
symmetry, acute versus chronic nature
Joint range of motion

Surrounding tissue findings
Muscle atrophy, subcutaneous nodules, popliteal cyst
Muscle strength (grip)

Significance

Nerve compressions associated with carpal tunnel syndrome, spinal stenosis, etc.
Associated with temporal arteritis, adverse effect of medication

Signs of inflammation

Decreased range of motion may indicate severity or progression of disease.

Extra-articular manifestations
Muscle strength decreases with increased disease activity.

elderly patients may be different in very old patients. One disease, OA, is the leading cause of disability and pain in the elderly (Porth & Matfin, 2009). OA may account for more total disability among elderly patients than many diseases (eg, stroke or cancer).

In some instances, the age of the patient and coexisting health problems make diagnosis difficult. A missed diagnosis is not unusual, because it is assumed that older people with joint problems have OA. In addition, it may be difficult to differentiate problems associated with aging from those caused by a rheumatic disease. For example, rheumatoid arthritis (RA), an autoimmune disorder that begins in the later years, has been shown to differ prognostically and therapeutically from RA that begins in childhood or early adulthood. In the older patient with early RA, the onset is more likely to be abrupt, but the clinical course does not appear to differ from that of RA with an insidious onset.

For the elderly person who has had a diffuse connective tissue disease, the risk of osteoporosis is increased. Pain, loss of mobility, diminished self-image, and increasing morbidity can result from progressive osteoporosis. Therefore, diagnosis and treatment of osteoporosis should not be overlooked in this population. Pharmacologic therapy including analgesic agents, exercise, postural assistance, modification of activities of daily living, and psychological support can be useful.

Other conditions (eg, soft tissue problems such as bursitis) usually are not problematic by themselves. However, when combined with other health problems and the normal physiologic processes of aging, these conditions may significantly affect the patient's quality of life. In fact, the effects of most forms of rheumatic disease may lead to considerable changes in the patient's lifestyle, possibly threatening his or her independence. Decreased vision and altered balance, often present in elderly people, may be problematic if rheumatic disease in the lower extremities affects locomotion. Also, the combination of decreased hearing and visual acuity, memory loss, and depression contributes to failure to follow the treatment regimen in elderly patients. Special techniques for promoting patient safety, self-management, and strategies such as memory aids for medications may be necessary.

Partly because of the more frequent contact of older adults with health care providers for a variety of health issues, overtreatment or inappropriate treatment is possible. Complaints of pain may be met with a prescription for an opioid analgesic agent rather than instructions for rest, use of an assistive device, and local comfort measures such as heat or cold. Acetaminophen may be appropriate and worth trying before other medications that pose a greater chance of side effects. Intra-articular corticosteroid injections, with their usually rapid relief of symptoms, may be requested by the patient who is unaware of the consequences of too-frequent use of this treatment. In addition, exercise programs may not be instituted or may be ineffective because the patient expects results to occur quickly or fails to appreciate the effectiveness of a program of exercise.

Pharmacologic treatment of rheumatic disease in older patients is more difficult than it is in younger patients. If therapeutic medications have an effect on the senses (hearing, cognition), this effect is intensified in the elderly. The cumulative effect of these medications is accentuated because of the physiologic changes of aging. For example, decreased renal function in the elderly alters the metabolism of certain medications, such as nonsteroidal anti-inflammatory drugs (NSAIDs). Older adults are more prone to side effects associated with the use of multiple-drug therapy for various disorders (Miller, 2009).

Elderly patients with rheumatic disease may unnecessarily accept or endure pain, loss of ambulation, and difficulty with activities of daily living. The need to view oneself as capable of managing life independently despite increasing age may take considerable energy. The body image and self-esteem of the elderly person with rheumatic disease, combined with underlying depression, may interfere with the use of assistive devices such as canes. Use of adaptive equipment such as long-handled reachers or tongs may be viewed as evidence of aging rather than as a means of increasing independence.

The elderly person usually has a lifelong pattern of dealing with the stresses of daily life. Depending on the success of that pattern, the elderly person can often maintain a

Table 54-1 COMMON BLOOD STUDIES FOR RHEUMATIC DISEASES

Test	Normal Value	Significance
Serum		
<i>Creatinine</i>		
Metabolic waste excreted through the kidneys	0.6–1.2 mg/dL (50–110 μ mol/L)	Increase may indicate renal damage in SLE, scleroderma, and polyarteritis.
<i>Erythrocyte Sedimentation Rate (ESR)</i>		
Measures the rate at which red blood cells settle out of unclotted blood in 1 h	Westergren = Men, 0–15 mm/h, Women, 0–25 mm/h Wintrobe = Men, 0–9 mm/h, Women 0–15 mm/h	Increase is usually seen in inflammatory connective tissue diseases. An increase indicates rising inflammation, resulting in clustering of RBCs, which makes them heavier than normal. The higher the ESR, the greater the inflammatory activity.
<i>Hematocrit</i>		
Measures the size, capacity, and number of cells present in blood	Men: 42–52% Women: 35–47%	Decrease can be seen in chronic inflammation (anemia of chronic disease); also, blood loss through bowel due to medication.
<i>Red Blood Cell Count</i>		
Measures circulating erythrocytes	Men: Average 4.8 million/ μ L Women: Average 4.3 million/ μ L	Decrease can be seen in RA, SLE.
<i>White Blood Cell Count</i>		
Measures circulating leukocytes	5000–10,000 cells/mm ³	Decrease may be seen in SLE.
<i>VDRL (Venereal Disease Research Laboratory)</i>		
Measures antibody to syphilis	Nonreactive	False-positive results are sometimes found with SLE.
<i>Uric Acid</i>		
Measures level of uric acid in serum	2.5–8 mg/dL (0.15–0.5 mmol/L)	Increase is seen with gout.
Serum Immunology		
<i>Antinuclear Antibody (ANA)</i>		
Measures antibodies that react with a variety of nuclear antigens If antibodies are present, further testing determines the type of ANA circulating in the blood (anti-DNA, anti-RNP).	Negative A few healthy adults have a positive ANA.	Positive test is associated with SLE, RA, scleroderma, Raynaud's disease, Sjögren's syndrome, necrotizing arteritis. The higher the titer, the greater the inflammation. The pattern of immunofluorescence (speckled, homogeneous, or nucleolar) helps determine the diagnosis.
<i>Anti-DNA, DNA Binding</i>		
Titer measurement of antibody to double-stranded DNA	Negative	High titer is seen in SLE; increases in titer may indicate increase in disease activity.
<i>Complement Levels—C3, C4</i>		
Complement is a protein substance that binds with antigen–antibody complexes for the purpose of lysis. When the number of complexes increases markedly, complement is used for lysis, thus depleting the amount available in the blood.	C3: 55–120 mg/dL (550–1200 mg/L) C4: 11–40 mg/dL (110–400 mg/L)	Decrease may be seen in RA and SLE. Decrease indicates autoimmune and inflammatory activity.
<i>C-Reactive Protein Test (CRP)</i>		
Shows presence of abnormal glycoprotein due to inflammatory process	<1 mg/dL (<10 mg/L)	A positive reading indicates active inflammation. Often is positive for RA and SLE
<i>Immunoglobulin Electrophoresis</i>		
Measures the values of immunoglobulins	IgA 80–400 mg/dL (0.8–4.0 g/L) IgG 600–1800 mg/dL (6.0–18.0 g/L) IgM 55–250 mg/dL (0.55–2.5 g/L)	Increased levels are found in people who have autoimmune disorders.
<i>Rheumatoid Factor (RF)</i>		
Determines the presence of abnormal antibodies seen in connective tissue disease	Negative	Positive titer >1:80 Present in 80% of those with RA Positive RF may also suggest SLE, Sjögren's syndrome, or mixed connective tissue disease. The higher the titer (number at right of colon), the greater the inflammation.
Tissue Typing		
<i>HLA-B27 Antigen</i>		
Measures presence of HLA antigens, which are used for tissue recognition	Negative	Found in 80–90% of those with ankylosing spondylitis and Reiter's syndrome.

DNA, deoxyribonucleic acid; HLA, human leukocyte antigen; RA, rheumatoid arthritis; RBCs, red blood cells; RNP, ribonucleoprotein; SLE, system lupus erythematosus.

positive attitude and self-esteem when faced with a rheumatic disease, especially if support is available. Previous stress management strategies are assessed. If these strategies have been effective, the patient is encouraged and supported in their use. If they were ineffective, the nurse assists the patient in identifying alternative strategies, encourages use of new strategies, and assesses their effectiveness.

Medical Management

A treatment program involving an interdisciplinary team, including the patient, is the basis for managing the rheumatic diseases. The chronic nature of most of these diseases mandates that the patient understand the disease, have the information necessary to make good self-management decisions, and be presented with a therapeutic program that is compatible with his or her lifestyle. Table 54-2 outlines goals and strategies for care of the patient with rheumatic diseases.

Pharmacologic Therapy

Medications are used with the rheumatic diseases to manage symptoms, to control inflammation, and, in some instances, to modify the disease. Useful medications include the salicylates, NSAIDs, and disease-modifying antirheumatic drugs (DMARDs). Table 54-3 reviews the medications commonly used.

Controlling the inflammation related to the disease process helps manage pain, but this is often a delayed response. Nonopioid medications are often used for pain management, especially early in the treatment program, until other measures can be instituted. Short-term use of low-dose antidepressant medications, such as amitriptyline (Elavil), may be prescribed to reestablish adequate sleep patterns and improve pain management (Karch, 2008).

Nonpharmacologic Pain Management

Nonpharmacologic methods of pain management are important. Heat applications are also helpful in relieving pain, stiff-

ness, and muscle spasm (Robinson, Brosseau, Casimiro, et al., 2006). Superficial heat may be applied in the form of warm tub baths or showers and warm moist compresses. Paraffin baths (dips), which offer concentrated heat, are helpful to patients with wrist and small-joint involvement. Maximum benefit is achieved within 20 minutes after application. More frequent use for shorter lengths of time is most beneficial. Therapeutic exercises can be carried out more comfortably and effectively after heat has been applied.

Devices such as braces, splints, and assistive devices for ambulation (eg, canes, crutches, walkers) ease pain by limiting movement or stress from putting weight on painful joints. Acutely inflamed joints can be rested by applying splints to limit motion. Splints also support the joint to relieve spasm. Canes and crutches can relieve stress from inflamed and painful weight-bearing joints while promoting safe ambulation. Cervical collars may be used to support the weight of the head and limit cervical motion. A metatarsal bar or special pads may be put into the patient’s shoes if foot pain or deformity is present (Egan, Brosseau, Farmer, et al., 2006). A combination of methods may be required, because different methods often work better at different times.

Exercise and Activity

The ongoing nature of most rheumatic diseases makes it important to maintain and, when possible, improve joint mobility and overall functional status. An individualized exercise program is crucial to movement. Table 54-4 summarizes the exercises appropriate for patients with rheumatic diseases. Appropriate programs of exercise have been shown to decrease pain and improve function (Miller, 2009). A mild analgesic agent may be suggested before exercise for a patient starting a program of exercise. Other strategies for decreasing pain include muscle relaxation techniques, imagery, self-hypnosis, and distraction, but acute or prolonged pain associated with exercise should be reported to a health care provider for evaluation. A weight reduction program may be recommended to relieve stress on painful joints.

The major challenge for the patient and the health care provider is the need to adjust all aspects of treatment according to the activity of the disease. Especially for the patient with an active diffuse connective tissue disease, such as RA or SLE, activity levels may vary from day to day and even within a single day.

Sleep

It is important to help the patient obtain restful sleep so he or she can cope with pain, minimize physical fatigue, and deal with the changes related to having a chronic disease. In patients with acute disease, sleep time is frequently reduced and fragmented by prolonged awakenings. Stiffness, depression, and medications may also compromise the quality of sleep and increase daytime fatigue. A sleep-inducing routine, medication, and comfort measures may help improve the quality of sleep.

Teaching sleep hygiene strategies may be helpful in promoting restorative sleep. These strategies include establishing a set time to sleep and a regular wake-up time, creating a quiet sleep environment with a comfortable room temperature,

Table 54-2 MANAGEMENT GOALS AND STRATEGIES FOR RHEUMATIC DISEASES

Goals	Management Strategies
Suppress inflammation and the autoimmune response	Optimize pharmacologic therapy (anti-inflammatory and disease-modifying agents)
Control pain	Protect joints; ease pain with splints, thermal modalities, relaxation techniques
Maintain or improve joint mobility	Implement exercise programs for joint motion and muscle strengthening and overall health
Maintain or improve functional status	Make use of adaptive devices and techniques
Increase patient’s knowledge of disease process	Provide and reinforce patient teaching
Promote self-management by patient compliance with the therapeutic regimen	Emphasize compatibility of therapeutic regimen and lifestyle

Table 54-3 MEDICATIONS USED IN RHEUMATIC DISEASES

Medication	Action, Use, and Indication	Nursing Considerations
Salicylates Acetylated: aspirin Nonacetylated: choline salicylate (Arthropan, Trilisate), salsalate (Disalcid), sodium salicylate	<i>Action:</i> anti-inflammatory, analgesic, antipyretic Acetylated salicylates are platelet aggregation inhibitors. Anti-inflammatory doses will produce blood salicylate levels of 20–30 mg/dL.	Administer with meals to prevent gastric irritation. Assess for tinnitus, gastric intolerance, GI bleeding, and purpura. Monitor for possible confusion in the elderly.
Nonsteroidal Anti-inflammatory Drugs (NSAIDs) diclofenac (Voltaren), diflunisal (Dolobid), etodolac (Lodine), flurbiprofen (Ansaid), ibuprofen (Motrin), indomethacin (Indocin), ketoprofen (Orudis, Oruvail), meclufenamate (Meclomen), meloxicam (Mobic), nabumetone (Relafen), naproxen (Naprosyn), oxaprozin (Daypro), piroxicam (Feldene), sulindac (Clinoril), tolmetin sodium (Tolectin) COX-2 enzyme blockers: celecoxib (Celebrex)	<i>Action:</i> anti-inflammatory, analgesic, antipyretic, platelet aggregation inhibitor Anti-inflammatory effect occurs 2–4 weeks after initiation. All NSAIDs are useful for short-term treatment of acute gout attack. NSAIDs are alternative to salicylates for first-line therapy in several rheumatic diseases. <i>Action:</i> Inhibit only cyclo-oxygenase-2 (COX-2) enzymes, which are produced during inflammation, and spare COX-1 enzymes, which can be protective to the stomach	Administer NSAIDs with food. Monitor for GI, CNS, cardiovascular, renal, hematologic, and dermatologic adverse effects. Avoid salicylates; use acetaminophen for additional analgesia. Watch for possible confusion in older adults. Monitoring the same as for other NSAIDs Increased risk of cardiovascular events, including myocardial infarction and stroke Appropriate for the elderly and patients who are at high risk for gastric ulcers
Disease-Modifying Antirheumatic Drugs (DMARDs) Antimalarials: hydroxychloroquine (Plaquenil), chloroquine (Aralen)	<i>Action:</i> Anti-inflammatory, inhibits lysosomal enzymes Slow-acting, onset may take 2–4 mo Useful in RA and SLE	Administer concurrently with NSAIDs. Assess for visual changes, GI upset, skin rash, headaches, photosensitivity, bleaching of hair. Emphasize need for ophthalmologic examinations (every 6–12 mo).
Gold-containing compounds: aurothioglucose (Solganal), gold sodium thiomalate (Myochrysin), auranofin (Ridaura)	<i>Action:</i> Inhibits T- and B-cell activity, suppresses synovitis during active stage of rheumatoid disease Slow-acting, onset may take 3–6 mo IM preparations are given weekly for about 6 mo, then every 2–4 weeks	Administer concurrently with NSAIDs. Assess for stomatitis, diarrhea, dermatitis, proteinuria, hematuria, bone marrow suppression (decreased WBCs and/or platelets), CBC, and urinalysis with every other injection.
sulfasalazine (Azulfidine)	<i>Action:</i> Anti-inflammatory, reduces lymphocyte response, inhibits angiogenesis Useful in RA, seronegative spondyloarthropathies	Administer concurrently with NSAIDs. Do not use in patients with allergy to sulfa medications or salicylates. Emphasize adequate fluid intake. Assess for GI upset, skin rash, headache, liver abnormalities, anemia.
penicillamine (Cuprimine, Depen)	<i>Action:</i> Anti-inflammatory, inhibits T-cell function, impairs antigen presentation Slow-acting, onset may take 2–3 mo Useful in RA and systemic sclerosis	Administer concurrently with NSAIDs. Assess for GI irritation, decreased taste, skin rash or itching, bone marrow suppression, proteinuria with CBC, and urinalysis every 2–4 weeks.
Immunosuppressives: methotrexate (Rheumatrex), azathioprine (Imuran), cyclophosphamide (Cytosan)	<i>Action:</i> Immune suppression, affect DNA synthesis and other cellular effects Have teratogenic potential; azathioprine and cyclophosphamide reserved for more aggressive or unresponsive disease Methotrexate is “gold standard” for RA treatment; also useful in SLE.	Assess for bone marrow suppression, GI ulcerations, skin rashes, alopecia, bladder toxicity, increased infections. Monitor CBC, liver enzymes, creatinine every 2–4 weeks. Advise patient of contraceptive measures because of teratogenicity.
Cyclosporine (Neoral)	<i>Action:</i> Immune suppression by inhibiting T lymphocytes Used for severe, progressive RA, unresponsive to other DMARDs Used in combination with methotrexate	Assess slow dose titration upward until response noted or toxicity occurs. Assess for toxic effects: bleeding gums, fluid retention, hair growth, tremors. Monitor blood pressure and creatinine every 2 weeks until stable.
Immunomodulators Pyrimidine synthesis inhibitor: leflunomide (Arava)	<i>Action:</i> Has antiproliferative and anti-inflammatory effects. Used in moderate to severe RA May be used alone or in combination with other DMARDs (except methotrexate)	Long half-life; requires loading dose followed by daily administration. Assess for diarrhea, hair loss, skin rash, mouth sores. Monitor liver function tests. Contraindicated in pregnancy and breastfeeding Administered orally

Continued

Table 54-3 MEDICATIONS USED IN RHEUMATIC DISEASES (Continued)

Medication	Action, Use, and Indication	Nursing Considerations
TNF blocking agents: adalimumab (Humira), etanercept (Enbrel), infliximab (Remicade), golimumab (Simponi)	<i>Action:</i> Biologic response modifier that binds to TNF, a cytokine involved in inflammatory and immune responses. Used in moderate to severe RA unresponsive to methotrexate. Can be used alone or with methotrexate or other DMARDs. Humira is administered every 1–2 weeks, and Enbrel is administered twice a week.	Patient should be tested for tuberculosis before beginning this medication. Teach patient subcutaneous self-injection of adalimumab (Humira) or etanercept (Enbrel). Infliximab (Remicade) is administered by IV line over 2 h or more. Medication must be refrigerated. Monitor for injection site reactions. Educate patient about increased risk for infection and to withhold medication if fever occurs.
Interleukin-1 receptor antagonist: anakinra (Kineret)	<i>Action:</i> Human interleukin-1 (IL-1) receptor antagonist; blocks IL-1 receptors, decreasing inflammatory and immunologic responses. Used in moderate to severe RA unresponsive to methotrexate. Can be used alone or with methotrexate or DMARDs other than TNF blocking agents	Administered daily by subcutaneous injection. Teach patient subcutaneous self-injection to be administered daily. Medication must be refrigerated. Monitor for injection site reactions. Educate patient about increased risk of infection and to withhold medication if fever occurs.
Corticosteroids: prednisone, prednisolone, hydrocortisone	<i>Action:</i> Anti-inflammatory Used for shortest duration and at lowest dose possible to minimize adverse effects Useful for unremitting RA, SLE, polymyalgia rheumatica, myositis, arteritis Fast-acting; onset in days Intra-articular injections useful for joints unresponsive to NSAIDs	Assess for toxicity: cataracts, GI irritation, hyperglycemia, hypertension, fractures, avascular necrosis, hirsutism, psychosis. Joints most amenable to injections include ankles, knees, hips, shoulders, and hands. Repeated injections can cause joint damage.
Topical Analgesics capsaicin (Zostrix)	<i>Action:</i> analgesic	Teach patient to apply sparingly, avoid areas of open skin, avoid contact with eyes and mucous membranes. Wash hands carefully after application. Assess for local skin irritation.

CBC, complete blood count; CNS, central nervous system; GI, gastrointestinal; RA, rheumatoid arthritis; TNF, tumor necrosis factor; SLE, systemic lupus erythematosus; WBCs, white blood cells.

avoiding factors that interfere with sleep (eg, use of alcohol and caffeine), using relaxation exercises, and getting out of bed and engaging in another activity (eg, reading) if unable to sleep (Bulechek, Butcher & Dochterman, 2008).

Nursing Management

The plan of nursing care in Chart 54-2 details the nursing diagnoses, interventions, and expected outcomes for the patient with a rheumatic disorder.

Table 54-4 EXERCISE TO PROMOTE MOBILITY

Type of Exercise	Purpose	Recommended Performance	Precautions
Range of motion	Maintain flexibility and joint motion	Active or active/self-assisted at least daily	Reduce number of repetitions when inflammation is present.
Isometric exercise	Improve muscle tone, static endurance, and strength; prepare for dynamic and weight-bearing exercises	Perform at 70% of maximal voluntary contraction daily.	Monitor blood pressure: isometric exercises may increase blood pressure and decrease blood flow to muscles.
Dynamic exercise	Maintain or increase dynamic strength and endurance; increase muscle power; enhance synovial blood flow; promote strength of bone and cartilage	Start with repetitions against gravity and add progressive resistance; perform 2–3 days per week.	May increase biomechanical stress on unstable or misaligned joints
Aerobic exercise	Improve cardiovascular fitness and endurance	Perform 3–5 days per week for 20–30 min of moderate-intensity exercise.	Progress slowly as activity tolerance and fitness improve.
Pool exercise	Water supports or resists movement; warm water may provide muscle relaxation.	Provides buoyant medium for performance of dynamic or aerobic exercise	Heated swimming pool; deep water to minimize joint compression; nonslip footwear for safety and comfort; receive appropriate instruction in a program designed for people with arthritis

Adapted from Firestein, G. S., Panayi, G. S. & Willheim, F. A. (2006). *Rheumatoid arthritis*. Oxford, UK: Oxford University Press.

 CHART
54-2

PLAN OF NURSING CARE
Care of the Patient With a Rheumatic Disorder

NURSING DIAGNOSIS: Acute and chronic pain related to inflammation and increased disease activity, tissue damage, fatigue, or lowered tolerance level

GOAL: Improvement in comfort level; incorporation of pain management techniques into daily life

Nursing Interventions

1. Provide variety of comfort measures
 - a. Application of heat or cold
 - b. Massage, position changes, rest
 - c. Foam mattress, supportive pillow, splints
 - d. Relaxation techniques, diversional activities
2. Administer anti-inflammatory, analgesic, and slow-acting antirheumatic medications as prescribed.
3. Individualize medication schedule to meet patient's need for pain management.
4. Encourage verbalization of feelings about pain and chronicity of disease.
5. Teach pathophysiology of pain and rheumatic disease, and assist patient to recognize that pain often leads to unproven treatment methods.
6. Assist in identification of pain that leads to use of unproven methods of treatment.
7. Assess for subjective changes in pain.

Rationale

1. Pain may respond to nonpharmacologic interventions such as joint protection, exercise, relaxation, and thermal modalities.
2. Pain of rheumatic disease responds to individual or combination medication regimens.
3. Previous pain experiences and management strategies may be different from those needed for persistent pain.
4. Verbalization promotes coping.
5. Knowledge of rheumatic pain and appropriate treatment may help patient avoid unsafe, ineffective therapies.
6. The impact of pain on an individual's life often leads to misconceptions about pain and pain management techniques.
7. The individual's description of pain is a more reliable indicator than objective measurements such as change in vital signs, body movement, and facial expression.

Expected Outcomes

- Identifies factors that exacerbate or influence pain response
- Identifies and uses pain management strategies
- Verbalizes decrease in pain
- Reports signs and symptoms of side effects in timely manner to prevent additional problems
- Verbalizes that pain is characteristic of rheumatic disease
- Establishes realistic pain relief goals
- Verbalizes that pain often leads to the use of nontraditional and unproven self-treatment methods
- Identifies changes in quality or intensity of pain

NURSING DIAGNOSIS: Fatigue related to increased disease activity, pain, inadequate sleep/rest, deconditioning, inadequate nutrition, and emotional stress/depression

GOAL: Incorporates as part of daily activities strategies necessary to modify fatigue

Nursing Interventions

1. Provide instruction about fatigue.
 - a. Describe relationship of disease activity to fatigue.
 - b. Describe comfort measures while providing them.
 - c. Develop and encourage a sleep routine (warm bath and relaxation techniques that promote sleep).
 - d. Explain importance of rest for relieving systematic, articular, and emotional stress.
 - e. Explain how to use energy conservation techniques (pacing, delegating, setting priorities).
 - f. Identify physical and emotional factors that can cause fatigue.
2. Facilitate development of appropriate activity/rest schedule.

Rationale

1. The patient's understanding of fatigue will affect his or her actions.
 - a. The amount of fatigue is directly related to the activity of the disease.
 - b. Relief of discomfort can relieve fatigue.
 - c. Effective bedtime routine promotes restorative sleep.
 - d. Different kinds of rest are needed to relieve fatigue and are based on patient need and response.
 - e. A variety of measures can be used to conserve energy.
 - f. Awareness of the various causes of fatigue provides the basis for measures to modify the fatigue.
2. Alternating rest and activity conserves energy while allowing most productivity.

Expected Outcomes

- Self-evaluates and monitors fatigue pattern
- Verbalizes the relationship of fatigue to disease activity
- Uses comfort measures as appropriate
- Practices effective sleep hygiene and routine
- Makes use of various assistive devices (splints, canes) and strategies (bed rest, relaxation techniques) to ease different kinds of fatigue
- Incorporates time management strategies in daily activities
- Uses appropriate measures to prevent physical and emotional fatigue
- Has an established plan to ensure well-paced, therapeutic activity schedule
- Adheres to therapeutic program
- Follows a planned conditioning program

Continued

CHART
54-2

PLAN OF NURSING CARE

Care of the Patient With a Rheumatic Disorder (Continued)

Nursing Interventions	Rationale	Expected Outcomes
<ol style="list-style-type: none"> 3. Encourage adherence to the treatment program. 4. Refer to and encourage a conditioning program. 5. Encourage adequate nutrition, including source of iron from food and supplements. 	<ol style="list-style-type: none"> 3. Overall control of disease activity can decrease the amount of fatigue. 4. Deconditioning resulting from lack of mobility, understanding, and disease activity contributes to fatigue. 5. A nutritious diet can help counteract fatigue. 	<ul style="list-style-type: none"> • Consumes a nutritious diet consisting of appropriate food groups and recommended daily allowance of vitamins and minerals

NURSING DIAGNOSIS: Impaired physical mobility related to decreased range of motion, muscle weakness, pain on movement, limited endurance, lack of or improper use of ambulatory devices
GOAL: Attains and maintains optimal functional mobility

Nursing Interventions	Rationale	Expected Outcomes
<ol style="list-style-type: none"> 1. Encourage verbalization regarding limitations in mobility. 2. Assess need for occupational or physical therapy consultation: <ol style="list-style-type: none"> a. Emphasize range of motion of affected joints. b. Promote use of assistive ambulatory devices. c. Explain use of safe footwear. d. Use individual appropriate positioning/posture. 3. Assist to identify environmental barriers. 4. Encourage independence in mobility and assist as needed. <ol style="list-style-type: none"> a. Allow ample time for activity. b. Provide rest period after activity. c. Reinforce principles of joint protection and work simplification. 5. Initiate referral to community health agency. 	<ol style="list-style-type: none"> 1. Mobility is not necessarily related to deformity. Pain, stiffness, and fatigue may temporarily limit mobility. The degree of mobility is not synonymous with the degree of independence. Decreased mobility may influence a person's self-concept and lead to social isolation. 2. Therapeutic exercises, proper footwear, and/or assistive equipment may improve mobility. Correct posture and positioning are necessary for maintaining optimal mobility. 3. Furniture and architectural adaptations may enhance mobility. 4. Changes in mobility may lead to a decrease in personal safety. 5. The degree of mobility may be slow to improve or may not improve with intervention. 	<ul style="list-style-type: none"> • Identifies factors that interfere with mobility • Describes and uses measures to prevent loss of motion • Identifies environmental (home, school, work, community) barriers to optimal mobility • Uses appropriate techniques and/or assistive equipment to aid mobility • Identifies community resources available to assist in managing decreased mobility

NURSING DIAGNOSIS: Self-care deficits related to contractures, fatigue, or loss of motion
GOAL: Achieves self-care independently or with the use of resources

Nursing Interventions	Rationale	Expected Outcomes
<ol style="list-style-type: none"> 1. Assist patient to identify self-care deficits and factors that interfere with ability to perform self-care activities. 2. Develop a plan based on the patient's perceptions and priorities on how to establish and achieve goals to meet self-care needs, incorporating joint protection, energy conservation, and work simplification concepts. <ol style="list-style-type: none"> a. Provide appropriate assistive devices. b. Reinforce correct and safe use of assistive devices. 	<ol style="list-style-type: none"> 1. The ability to perform self-care activities is influenced by the disease activity and the accompanying pain, stiffness, fatigue, muscle weakness, loss of motion, and depression. 2. Assistive devices may enhance self-care abilities. Effective planning for changes must include the patient, who must accept and adopt the plan. 	<ul style="list-style-type: none"> • Identifies factors that interfere with the ability to perform self-care activities • Identifies alternative methods for meeting self-care needs • Uses alternative methods for meeting self-care needs • Identifies and uses other health care resources for meeting self-care needs

Continued on following page

 CHART
54-2

PLAN OF NURSING CARE
Care of the Patient With a Rheumatic Disorder (Continued)

Nursing Interventions	Rationale	Expected Outcomes
c. Allow patient to control timing of self-care activities. d. Explore with the patient different ways to perform difficult tasks or ways to enlist the help of someone else. 3. Consult with community health care agencies when individuals have attained a maximum level of self-care yet still have some deficits, especially regarding safety.	3. Individuals differ in ability and willingness to perform self-care activities. Changes in ability to care for self may lead to a decrease in personal safety.	
NURSING DIAGNOSIS: Disturbed body image related to physical and psychological changes and dependency imposed by chronic illness GOAL: Adapts to physical and psychological changes imposed by the rheumatic disease		
Nursing Interventions	Rationale	Expected Outcomes
1. Help patient identify elements of control over disease symptoms and treatment. 2. Encourage patient's verbalization of feelings, perceptions, and fears. <ol style="list-style-type: none"> Help to assess present situation and identify problems. Assist to identify past coping mechanisms. Assist to identify effective coping mechanisms. 	1. The individual's self-concept may be altered by the disease or its treatment. 2. NURSING DIAGNOSIS: Ineffective coping related to actual or perceived lifestyle or role changes GOAL: Use of effective coping behaviors for dealing with actual or perceived limitations and role changes		
Nursing Interventions	Rationale	Expected Outcomes
1. Identify areas of life affected by disease. Answer questions and dispel possible myths. 2. Develop plan for managing symptoms and enlisting support of family and friends to promote daily function.	1. The effects of disease may be more or less manageable once identified and explored reasonably. 2. By taking action and involving others appropriately, patient develops or draws on coping skills and community support.	<ul style="list-style-type: none"> Names functions and roles affected and not affected by disease process Describes therapeutic regimen and states actions to take to improve, change, or accept a particular situation, function, or role
COLLABORATIVE PROBLEMS: Complications secondary to effects of medications GOAL: Absence or resolution of complications		
Nursing Interventions	Rationale	Expected Outcomes
1. Perform periodic clinical assessment and laboratory evaluation. 2. Instruct in correct self-administration, potential side effects, and importance of monitoring. 3. Counsel regarding methods to reduce side effects and manage symptoms. 4. Administer medications in modified doses as prescribed if complications occur.	1. Skillful assessment helps detect early symptoms of side effects of medications. 2. The patient needs accurate information about medications and potential side effects to avoid or manage them. 3. Appropriate identification and early intervention may minimize complications. 4. Modifications may help minimize side effects or other complications.	<ul style="list-style-type: none"> Complies with monitoring procedures and experiences minimal side effects Takes medication as prescribed and lists potential side effects Identifies strategies to reduce or manage side effects Reports that side effects or complications have subsided

Diffuse Connective Tissue Diseases

Diffuse connective tissue disease refers to a group of systematic disorders that are chronic in nature and are characterized by diffuse inflammation and degeneration in the connective tissues. These disorders share similar clinical features and may affect some of the same organs. The characteristic clinical course is one of exacerbations and remissions. Although the diffuse connective tissue diseases have unknown causes, they are thought to be the result of immunologic abnormalities. They include **rheumatoid arthritis** (RA), SLE, scleroderma, polymyositis, and polymyalgia rheumatica.

RHEUMATOID ARTHRITIS

RA is an autoimmune disease of unknown origin that affects 1% of the population worldwide, with a female-to-male ratio between 2:1 and 4:1 (Khanna, Arnold, Pencharz, et al., 2006).

Pathophysiology

In RA, the autoimmune reaction (Fig. 54-1) primarily occurs in the synovial tissue. Phagocytosis produces enzymes within the joint. The enzymes break down collagen, causing edema, proliferation of the synovial membrane, and ultimately pannus formation. Pannus destroys cartilage and erodes the bone. The consequence is loss of articular surfaces and joint motion. Muscle fibers undergo degenerative changes. Tendon and ligament elasticity and contractile power are lost.

Clinical Manifestations

Clinical manifestations of RA vary, usually reflecting the stage and severity of the disease. Joint pain, swelling, warmth, erythema, and lack of function are classic symptoms. Palpation of the joints reveals spongy or boggy tissue. Often fluid can be aspirated from the inflamed joint. Characteristically, the pattern of joint involvement begins in the small joints of the hands, wrists, and feet (Bickley, 2007). As the disease progresses, the knees, shoulders, hips, elbows, ankles, cervical spine, and temporomandibular joints are affected. The onset of symptoms is usually acute. Symptoms are usually bilateral and symmetric. In addition to joint pain and swelling, another classic sign of RA is joint stiffness in the morning.

In the early stages of disease, even before bony changes occur, limitation in function can occur when there is active inflammation in the joints. Joints that are hot, swollen, and painful are not easily moved. The patient tends to guard or protect these joints by immobilizing them. Immobilization for extended periods can lead to contractures, creating soft tissue deformity.

Deformities of the hands and feet are common in RA (see Chapter 66, Fig. 66-6). The deformity may be caused by misalignment resulting from swelling, progressive joint destruction, or the subluxation (partial dislocation) that occurs when one bone slips over another and eliminates the joint space.

RA is a systemic disease with multiple extra-articular features. Most common are fever, weight loss, fatigue, ane-

mia, lymph node enlargement, and Raynaud's phenomenon (cold- and stress-induced vasospasm causing episodes of digital blanching or cyanosis). Rheumatoid nodules may be noted in patients with more advanced RA, and they develop at some time in the course of the disease in about 25% of patients. These nodules are usually nontender and movable in the subcutaneous tissue. They usually appear over bony prominences such as the elbow, are varied in size, and can disappear spontaneously. Nodules occur only in people who have rheumatoid factor. The nodules often are associated with rapidly progressive and destructive disease. Other extra-articular features include arteritis, neuropathy, scleritis, pericarditis, splenomegaly, and Sjögren's syndrome (dry eyes and dry mucous membranes).

Assessment and Diagnostic Findings

Several factors can contribute to a diagnosis of RA: rheumatoid nodules, joint inflammation detected on palpation, and laboratory findings. The history and physical examination address manifestations such as bilateral and symmetric stiffness, tenderness, swelling, and temperature changes in the joints. The patient is also assessed for extra-articular changes; these often include weight loss, sensory changes, lymph node enlargement, and fatigue. Rheumatoid factor is present in about three fourths of patients with RA, but its presence alone is not diagnostic of RA, and its absence does not rule out the diagnosis. The ESR is significantly elevated in RA. The red blood cell count and C4 complement component are decreased. C-reactive protein and antinuclear antibody (ANA) test results may also be positive (Karpoff & Labus, 2008) (Chart 54-3). Arthrocentesis shows synovial fluid that is cloudy, milky, or dark yellow and contains numerous inflammatory components, such as leukocytes and complement.

X-rays show bony erosions and narrowed joint spaces. X-rays of the hands and feet should be performed at baseline to help establish the diagnosis of RA and then every 3 years to monitor the progression of the disease (Khanna, et al., 2006).

Medical Management

Early Rheumatoid Arthritis

Patients with RA should receive aggressive and early treatment (Khanna, et al., 2006). Treatment includes education, a balance of rest and exercise, and referral to appropriate community agencies (such as the Arthritis Foundation) for support. Medical management begins with therapeutic doses of salicylates or NSAIDs. When used in full therapeutic dosages, these medications provide both anti-inflammatory and analgesic effects.

Several cyclo-oxygenase 2 (COX-2) enzyme blockers, another class of NSAIDs, have been approved for treatment of RA. Cyclo-oxygenase is an enzyme that is involved in the inflammatory process. COX-2 medications block the enzyme involved in inflammation (COX-2) while leaving intact the enzyme involved in protecting the stomach lining (COX-1). As a result, COX-2 enzyme blockers are less likely to cause gastric irritation and ulceration than other

NURSING RESEARCH PROFILE

Managing Symptoms in Rheumatoid Arthritis

Sousa, K. H., Ryu, E., Kwok, O., et al. (2007). Development of a model to measure symptom status in persons living with rheumatoid arthritis. *Nursing Research*, 56(6), 434–440.

Purpose

Rheumatoid arthritis (RA) is a chronic, progressive, inflammatory disease of unknown etiology that causes disability as well as morbidity and mortality. RA has a constellation of symptoms (eg, blurred vision, pain, dizziness) that affect quality of life. The purpose of this study was to develop and validate a structured model to measure symptom status in patients with RA.

Design

This study was a secondary analysis of symptom checklists available from 901 women enrolled in the Arthritis, Rheumatism, and Aging Medical Information System. The symptom checklists contained a list of 31 symptoms, and participants were asked to check off all symptoms they had experienced

in the previous 6 months. Factor analysis was used to develop the model to measure symptoms.

Findings

Results of the factor analysis supported a two-factor model for the measurement of symptom status. The factors were (1) RA pain symptoms and (2) general symptoms. The two factors were found to be significantly different from each other, and the RA pain symptoms factor had a stronger impact on functional health than general symptoms.

Nursing Implications

The first aspect of effective symptom management for patients with RA is nursing assessment. This study provides a model and validated structure for such an assessment. For example, the symptoms that form the RA pain cluster could serve as a baseline assessment for nurses to identify goals and interventions to help improve the functional health and quality of life of patients with RA.

NSAIDs; however, they are associated with increased risk of cardiovascular disease and must be used with caution (Karch, 2008).

A window of opportunity for symptom control and improved disease management occurs within the first 2 years after disease onset. Therefore, it is recommended that treatment with the DMARDs (antimalarials, gold, penicillamine, or sulfasalazine) begin within 3 months of disease onset. If symptoms are aggressive (ie, early bony erosions as seen on x-rays), methotrexate may be considered. Methotrexate (Rheumatrex) is currently the standard treatment of RA because of its success in preventing both joint destruction and long-term disability (Schmajuk, et al., 2007).

An alternative treatment approach for RA has emerged in the area of biologic therapies. Biologic response modifiers are a group of agents that consist of molecules produced by cells of the immune system or by cells that participate in the inflammatory reactions. Research (Voulgari, Alamanos, Nikas, et al., 2005) using tumor necrosis factor- α (TNF- α) inhibitors in combination with other medications has shown that patients demonstrate significant improvement. Examples of biologic response modifiers that are currently available are etanercept (Enbrel), infliximab (Remicade), adalimumab (Humira), golimumab (Simponi), and anakinra (Kineret). Etanercept, infliximab, adalimumab, and golimumab inhibit the function of TNF- α , a key cytokine known to play a role in the disease process in RA (Porth & Matfin, 2009), whereas anakinra inhibits the function of interleukin-1, another cytokine that contributes to the destruction of the joint. Research in this area is ongoing.

Additional analgesia may be prescribed for periods of extreme pain. Opioid analgesic agents are avoided because of the potential for continuing need for pain relief. Nonpharmacologic pain management techniques (eg, relaxation techniques, heat and cold applications) are taught.

Moderate, Erosive Rheumatoid Arthritis

For moderate, erosive RA, a formal program with occupational and physical therapy is prescribed to educate the patient about principles of joint protection, pacing activities, work simplification, range of motion, and muscle-strengthening exercises. The patient is encouraged to participate actively in the management program. The medication program is reevaluated periodically, and appropriate changes are made if indicated. Cyclosporine (Neoral), an immunosuppressant, may be added to enhance the disease-modifying effect of methotrexate.

Persistent, Erosive Rheumatoid Arthritis

For persistent, erosive RA, reconstructive surgery and corticosteroids are often used. Reconstructive surgery is indicated when pain cannot be relieved by conservative measures and the threat of loss of independence is eminent. Surgical procedures include synovectomy (excision of the synovial membrane), tenorrhaphy (suturing of a tendon), arthrodesis (surgical fusion of the joint), and **arthroplasty** (surgical repair and replacement of the joint). Surgery is not performed during disease flares.

Systemic corticosteroids are used when the patient has unremitting inflammation and pain or needs a “bridging” medication while waiting for the slower DMARDs (eg, methotrexate) to begin taking effect. Low-dose corticosteroid therapy is prescribed for the shortest time necessary to minimize side effects (Khanna, et al., 2006). Single large joints that are severely inflamed and fail to respond promptly to the measures outlined previously may be treated by local injection of a corticosteroid.

Advanced, Unremitting Rheumatoid Arthritis

For advanced, unremitting RA, immunosuppressive agents are prescribed because of their ability to affect the production

of antibodies at the cellular level. These include high-dose methotrexate (Rheumatrex), cyclophosphamide (Cytoxan), azathioprine (Imuran), and leflunomide (Arava). However, these medications are highly toxic and can produce bone marrow suppression, anemia, gastrointestinal disturbances, and rashes.

For most patients with RA, depression and sleep deprivation may require the short-term use of low-dose antidepressant medications, such as amitriptyline (Elavil), paroxetine (Paxil), or sertraline (Zoloft), to reestablish an adequate sleep pattern and to manage chronic pain.

The U.S. Food and Drug Administration (FDA) has approved a medical device for use in treating patients with more severe and long-standing RA who have had no response to or are intolerant of DMARDs. The device, a protein A immunoabsorption column (Proisorba), is used in 12 weekly 2-hour apheresis treatments to bind immunoglobulin G (IgG) (ie, circulating immune complex). In this unique population of patients, a significant improvement using the American College of Rheumatology criteria for improvement has been demonstrated (Eustice & Eustice, 2008).

Nutrition Therapy

Patients with RA frequently experience anorexia, weight loss, and anemia. A dietary history identifies usual eating habits and food preferences. Food selection should include the daily requirements from the basic food groups, with emphasis on foods high in vitamins, protein, and iron for tissue building and repair. For the patient who is extremely anorexic, small, frequent feedings with increased protein supplements may be prescribed. Supplemental vitamins and minerals may also be prescribed as needed (Klippel, Stone, Crofford, et al., 2008). Certain medications (ie, oral corticosteroids) used in RA treatment stimulate the appetite and, when combined with decreased activity, may lead to weight gain. Therefore, patients may need to be counseled about eating a healthy, calorie-restricted diet.

Nursing Management

Nursing care of the patient with RA follows the basic plan of care presented earlier (see Chart 54-2). The most common issues for the patient with RA include pain, sleep disturbance, fatigue, altered mood, and limited mobility (Sousa, Ryu, Kwok, et al., 2007). The patient with newly diagnosed RA needs information about the disease to make daily self-management decisions and to cope with having a chronic disease.

Monitoring and Managing Potential Complications

Medications used for treating RA may cause serious and adverse effects. These medication-induced complications may include bone marrow suppression, anemia, gastrointestinal disturbances, and rashes. The primary health care provider bases the prescribed medication regimen on clinical findings and past medical history, and then with the help of the nurse, monitors for side effects using periodic clinical assessments and laboratory testing. The nurse, who can be available for consultation between physician visits, works to help the patient recognize and deal with these side effects (see Table 54-3). The medication may need to be stopped or the dose reduced. If the patient experiences an increase in symptoms while the complication is being resolved or a new medication is being initiated, the nurse’s counseling regarding symptom management may relieve potential anxiety and distress.

Promoting Home and Community-Based Care

Teaching Patients Self-Care

Patient teaching is an essential aspect of nursing care of the patient with RA to enable the patient to maintain as much independence as possible, to take medications accurately and safely, and to use adaptive devices correctly. Patient teaching focuses on the disorder itself, the possible changes related to the disorder, the therapeutic regimen prescribed to treat it, the potential side effects of medications, strategies to maintain independence and function, and patient safety in the home (Chart 54-4).

 CHART 54-4 HOME CARE CHECKLIST The Patient With Rheumatoid Arthritis		
At the completion of the home care instruction, the patient or caregiver will be able to:	PATIENT	CAREGIVER
• Explain the nature of the disease and principles of disease management.	✓	✓
• Describe the medication regimen (name of medications, dosage, schedule of administration, precautions, potential side effects, and desired effects).	✓	✓
• Identify monitoring procedures and strategies that should be implemented.	✓	✓
• Identify sources of additional information, if necessary.	✓	✓
• Demonstrate accurate and safe self-administration of medications.	✓	✓
• Describe and demonstrate use of pain management techniques.	✓	✓
• Demonstrate use of joint protection techniques in activities of daily living (ADLs).	✓	✓
• Demonstrate ability to perform self-care activities independently or with assistive devices.	✓	
• Demonstrate a safe exercise program.	✓	
• Demonstrate a relaxation technique.	✓	

The patient and family are encouraged to verbalize their concerns and ask questions. Because RA commonly affects young women, major concerns may be related to the effects of the disease on childbearing potential, caring for family, or work responsibilities. The patient with a chronic illness may seek a “cure” or have questions about alternative therapies. One alternative therapy, an expensive one, used by many patients with RA is elk antler velvet. The velvet from elk antlers is harvested, ground, and put into capsules. In one randomized clinical trial of 168 patients with early stages of RA, researchers found that elk velvet has no clinical efficacy in the symptom management of the disease (Allen, Oberle, Grace, et al., 2008).

Pain, fatigue, and depression can interfere with the patient’s ability to learn and should be addressed before teaching is initiated. Various educational strategies may then be used, depending on the patient’s previous knowledge base, interest level, degree of comfort, social or cultural influences, and readiness to learn. The nurse instructs the patient about basic disease management and necessary adaptations in lifestyle. Because suppression of inflammation and autoimmune responses requires the use of anti-inflammatory, disease-modifying antirheumatic, and immunosuppressive agents, the patient is taught about prescribed medications, including type, dosage, rationale, potential side effects, self-administration, and required monitoring procedures. If hospitalized, the patient is encouraged to practice new self-management skills with support from caregivers and significant others. The nurse then reinforces disease management skills during each patient contact. Barriers to compliance are assessed, and measures are taken to promote adherence to medications and the treatment program.

Continuing Care

Depending on the severity of the disorder and the patient’s resources and supports, referral for home care may or may not be warranted. However, the patient who is elderly or frail, has RA that limits function significantly, and lives alone may need referral for home care.

The impact of RA on everyday life is not always evident when the patient is seen in the hospital or in an ambulatory care setting. The increased frequency with which nurses see patients in the home provides opportunities for recognizing problems and implementing interventions aimed at improving the quality of life of patients with RA.

During home visits, the nurse has the opportunity to assess the home environment and its adequacy for patient safety and management of the disorder. Adherence to the treatment program can be more easily monitored in the home setting, where physical and social barriers to adherence are more readily identified. For example, a patient who also has diabetes and requires insulin may be unable to fill the syringe accurately or unable to administer the insulin because of impaired joint mobility. Appropriate adaptive equipment needed for increased independence is often identified more readily when the nurse sees how the patient functions in the home. Any barriers to adherence are identified, and appropriate referrals are made.

For patients at risk for impaired skin integrity, the home care nurse can closely monitor skin status and also instruct, provide, or supervise the patient and family in preventive skin care measures. The nurse also assesses the patient’s need for assistance in the home and supervises home health aides who may meet many of the needs of the patient with RA. Referrals to physical and occupational therapists may be made as problems are identified and limitations increase. A home care nurse may visit the home to make sure the patient can function as independently as possible despite mobility problems and can safely manage treatments, including pharmacotherapy. The patient and family should be informed about support services such as Meals on Wheels and local Arthritis Foundation chapters.

Because many of the medications used to suppress inflammation are injectable, the nurse may administer the medication to the patient or teach self-injection. These frequent contacts allow the nurse to reinforce other disease management techniques.

The nurse also assesses the patient’s physical and psychological status, adequacy of symptom management, and adherence to the management plan. Patients should know which type of rheumatic disease they have, not just that they have “arthritis” or “arthritis of the knee.” The importance of attending follow-up appointments is emphasized to the patient and family, and they should be reminded about the importance of participating in other health promotion activities and health screening. Patients with chronic disorders such as RA often focus on the chronic disease and neglect general health issues.

SYSTEMIC LUPUS ERYTHEMATOSUS

The overall prevalence of SLE is estimated to be 1 per 2500 persons. It occurs 10 times more frequently in women than in men and approximately three times more frequently in African Americans than in Caucasians (Wandstrat, Carr-Johnson, Branch, et al., 2006).

Pathophysiology

SLE is a result of disturbed immune regulation that causes an exaggerated production of autoantibodies. This immunoregulatory disturbance is brought about by some combination of genetic factors, hormonal factors (as evidenced by the usual onset during the childbearing years), and environmental factors (eg, sunlight, thermal burns). Certain medications, such as hydralazine (Apresoline), procainamide (Pronestyl), isoniazid (INH), chlorpromazine (Thorazine), and some antiseizure medications, have been implicated in chemical or drug-induced SLE.

Specifically, B cells and T cells both contribute to the immune response in SLE (Croker & Kimberly, 2005). B cells are instrumental in promoting the onset and flares of the disease (Tieng & Peeva, 2008).

Clinical Manifestations

SLE is an autoimmune systemic disease that can affect any body system. Involvement of the musculoskeletal system, with arthralgias and arthritis (synovitis), is a common

presenting feature of SLE. Joint swelling, tenderness, and pain on movement are also common. Frequently, these are accompanied by morning stiffness. The onset of disease may be insidious or acute.

Several different types of skin manifestations may occur in patients with SLE, including subacute cutaneous lupus erythematosus, which involves papulosquamous or annular polycyclic lesions, and discoid lupus erythematosus, which is a chronic rash that has erythematous papules or plaques and scaling and can cause scarring and pigmentation changes. The most familiar skin manifestation (occurring in more than 50% of patients with SLE) is an acute cutaneous lesion consisting of a butterfly-shaped rash across the bridge of the nose and cheeks (Bickley, 2007) (Fig. 54-2). In some cases of discoid lupus erythematosus, only skin involvement occurs. In some patients with SLE, the initial skin involvement is the precursor to more systemic involvement. The lesions often worsen during exacerbations (flares) of the systemic disease and possibly are provoked by sunlight or artificial ultraviolet light. Oral ulcers, which may accompany skin lesions, may involve the buccal mucosa or the hard palate, occur in crops, and are often associated with exacerbations.

Pericarditis is the most common cardiac manifestation. Women who have SLE are also at risk for early atherosclerosis.

Serum creatinine levels and urinalysis are used in screening for renal involvement. Early detection allows for prompt treatment so that renal damage can be prevented. Renal involvement may lead to hypertension, which also requires careful monitoring and management (see Chapter 32).

Central nervous system involvement is widespread, encompassing the entire range of neurologic disease. The

Figure 54-2 The characteristic butterfly rash of systemic lupus erythematosus.

varied and frequent neuropsychiatric presentations of SLE are now widely recognized. These are generally demonstrated by subtle changes in behavior patterns or cognitive ability.

Assessment and Diagnostic Findings

Diagnosis of SLE is based on a complete history, physical examination, and blood tests. Typically, assessment reveals classic symptoms, including fever, fatigue, weight loss, and possibly arthritis, pleurisy, and pericarditis. Interactions with the patient and family may provide further evidence of systemic involvement.

In addition to the general assessment performed for any patient with a rheumatic disease, assessment for known or suspected SLE has special features. The skin is inspected for erythematous rashes. Cutaneous erythematous plaques with an adherent scale may be observed on the scalp, face, or neck. Areas of hyperpigmentation or depigmentation may be noted, depending on the phase and type of the disease. The patient should be questioned about skin changes (because these may be transitory) and specifically about sensitivity to sunlight or artificial ultraviolet light. The scalp should be inspected for alopecia and the mouth and throat for ulcerations reflecting gastrointestinal involvement.

Cardiovascular assessment includes auscultation for pericardial friction rub, possibly associated with myocarditis and accompanying pleural effusions. The pleural effusions and infiltrations, which reflect respiratory insufficiency, are demonstrated by abnormal lung sounds. Papular, erythematous, and purpuric lesions developing on the fingertips, elbows, toes, and extensor surfaces of the forearms or lateral sides of the hand that may become necrotic suggest vascular involvement.

Joint swelling, tenderness, warmth, pain on movement, stiffness, and edema may be detected on physical examination. The joint involvement is often symmetric and similar to that found in RA.

The neurologic assessment is directed at identifying and describing any central nervous system changes. The patient and family members are asked about any behavioral changes, including manifestations of neurosis or psychosis. Signs of depression are noted, as are reports of seizures, chorea, or other central nervous system manifestations.

No single laboratory test confirms SLE; rather, blood testing reveals moderate to severe anemia, thrombocytopenia, leukocytosis, or leukopenia and positive ANAs (Wandstrat, et al., 2006). Other diagnostic immunologic tests support but do not confirm the diagnosis.

Medical Management

Treatment of SLE includes management of acute and chronic disease. Although SLE can be life-threatening, advances in its treatment have led to improved survival and reduced morbidity. Acute disease requires interventions directed at controlling increased disease activity or exacerbations that can involve any organ system. Disease activity is a composite of clinical and laboratory features that reflect active inflammation secondary to SLE. Management of the

more chronic condition involves periodic monitoring and recognition of meaningful clinical changes requiring adjustments in therapy.

The goals of treatment include preventing progressive loss of organ function, reducing the likelihood of acute disease, minimizing disease-related disabilities, and preventing complications from therapy. Management of SLE involves regular monitoring to assess disease activity and therapeutic effectiveness.

Pharmacologic Therapy

Medication therapy for SLE is based on the concept that local tissue inflammation is mediated by exaggerated or heightened immune responses, which can vary widely in intensity and require different therapies at different times. Corticosteroids are the single most important medication available for treatment. They are used topically for cutaneous manifestations, in low oral doses for minor disease activity, and in high doses for major disease activity. Intravenous (IV) administration of corticosteroids is an alternative to traditional high-dose oral use. Antimalarial medications are effective for managing cutaneous, musculoskeletal, and mild systemic features of SLE. The NSAIDs used for minor clinical manifestations are often used along with corticosteroids in an effort to minimize corticosteroid requirements.

Immunosuppressive agents (alkylating agents and purine analogues) are used because of their effect on immune function. These medications are generally reserved for patients who have serious forms of SLE that have not responded to conservative therapies. B-cell depleting therapies are the newest treatment for SLE. Monoclonal antibodies, rituximab (Rituxan), and epratuzumab (humanized anti-CD22 antibody) have shown good therapeutic results in clinical trials (Tieng & Peeva, 2008).

Nursing Management

Nursing care of the patient with SLE is based on the fundamental plan presented earlier in the chapter (see Chart 54-2). The most common nursing diagnoses include fatigue, impaired skin integrity, body image disturbance, and lack of knowledge for self-management decisions. The disease or its treatment may produce dramatic changes in appearance and considerable distress for the patient. The changes and the unpredictable course of SLE necessitate expert assessment skills and nursing care with sensitivity to the psychological reactions of the patient. The patient may benefit from participation in support groups, which can provide disease information, daily management tips, and social support. Because sun and ultraviolet light exposure can increase disease activity or cause an exacerbation, patients should be taught to avoid exposure or to protect themselves with sunscreen and clothing.

Because of the increased risk of involvement of multiple organ systems, patients should understand the need for routine periodic screenings as well as health promotion activities. A dietary consultation may be indicated to ensure that the patient is knowledgeable about dietary recommendations, given the increased risk of cardiovas-

cular disease, including hypertension and atherosclerosis. The nurse instructs the patient about the importance of continuing prescribed medications and addresses the changes and potential side effects that are likely to occur with their use. The patient is reminded of the importance of monitoring because of the increased risk of systemic involvement, including renal and cardiovascular effects.

SCLERODERMA

Scleroderma (“hard skin”) is a relatively rare disease that is poorly understood; the cause is unknown. The incidence of scleroderma (also known as systemic sclerosis) is 18 to 20 cases per million per year (Seibold, 2005). Like other diffuse connective tissue diseases, it has a variable course with remissions and exacerbations. Its prognosis is not as optimistic as that of SLE.

Pathophysiology

Scleroderma commonly begins with skin involvement. Mononuclear cells cluster on the skin and stimulate lymphokines to stimulate procollagen. Insoluble collagen is formed and accumulates excessively in the tissues. Initially, the inflammatory response causes edema formation, with a resulting taut, smooth, and shiny skin appearance. The skin then undergoes fibrotic changes, leading to loss of elasticity and movement. Eventually, the tissue degenerates and becomes nonfunctional. This chain of events, from inflammation to degeneration, also occurs in blood vessels, major organs, and body systems (Klippel, et al., 2008).

Clinical Manifestations

Scleroderma starts insidiously with Raynaud’s phenomenon and swelling in the hands. The skin and the subcutaneous tissues become increasingly hard and rigid and cannot be pinched up from the underlying structures. Wrinkles and lines are obliterated. The skin is dry because sweat secretion over the involved region is suppressed. The extremities stiffen and lose mobility. The condition spreads slowly; for years, these changes may remain localized in the hands and the feet. The face appears masklike, immobile, and expressionless, and the mouth becomes rigid.

The changes within the body, although not visible directly, are vastly more important than the visible changes. The left ventricle of the heart is involved, resulting in heart failure. The esophagus hardens, interfering with swallowing. The lungs become scarred, impeding respiration. Digestive disturbances occur because of hardening (sclerosing) of the intestinal mucosa. Progressive renal failure may occur.

The patient may manifest a variety of symptoms referred to as the CREST syndrome. CREST stands for calcinosis (calcium deposits in the tissues), Raynaud’s phenomenon, esophageal hardening and dysfunction, sclerodactyly (scleroderma of the digits), and telangiectasia (capillary dilation that forms a vascular lesion).

Assessment and Diagnostic Findings

Assessment focuses on the sclerotic changes in the skin, contractures in the fingers, and color changes or lesions in the fingertips. Assessment of systemic involvement requires a systems review with special attention to gastrointestinal, pulmonary, renal, and cardiac symptoms. Limitations in mobility and self-care activities should be assessed, along with the impact the disease has had (or will have) on body image.

There is no one conclusive test to diagnose scleroderma. A skin biopsy is performed to identify cellular changes specific to scleroderma. Pulmonary studies show ventilation–perfusion abnormalities. Echocardiography identifies pericardial effusion (often present with cardiac involvement). Esophageal studies demonstrate decreased motility in most patients with scleroderma. Blood tests may detect ANAs, indicating a connective tissue disorder and possibly distinguishing the subgroup (diffuse or limited) of scleroderma. A positive ANA test result is common in patients with scleroderma.

Medical Management

Treatment of scleroderma depends on the clinical manifestations. All patients require counseling, during which realistic individual goals may be determined. Support measures include strategies to decrease pain and limit disability. A moderate exercise program is encouraged to prevent joint contractures. Patients are advised to avoid extreme temperatures and to use lotion to minimize skin dryness.

Pharmacologic Therapy

No medication regimen has proved effective in modifying the disease process in scleroderma, but various medications are used to treat organ system involvement. Calcium channel blockers and other antihypertensive agents may provide improvement in symptoms of Raynaud’s phenomenon. Anti-inflammatory medications can be used to control arthralgia, stiffness, and general musculoskeletal discomfort (Seibold, 2005).

Nursing Management

The nursing care of the patient with scleroderma is based on the fundamental plan of nursing care presented earlier (see Chart 54-2). The most common nursing diagnoses of the patient with scleroderma are impaired skin integrity; self-care deficits; imbalanced nutrition, less than body requirements; and disturbed body image. The patient with advanced disease may also have impaired gas exchange, decreased cardiac output, impaired swallowing, and constipation.

Providing meticulous skin care and preventing the effects of Raynaud’s phenomenon are major nursing challenges. Patient teaching must include the importance of avoiding cold and protecting the fingers with mittens in cold weather and when shopping in the frozen-food section of the grocery store. Warm socks and properly fitting shoes are helpful in preventing ulcers. Careful, frequent inspection for early ulcers is important. Smoking cessation is critical.

POLYMYOSITIS

Polymyositis is a group of diseases that are termed idiopathic inflammatory myopathies (Klippel, et al., 2008). They are rare conditions, with an incidence estimated at 5 to 10 cases per million adults per year.

Pathophysiology

Polymyositis is classified as autoimmune because autoantibodies are present. However, these antibodies do not cause damage to muscle cells, indicating only an indirect role in tissue damage. The pathogenesis is multifactorial, and a genetic predisposition is likely. Drug-induced disease is rare. Some evidence suggests a viral link.

Clinical Manifestations

The onset ranges from sudden with rapid progression to very slow and insidious. Proximal muscle weakness is typically a first symptom. Muscle weakness is usually symmetric and diffuse. Dermatomyositis, a related condition, is most commonly identified by an erythematous smooth or scaly lesion found over the joint surface.

Assessment and Diagnostic Findings

A complete history and physical examination help exclude other muscle-related disorders. As with other diffuse connective tissue disorders, no single test confirms polymyositis. An electromyogram is performed to rule out degenerative muscle disease. A muscle biopsy may reveal inflammatory infiltrate in the tissue. Serum studies indicate increased muscle enzyme activity.

Medical Management

Management involves high-dose corticosteroid therapy initially, followed by a gradual dosage reduction over several months as muscle enzyme activity decreases. Patients who do not respond to corticosteroids require the addition of an immunosuppressive agent. Plasmapheresis, lymphapheresis, and total-body irradiation have been used if there is no response to corticosteroids and immunosuppressive medications. The antimalarial agent hydroxychloroquine (Plaquenil) may be effective for skin rashes. Physical therapy is initiated slowly, with range-of-motion exercises to maintain joint mobility, followed by gradual strengthening exercises (Klippel, et al., 2008).

Nursing Management

Nursing care is based on the fundamental plan of nursing care presented earlier (see Chart 54-2). The most frequent nursing diagnoses for the patient with polymyositis are impaired physical mobility, fatigue, self-care deficit, and insufficient knowledge of self-management techniques.

Patients with polymyositis may have symptoms similar to those of other inflammatory diseases. However, proximal muscle weakness is characteristic, making activities such as combing the hair, reaching overhead, and using stairs difficult. Therefore, use of assistive devices may be recommended, and referral to occupational or physical therapy may be warranted.

POLYMYALGIA RHEUMATICA

Pathophysiology

The underlying mechanism involved with polymyalgia rheumatica is unknown. This disease occurs predominately in Caucasians and often in first-degree relatives. An association with the genetic marker HLA-DR4 suggests a familial predisposition. Immunoglobulin deposits in the walls of inflamed temporal arteries also suggest an autoimmune process.

Polymyalgia rheumatica and giant cell arteritis are found almost exclusively in people older than 50 years of age. Polymyalgia rheumatica has an annual incidence rate of 52 cases per 100,000 people older than 50 years. Giant cell arteritis varies by geographic location and has the highest incidence in Scandinavian countries (Klippel, et al., 2008).

Clinical Manifestations

Polymyalgia rheumatica is characterized by severe proximal muscle discomfort with mild joint swelling. Severe aching in the neck, shoulder, and pelvic muscles is common. Stiffness is noticeable most often in the morning and after periods of inactivity. Systemic features include low-grade fever, weight loss, malaise, anorexia, and depression. Because polymyalgia rheumatica usually occurs in people 50 years of age and older, it may be confused with, or dismissed as, an inevitable consequence of aging.

Giant cell arteritis, sometimes associated with polymyalgia rheumatica, may cause headaches, changes in vision, and jaw claudication. These symptoms should be evaluated immediately because of the potential for a sudden and permanent loss of vision if the condition is left untreated. Polymyalgia rheumatica and giant cell arteritis typically have a self-limited course, lasting several months to several years (Klippel, et al., 2008).

Assessment and Diagnostic Findings

Assessment focuses on musculoskeletal tenderness, weakness, and decreased function. Careful attention should be directed toward assessing the head (for changes in vision, headaches, and jaw claudication).

Often, diagnosis is difficult because of the lack of specificity of tests. A markedly high ESR is a screening test but is not definitive. Diagnosis is more likely to be made by eliminating other potential diagnoses, but this is highly dependent on the skills and experience of the diagnostician. The dramatic and immediate response to treatment with corticosteroids is considered by some to be diagnostic.

Medical Management

The treatment for patients with polymyalgia rheumatica (without giant cell arteritis) is moderate doses of corticosteroids (Klippel, et al., 2008). NSAIDs are sometimes used for mild disease. The treatment for patients with giant cell arteritis is rapid initiation of and strict adherence to a regimen of corticosteroids. This is essential to avoid the complication of blindness. Aspirin is a useful adjunctive

treatment that also helps reduce the risk of visual loss (Klippel, et al., 2008).

Nursing Management

Nursing care of the patient with polymyalgia rheumatica is based on the fundamental plan of nursing care presented earlier (see Chart 54-2). The most common nursing diagnoses are pain and insufficient knowledge of the medication regimen.

A management concern is that the patient will take the prescribed medication, frequently corticosteroids, until symptoms improve and then discontinue the medication. The decision to discontinue the medication should be based on clinical and laboratory findings and the physician's prescription. Nursing implications are related to helping the patient prevent and monitor side effects of medications (eg, infections, diabetes mellitus, gastrointestinal problems, and depression) and adjust to those side effects that cannot be prevented (eg, increased appetite and altered body image).

NURSING ALERT

The nurse must emphasize to the patient the need for continued adherence to the prescribed medication regimen to avoid complications of giant cell arteritis, such as blindness.

The loss of bone mass with corticosteroid use increases the risk of osteoporosis in this already at-risk population. Interventions to promote bone health, such as adequate dietary calcium and vitamin D, measurement of bone mineral density, weight-bearing exercise, smoking cessation, and reduction of alcohol consumption if indicated, should be emphasized.

Degenerative Joint Disease (Osteoarthritis)

Osteoarthritis, also known as degenerative joint disease or osteoarthrosis (even though inflammation may be present), is the most common and most frequently disabling of the joint disorders. OA is both overdiagnosed and trivialized; it is frequently overtreated or undertreated. The functional impact of OA on quality of life, especially for elderly patients, is often ignored.

OA has been classified as primary (idiopathic), with no prior event or disease related to the OA, and secondary, resulting from previous joint injury or inflammatory disease. The distinction between primary and secondary OA is not always clear.

Increasing age directly relates to the degenerative process in the joint, because the ability of the articular cartilage to resist microfracture with repetitive low loads diminishes with age. OA often begins in the third decade of life and peaks between the fifth and sixth decades. By 40 years of age, 90% of the population have degenerative joint changes in their weight-bearing joints, even though clinical symptoms are usually absent. Prevalence of OA is

between 50% and 80% in the elderly (Ganz, Chang, Roth, et al., 2006).

Pathophysiology

OA may be thought of as the end result of many factors that, when combined, predispose the patient to the disease. OA affects the articular cartilage, **subchondral bone** (the bony plate that supports the articular cartilage), and synovium. A combination of cartilage degradation, bone stiffening, and reactive inflammation of the synovium occurs. Understanding of OA has been greatly expanded beyond what previously was thought of as simply “wear and tear” related to aging. The basic degenerative process in the joint exemplified in OA is presented in Figure 54-3.

Congenital and developmental disorders of the hip are well known for predisposing a person to OA of the hip. These include congenital subluxation–dislocation of the hip, acetabular dysplasia, Legg-Calvé-Perthes disease, and slipped capital femoral epiphysis.

Risk factors for OA include increased age, obesity, previous joint damage, repetitive use (occupational or recreational), anatomic deformity, and genetic susceptibility. Being overweight or obese also increases symptoms associated with the disease (Klippel, et al., 2008). Research has shown that a weight loss of 10% improves function by 28% in people with OA affecting the knee (Christensen, Astrup & Bliddal, 2005).

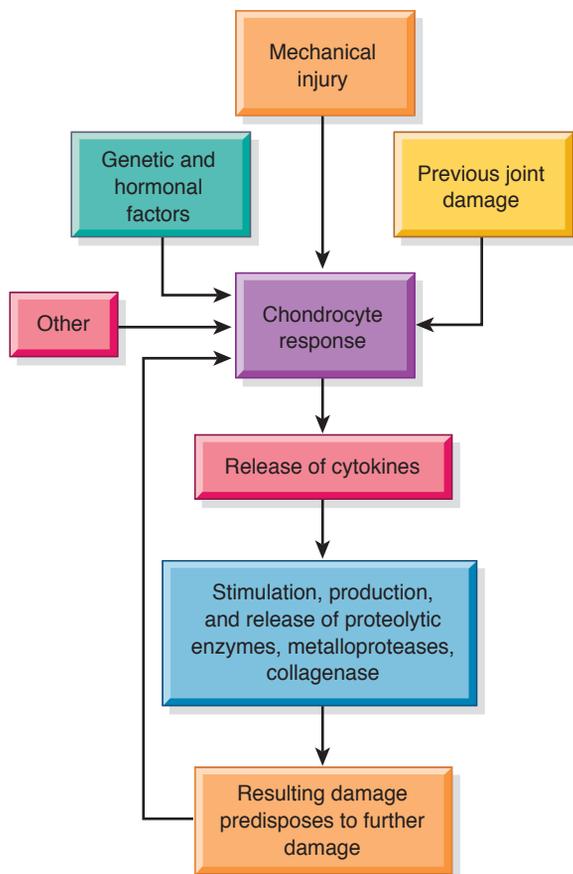

Figure 54-3 Pathophysiology of osteoarthritis.

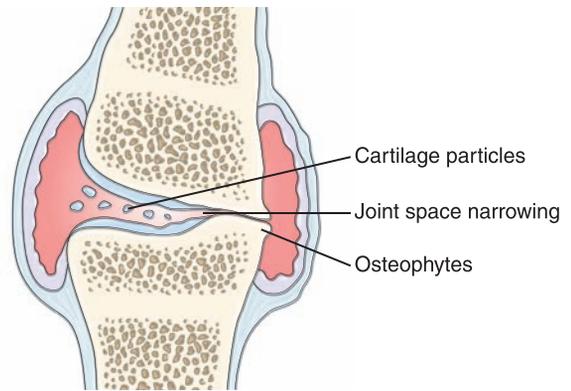

Figure 54-4 Joint space narrowing and osteophytes (bone spurs) are characteristic of degenerative changes in joints.

Clinical Manifestations

The primary clinical manifestations of OA are pain, stiffness, and functional impairment. The pain is caused by an inflamed synovium, stretching of the joint capsule or ligaments, irritation of nerve endings in the periosteum over **osteophytes** (bone spurs), trabecular microfracture, intraosseous hypertension, bursitis, tendinitis, and muscle spasm (Fig 54-4). Stiffness, which is most commonly experienced in the morning or after awakening, usually lasts less than 30 minutes and decreases with movement. Functional impairment results from pain on movement and limited motion caused by structural changes in the joints.

Although OA occurs most often in weight-bearing joints (hips, knees, cervical and lumbar spine), the proximal and distal finger joints are also often involved. Characteristic bony nodes may be present; on inspection and palpation, these are usually painless, unless inflammation is present.

Assessment and Diagnostic Findings

Diagnosis of OA is complicated because only 30% of patients with changes seen on x-ray report symptoms. Physical assessment of the musculoskeletal system reveals tender and enlarged joints. Inflammation, when present, is not the destructive type seen in the connective tissue diseases such as RA. OA is characterized by a progressive loss of the joint cartilage, which appears on x-ray as a narrowing of the joint space. In addition, reactive changes occur at the joint margins and on the subchondral bone in the form of osteophytes as the cartilage attempts to regenerate. Neither the presence of osteophytes nor joint space narrowing alone is specific for OA; however, when combined, these are sensitive and specific findings. In early or mild OA, there is only a weak correlation between joint pain and synovitis. Blood tests are not useful in the diagnosis of OA.

Medical Management

Although no treatment halts the degenerative process, certain preventive measures can slow the progress if undertaken early enough. These include weight reduction,

prevention of injuries, perinatal screening for congenital hip disease, and ergonomic modifications.

Conservative treatment measures include patient education, the use of heat, weight reduction, joint rest and avoidance of joint overuse, orthotic devices (eg, splints, braces) to support inflamed joints, isometric and postural exercises, and aerobic exercise. Other miscellaneous physical modalities, such as massage, yoga, pulsed electromagnetic fields, transcutaneous electrical nerve stimulation (TENS), and music therapy, have unproven value in the treatment of OA. Occupational and physical therapy can help the patient adopt self-management strategies.

Patients with arthritis often use complementary and alternative therapies, many of which are not traditionally taught in American medical schools and are not traditionally available in American hospitals. These may include herbal and dietary supplements, other special diets, acupuncture, acupressure, wearing copper bracelets or magnets, and participation in T'ai chi. Research is under way to determine the effectiveness of many of these treatments (Little, Parsons & Logan, 2006).

Pharmacologic Therapy

Pharmacologic management of OA is directed toward symptom management and pain control. Selection of medication is based on the patient's needs, the stage of disease, and the risk of side effects. Medications are used in conjunction with nonpharmacologic strategies. In most patients with OA, the initial analgesic therapy is acetaminophen. Some patients respond to the nonselective NSAIDs, and patients who are at increased risk for gastrointestinal complications, especially gastrointestinal bleeding, have been managed effectively with COX-2 enzyme blockers. However, COX-2 enzyme blockers must be used with caution because of the associated risk of cardiovascular disease. Other medications that may be considered are the opioids and intra-articular corticosteroids. Topical analgesic agents such as capsaicin (Capsin, Zostrix) and methylsalicylate are also used (Klippel, et al., 2008).

Other therapeutic approaches include glucosamine and chondroitin. Although it has been suggested that these substances modify cartilage structure, studies have not shown them to be effective (Towheed, Maxwell, Anastassiades, et al., 2006). Viscosupplementation, the injection of gel-like substances (hyaluronates), into a joint (intra-articular) is thought to supplement the viscous properties of synovial fluid. Five hyaluronates are currently approved by the FDA for joint injection in OA (Eustice & Eustice, 2006).

Surgical Management

In moderate to severe OA, when pain is severe or because of loss of function, surgical intervention may be used. The procedures most commonly used are osteotomy (to alter the distribution of weight within the joint) and arthroplasty. In arthroplasty, diseased joint components are replaced (see Chapter 67).

Nursing Management

Nursing management of the patient with OA includes both pharmacologic and nonpharmacologic approaches. Nonpharmacologic interventions are used first and continued with pharmacologic agents. Pain management and optimal functional ability are major goals of nursing intervention. The patient's understanding of the disease process and symptom pattern is critical to a plan of care. Because patients with OA usually are older, they may have other health problems. Commonly they are overweight, and they may have a sedentary lifestyle. Weight loss and exercise are important approaches to pain and disability improvement (Christensen, et al., 2005; Klippel, et al., 2008). A referral for physical therapy or to an exercise program for people with similar problems can be very helpful. Canes or other assistive devices for ambulation should be considered. Exercises such as walking should be begun in moderation and increased gradually. Patients should plan their daily exercise for a time when the pain is least severe or plan to use an analgesic agent, if appropriate, before exercising. Adequate pain management is important for the success of an exercise program. Open discussion regarding the use of complementary and alternative therapies is important to maintain safe and effective practices for patients looking for a "cure."

Spondyloarthropathies

The spondyloarthropathies are another category of systemic inflammatory disorders of the skeleton. The spondyloarthropathies include ankylosing spondylitis, reactive arthritis (Reiter's syndrome), and psoriatic arthritis. Spondyloarthritis is also associated with inflammatory bowel diseases such as regional enteritis (Crohn's disease) and ulcerative colitis.

These rheumatic diseases share several clinical features. The inflammation tends to occur peripherally at the sites of attachment—at tendons, joint capsules, and ligaments. Periosteal inflammation may be present. Many patients have arthritis of the sacroiliac joints. Onset tends to occur during young adulthood, with the disease affecting men more often than women. There is a strong tendency for these conditions to occur in families. Frequently, the HLA-B27 genetic marker is found.

Types of Spondyloarthropathies

Ankylosing Spondylitis

Ankylosing spondylitis affects the cartilaginous joints of the spine and surrounding tissues. Occasionally, the large synovial joints, such as the hips, knees, or shoulders, may be involved. Ankylosing spondylitis is more prevalent in males than in females and is usually diagnosed in the second or third decade of life. The disease is more severe in males, and significant systemic involvement is likely. Back pain is the characteristic feature. As the disease progresses, ankylosis of the entire spine may occur, leading to respiratory compromise and complications.

Reactive Arthritis (Reiter's Syndrome)

The disease process involved in Reiter's syndrome is called reactive because the arthritis occurs after an infection. It mostly affects young adult males and is characterized primarily by urethritis, arthritis, and conjunctivitis. Dermatitis and ulcerations of the mouth and penis may also be present. Low back pain is common.

Psoriatic Arthritis

Psoriatic arthritis is characterized by synovitis, polyarthritis, and spondylitis. Both psoriasis and arthritis are common conditions, and one theory suggests that the overlap of the two conditions is a chance occurrence. However, epidemiologic data suggest that the prevalence of arthritis in patients with psoriasis is 15% to 25%, exceeding the rate in the general population. Similarly, the prevalence of psoriasis in persons with arthritis is 2.6% to 7.0%, compared with 0.1% to 2.8% in the general population, supporting the theory that these two processes occur together in a unique disease process (Klippel, et al., 2008).

Medical Management

Medical management of spondyloarthropathies focuses on treating pain and maintaining mobility by suppressing inflammation. For the patient with ankylosing spondylitis, good body positioning and posture are essential, so that if **ankylosis** (fixation) does occur, the patient is in the most functional position. Maintaining range of motion with a regular exercise and muscle-strengthening program is especially important.

Pharmacologic Management

NSAIDs and corticosteroids often produce marked improvement in back, skin, and joint symptoms. Sulfasalazine (Azulfidine) and methotrexate (Rheumatrex) may help with peripheral joint disease. Methotrexate is also used to control psoriasis. More recently, anti-TNF therapy is under investigation for treatment of the spondyloarthropathies (Klippel, et al., 2008).

Surgical Management

Surgical management may include total joint replacement (see Chapter 67).

Nursing Management

Major nursing interventions in the spondyloarthropathies are related to symptom management and maintenance of optimal functioning. Affected patients are primarily young men. Their major concerns are often related to prognosis and job modification, especially among those who perform physical work. Patients may also express concerns about leisure and recreational activities.

Metabolic and Endocrine Diseases Associated With Rheumatic Disorders

Metabolic and endocrine diseases may be associated with rheumatic disorders. These include biochemical abnormalities (amyloidosis and scurvy), endocrine diseases (diabetes

mellitus and acromegaly), immunodeficiency diseases (human immunodeficiency virus [HIV] infection, acquired immunodeficiency syndrome [AIDS]), and some inherited disorders (hypermobility syndromes). However, the most common conditions are the crystal-induced arthropathies, in which crystals such as monosodium urate (gout) or calcium pyrophosphate (calcium pyrophosphate dihydrate disease [CPPD] or pseudogout) are deposited within joints and other tissues.

GOUT

Gout is a heterogeneous group of conditions related to a genetic defect of purine metabolism that results in hyperuricemia. Oversecretion of uric acid or a renal defect resulting in decreased excretion of uric acid, or a combination of both, occurs. The prevalence is reported to be about 2% and appears to be on the rise. The incidence of gout increases with age and body mass index, and the disorder occurs more commonly in males than in females (Singh, Hodges, Toscano, et al., 2007).

In primary hyperuricemia, elevated serum urate levels or manifestations of urate deposition appear to be consequences of faulty uric acid metabolism. Primary hyperuricemia may be caused by severe dieting or starvation, excessive intake of foods that are high in purines (shellfish, organ meats), or heredity. In secondary hyperuricemia, gout is a clinical feature secondary to any of a number of genetic or acquired processes, including conditions in which there is an increase in cell turnover (leukemia, multiple myeloma, some types of anemias, psoriasis) and an increase in cell breakdown. Altered renal tubular function, either as a major action or as an unintended side effect of certain pharmacologic agents (eg, diuretics such as thiazides and furosemide), low-dose salicylates, or ethanol, can contribute to uric acid underexcretion.

Pathophysiology

Hyperuricemia (serum concentration greater than 7 mg/dL) can, but does not always, cause urate crystal deposition (Karpoff & Labus, 2008). However, as uric acid levels increase, the risk becomes greater. Attacks of gout appear to be related to sudden increases or decreases of serum uric acid levels. When the urate crystals precipitate within a joint, an inflammatory response occurs, and an attack of gout begins. With repeated attacks, accumulations of sodium urate crystals, called **tophi**, are deposited in peripheral areas of the body, such as the great toe, the hands, and the ear. Renal urate lithiasis (kidney stones), with chronic renal disease secondary to urate deposition, may develop.

The finding of urate crystals in the synovial fluid of asymptomatic joints suggests that factors other than crystals may be related to the inflammatory reaction. Recovered monosodium urate crystals are coated with immunoglobulins that are mainly IgG. IgG enhances crystal phagocytosis, thereby demonstrating immunologic activity (Klippel, et al., 2008).

Clinical Manifestations

Manifestations of the gout syndrome include acute gouty arthritis (recurrent attacks of severe articular and periarticular inflammation), tophi (crystalline deposits

accumulating in articular tissue, osseous tissue, soft tissue, and cartilage), gouty nephropathy (renal impairment), and uric acid urinary calculi. Four stages of gout can be identified: asymptomatic hyperuricemia, acute gouty arthritis, intercritical gout, and chronic tophaceous gout. The subsequent development of gout is directly related to the duration and magnitude of the hyperuricemia. Therefore, the commitment to lifelong pharmacologic treatment of hyperuricemia is deferred until there is an initial attack of gout.

For hyperuricemic people who are going to develop gout, acute arthritis is the most common early clinical manifestation. The metatarsophalangeal joint of the big toe is the most commonly affected joint (90% of patients) (Porth & Matfin, 2009). The tarsal area, ankle, or knee may also be affected. Less commonly, the wrists, fingers, and elbows may be affected. Trauma, alcohol ingestion, dieting, medications, surgical stress, or illness may trigger the acute attack. The abrupt onset often occurs at night, awakening the patient with severe pain, redness, swelling, and warmth of the affected joint. Early attacks tend to subside spontaneously over 3 to 10 days even without treatment. The attack is followed by a symptom-free period (the intercritical stage) until the next attack, which may not come for months or years. However, with time, attacks tend to occur more frequently, to involve more joints, and to last longer.

Tophi are generally associated with more frequent and severe inflammatory episodes. Higher serum concentrations of uric acid are also associated with more extensive tophus formation. Tophi most commonly occur in the synovium, olecranon bursa, subchondral bone, infrapatellar and Achilles tendons, and subcutaneous tissue on the extensor surface of the forearms and overlying joints. They have also been found in the aortic walls, heart valves, nasal and ear cartilage, eyelids, cornea, and sclerae. Joint enlargement may cause a loss of joint motion. Uric acid deposits may cause renal stones and kidney damage.

Medical Management

A definitive diagnosis of gouty arthritis is established by polarized light microscopy of the synovial fluid of the involved joint. Uric acid crystals are seen within the polymorphonuclear leukocytes in the fluid. Colchicine (oral or parenteral), an NSAID such as indomethacin, or a corticosteroid is prescribed to relieve an acute attack of gout. Management of hyperuricemia, tophi, joint destruction, and renal disorders is usually initiated after the acute inflammatory process has subsided. Uricosuric agents, such as probenecid (Benemid), correct hyperuricemia and dissolve deposited urate. When reduction of the serum urate level is indicated, uricosuric agents are the medications of choice. If the patient has, or is at risk for, renal insufficiency or renal calculi (kidney stones), allopurinol, a xanthine oxidase inhibitor, is recommended (Singh, et al., 2007). A new medication, febuxostat (Uloric), was approved by the FDA in 2009 for the treatment of gout that does not respond to usual treatment. Corticosteroids may also be used in patients who have no response to other therapy. If the patient experiences several acute episodes or there is evidence of tophi formation, prophylactic treatment is considered. Specific treatment is based on the serum uric acid level, 24-hour urinary uric acid excretion, and renal function (Table 54-5).

teroid is prescribed to relieve an acute attack of gout. Management of hyperuricemia, tophi, joint destruction, and renal disorders is usually initiated after the acute inflammatory process has subsided. Uricosuric agents, such as probenecid (Benemid), correct hyperuricemia and dissolve deposited urate. When reduction of the serum urate level is indicated, uricosuric agents are the medications of choice. If the patient has, or is at risk for, renal insufficiency or renal calculi (kidney stones), allopurinol, a xanthine oxidase inhibitor, is recommended (Singh, et al., 2007). A new medication, febuxostat (Uloric), was approved by the FDA in 2009 for the treatment of gout that does not respond to usual treatment. Corticosteroids may also be used in patients who have no response to other therapy. If the patient experiences several acute episodes or there is evidence of tophi formation, prophylactic treatment is considered. Specific treatment is based on the serum uric acid level, 24-hour urinary uric acid excretion, and renal function (Table 54-5).

Nursing Management

Historically, gouty arthritis was thought to be a condition of royalty and the very rich, with the disease attributed to “high living.” This has not been shown to be entirely true. Although severe dietary restriction is not necessary, the nurse should encourage the patient to restrict consumption of foods high in purines, especially organ meats, and to limit alcohol intake. Maintenance of normal body weight should be encouraged. In an acute episode of gouty arthritis, pain management with prescribed medications is essential, along with avoidance of factors that increase pain and inflammation, such as trauma, stress, and alcohol. Between acute episodes, the patient feels well and may abandon preventive behaviors, which may result in an acute attack. Acute attacks are most effectively treated if therapy is begun early in the course.

Fibromyalgia

Fibromyalgia is a chronic pain syndrome that involves chronic fatigue, generalized muscle aching, and stiffness. Two percent of the United States population is affected by this syndrome, with a prevalence rate of 4% in women and 0.5% in men (Klippel, et al., 2008). See Chapter 13.

Table 54-5  **MEDICATIONS USED TO TREAT GOUT**

Medication	Actions and Use	Nursing Implications
colchicine	Lowers the deposition of uric acid and interferes with leukocyte infiltration, thus reducing inflammation; does not alter serum or urine levels of uric acid; used in acute and chronic management	<i>Acute management:</i> Administer when attack begins; dosage increased until pain is relieved or diarrhea develops <i>Chronic management:</i> Causes GI upset in most patients Be alert for nausea and rash.
probenecid (Benemid)	Uricosuric agent; inhibits renal reabsorption of urates and increases the urinary excretion of uric acid; prevents tophi formation	Monitor for side effects, including bone marrow depression, vomiting, and abdominal pain.
allopurinol (Zyloprim) febuxostat (Uloric)	Xanthine oxidase inhibitors; interrupt the breakdown of purines before uric acid is formed; inhibits xanthinoxidase because it blocks uric acid formation	

Medical Management

Treatment consists of attention to the specific symptoms reported by the patient. NSAIDs may be used to treat the diffuse muscle aching and stiffness. Tricyclic antidepressants are used to improve or restore normal sleep patterns. In addition, selective serotonin reuptake inhibitors and anticonvulsants have been effective in preliminary reports (Klippel, et al., 2008). Individualized programs of exercise are used to decrease muscle weakness and discomfort and to improve the general deconditioning that occurs in affected patients.

Nursing Management

Typically, patients with fibromyalgia have endured their symptoms for a long period of time. They may feel as if their symptoms have not been taken seriously. Nurses need to pay special attention to supporting these patients and providing encouragement as they begin their program of therapy. Patient support groups may be helpful. Careful listening to patients' descriptions of their concerns and symptoms is essential to help them make the changes that are necessary to improve their quality of life (Schaefer, 2005).

Arthritis Associated With Infectious Organisms

Arthritis, tenosynovitis, and bursitis can be associated with infectious organisms. Some inflammation of joints, tendons, and bursae is directly related to infection caused by bacterial, viral, fungal, or parasitic agents. Bacterial arthritis is the most rapidly destructive form of infectious arthritis. There are two major classes of bacterial arthritis: that caused by *Neisseria gonorrhoeae* and that caused by a nongonococcal bacterium. The most prevalent of the nongonococcal organisms include *Staphylococcus aureus* and the various streptococcal variants. Less common pathogens are related to syphilis, tuberculosis, leprosy, fungi (particularly coccidioidomycosis), mycoplasmas, and viral agents such as rubella, parvovirus, and hepatitis B.

Clinical Manifestations

The characteristic symptom is acute onset of a warm, swollen joint. Culture of the bacterium from the synovial fluid confirms the diagnosis. The patient often immobilizes the joint and elevates the affected extremity because of pain and swelling. Fever may be high, or it may be absent. Signs of systemic infection may be absent in elderly patients, in those with diabetes, and in those with suppressed immune systems. Diagnosis and treatment may be delayed by patients with preexisting arthritic conditions if they attribute the symptoms to a flare-up of arthritis.

Management

This condition is a medical emergency necessitating early diagnosis and appropriate treatment to eliminate the causative organism; otherwise, the joint may be destroyed relatively quickly. Treatment consists of parenteral

antibiotics and drainage of the joint. The results of cultures are used to determine the appropriate antibiotic therapy. Immobilization of the joint and repeated joint aspirations may be necessary along with IV antibiotics. Nursing management focuses on providing pain relief, administering antibiotics, and assisting the patient with self-care activities. If the patient is sent home on IV antibiotic therapy, the nurse arranges for home care and instructs the patient and care providers in safe administration of the drug and changes that should be reported to a health care provider.

Neoplasms and Neurovascular, Bone, and Extra-Articular Disorders

Primary neoplasms of joints, tendon sheaths, and bursae are rare. Most neoplasms are benign, arising from the synovium. These benign tumors include lipoma, hemangioma, fibroma, and tumorlike lesions such as ganglion, bursitis, and synovial cyst. Malignant tumors include primary tumors, such as synovial and bone sarcomas, and secondary involvement as manifestations of joint invasion by leukemia, lymphoma, myeloma, or metastasis. Neoplasms may manifest as back or neck pain.

Neurovascular disorders include the compression syndromes, such as those with peripheral entrapment (eg, carpal tunnel syndrome), radiculopathy, and spinal stenosis. Raynaud's phenomenon and erythromelalgia (throbbing and burning pain often affecting the hands and feet) are also included in this category.

Bone and cartilage disorders include osteoporosis, osteomalacia, hypertrophic osteoarthropathy, diffuse idiopathic skeletal hyperostosis, Paget's disease, osteonecrosis, avascular necrosis, costochondritis, osteolysis or chondrolysis, and biomechanical or anatomic abnormalities. Notably, these conditions involve resorption, destruction, infection, or remodeling of bone.

Extra-articular rheumatism is a descriptive term for a group of conditions that affect structures other than the joints. Included are general and regional pain syndromes, low back pain and intervertebral disk disorders, tendonitis and bursitis, and ganglion cysts.

Miscellaneous Disorders

The last category in the classification of the rheumatic diseases is aptly labeled miscellaneous disorders because it contains a mix of disorders that are frequently associated with arthritis and other conditions. These include the direct consequences of trauma (including internal derangement and loose bodies of joints), pancreatic disease (related to avascular necrosis or osteonecrosis), sarcoidosis (a multisystem disorder particularly of the lymph nodes and lungs), and palindromic rheumatism (an uncommon variety of recurring and acute arthritis and periartthritis that in some may progress to RA but is characterized by symptom-free periods of days to months). Other conditions include villonodular synovitis, chronic active hepatitis, and drug-related rheumatic syndromes. The nursing

interventions related to these varied conditions are specific to the multisystemic problems experienced by the patient. However, the musculoskeletal components should not be neglected or overlooked. Further information about these rare disorders can be found in specialty references.

CRITICAL THINKING EXERCISES

1 Your patient with a rheumatic disorder has NSAIDs, corticosteroids, and a biologic response modifier prescribed. How do the actions, uses, and indications of these medications differ? What instructions and recommendations would you give to the patient to ensure their safe administration?

EBP 2 A 30-year-old woman with a recent diagnosis of RA states she is having joint pain, stiffness, and swelling, especially in her hands and wrists. What resources would you use to identify the current guidelines for treatment of patients with RA? What is the evidence base for these treatment practices? Identify the criteria used to evaluate the strength of the evidence for these practices.

3 A 79-year-old woman with a 10-year history of OA of the right knee complains of pain every day and difficulty walking. She is taking multiple medications and currently she uses a walker to ambulate but needs to stop and rest every so often because of the pain. Describe the pharmacologic treatment and nursing measures that are indicated for this patient. What teaching is important for the patient? How would you modify your teaching if the patient understands little English?

Integumentary Function

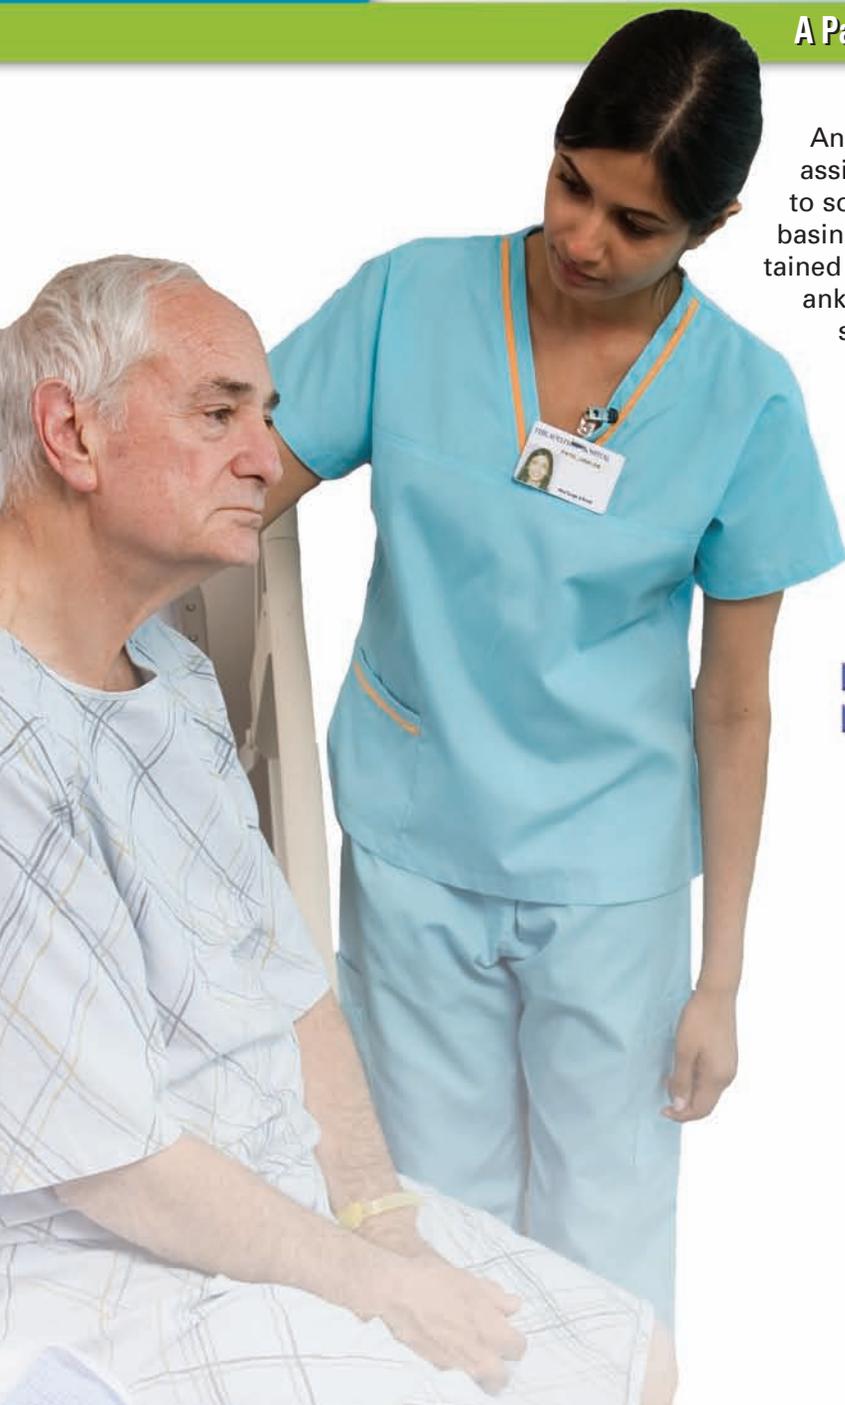

Case Study • Applying Concepts From NANDA, NIC, and NOC

A Patient With a Thermal Injury

An 87-year-old man who lives with his wife at an assisted living residence. He filled a basin of water to soak his feet and immersed his left foot in the basin before checking the water temperature. He sustained a deep partial-thickness burn on his foot and ankle and has been admitted to the residence's skilled nursing unit. The nurse notes that the skin of his left foot is bright red and there are three 2- to 4-cm blisters on the dorsum. The burn is quite painful and he cannot bear weight on his foot. His wife states that she is concerned because he is not eating his meals.

Visit thePoint to view a concept map that illustrates the relationships that exist between the nursing diagnoses, interventions, and outcomes for the patient's clinical problems.

Nursing Classifications and Languages

NANDA NURSING DIAGNOSES	NIC NURSING INTERVENTIONS	NOC NURSING OUTCOMES
		Return to functional baseline status, stabilization of, or improvement in:
IMPAIRED SKIN INTEGRITY —Altered epidermis and/or dermis	SKIN CARE: TOPICAL TREATMENTS —Application of topical substances or manipulation of devices to promote skin integrity and minimize skin breakdown	WOUND HEALING: SECONDARY INTENTION —Extent of regeneration of cells and tissues in an open wound
ACUTE PAIN —Unpleasant sensory and emotional experience arising from actual or potential tissue damage or described in terms of such damage; sudden or slow onset of any intensity from mild to severe with an anticipated or predictable end and a duration of less than 6 months	WOUND CARE —Prevention of wound complications and promotion of wound healing	PAIN CONTROL —Personal actions to control pain
RISK FOR INFECTION —At increased risk for being invaded by pathogenic organisms	PAIN MANAGEMENT —Alleviation of pain or reduction in pain to a level of comfort that is acceptable to the patient	INFECTION SEVERITY —Severity of infection and associated symptoms
RISK FOR IMBALANCED NUTRITION: LESS THAN BODY REQUIREMENTS —At risk for intake of nutrients insufficient to meet metabolic needs	INFECTION PROTECTION —Prevention and early detection of infection in a patient at risk	NUTRITIONAL STATUS —Extent to which nutrients are available to meet metabolic needs
	NUTRITION MANAGEMENT —Assisting with or providing a balanced dietary intake of foods and fluids

Chapter 55

Assessment of Integumentary Function

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

- 1 Identify the structures and functions of the skin.
- 2 Differentiate the composition and function of each skin layer: epidermis, dermis, and subcutaneous tissue.
- 3 Describe the normal aging process of the skin and skin changes common in elderly patients.
- 4 List appropriate questions that help elicit information during an assessment of the skin.
- 5 Describe the components of physical assessment that are most useful when examining the skin, hair, and nails.
- 6 Identify and describe primary and secondary skin lesions and their pattern and distribution.
- 7 Recognize common skin eruptions and manifestations associated with systemic disease.
- 8 Discuss common skin tests and procedures used in diagnosing skin and related disorders.

GLOSSARY

- alopecia:** loss of hair from any cause
dermatosis: any abnormal skin condition
erythema: redness of the skin caused by congestion of the capillaries
hirsutism: the condition of having excessive hair growth
hyperpigmentation: increase in the melanin of the skin, resulting in an increase in pigmentation
hypopigmentation: decrease in the melanin of the skin, resulting in a loss of pigmentation
keratin: an insoluble, fibrous protein that forms the outer layer of skin
Langerhans cells: dendritic clear cells in the epidermis that carry surface receptors for immunoglobulin and complement and that are active participants in delayed hypersensitivity of the skin
melanin: the substance responsible for coloration of the skin
melanocytes: cells of the skin that produce melanin
Merkel cells: cells of the epidermis that play a role in transmission of sensory messages
petechiae: pinpoint red spots that appear on the skin as a result of blood leakage into the skin
rete ridges: undulations and furrows that appear at the dermis–epidermis junction and are responsible for cementing together the two layers
sebaceous glands: glands that exist within the epidermis and secrete sebum to keep the skin soft and pliable
sebum: fatty secretion of the sebaceous glands
telangiectases: red marks on the skin caused by distention of the superficial blood vessels
vitiligo: a localized or widespread condition characterized by destruction of the melanocytes in circumscribed areas of the skin, resulting in white patches
Wood's light: a blue light used for diagnosing skin conditions

Skin disorders are encountered frequently in nursing practice. Skin-related disorders account for up to 10% of all ambulatory patient visits in the United States. Because the skin mirrors the general condition of the patient, many systemic conditions may be accompanied by dermatologic manifestations.

The psychological stress of illness or various personal and family problems is commonly exhibited outwardly as dermatologic problems. Any hospitalized patient may suddenly develop itching and a rash from the treatment regimen. In certain systemic conditions, such as hepatitis and some cancers, dermatologic manifestations may be the first sign of the disorder and the primary reason that a patient seeks health care.

Anatomic and Physiologic Overview

The largest organ system of the body, the skin, is essential for human life. It forms a barrier between the internal organs and the external environment and participates in many vital body functions. The skin is contiguous with the mucous membrane at the external openings of the digestive, respiratory, and urogenital systems.

Anatomy of the Skin, Hair, Nails, and Glands of the Skin

Skin

The skin is composed of three layers: epidermis, dermis, and subcutaneous tissue (Fig. 55-1). The epidermis is an outermost layer of stratified epithelial cells composed predominantly of keratinocytes. It ranges in thickness from about 0.1 mm on the eyelids to about 1 mm on the palms of the hands and soles of the feet. Four distinct layers compose the epidermis; from innermost to outermost they are the

stratum germinativum, stratum granulosum, stratum lucidum, and stratum corneum. Each layer becomes more differentiated (ie, mature and with more specific functions) as it rises from the basal stratum germinativum layer to the outermost stratum corneum layer.

Epidermis

The epidermis, which is contiguous with the mucous membranes and the lining of the ear canals, consists of live, continuously dividing cells covered on the surface by dead cells that were originally deeper in the dermis but were pushed upward by the newly developing, more differentiated cells underneath. This external layer is almost completely replaced every 3 to 4 weeks. The dead cells contain large amounts of **keratin**, an insoluble, fibrous protein that forms the outer barrier of the skin and has the capacity to repel pathogens and prevent excessive fluid loss from the body. Keratin is the principal hardening ingredient of the hair and nails.

Melanocytes are the special cells of the epidermis that are primarily involved in producing the pigment **melanin**, which colors the skin and hair. Skin color darkens as melanin content increases. Most of the skin of dark-skinned people and the darker areas of the skin on light-skinned people (eg, the nipple) contain larger amounts of this pigment. Normal skin color depends on race and varies from pale, almost ivory, to deep brown, almost pure black. Systemic disease affects skin color as well. For example, the skin appears bluish when there is insufficient oxygenation of the blood, yellow-green in people with jaundice, or red or flushed when there is inflammation or fever.

Production of melanin is controlled by a hormone secreted from the hypothalamus of the brain called melanocyte-stimulating hormone. It is believed that melanin can absorb ultraviolet light in sunlight.

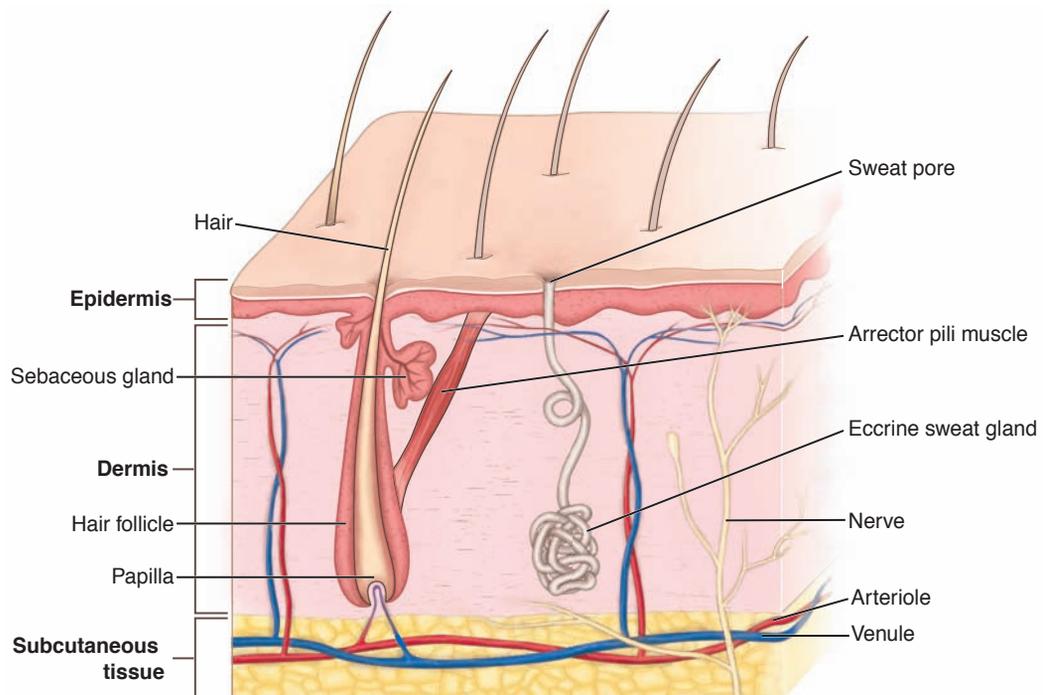

Figure 55-1 Anatomic structures of the skin.

Two other types of cells are common to the epidermis: Merkel and Langerhans cells. **Merkel cells** are receptors that transmit stimuli to the axon through a chemical synapse. **Langerhans cells** are believed to play a significant role in cutaneous immune system reactions. These accessory cells of the afferent immune system process invading antigens and transport the antigens to the lymph system to activate the T lymphocytes.

The characteristics of the epidermis vary in different areas of the body. It is thickest over the palms of the hands and soles of the feet and contains increased amounts of keratin. The thickness of the epidermis can increase with use and can result in calluses forming on the hands or corns forming on the feet.

The junction of the epidermis and dermis is an area of many undulations and furrows called **rete ridges**. This junction anchors the epidermis to the dermis and permits the free exchange of essential nutrients between the two layers. This interlocking between the dermis and epidermis produces ripples on the surface of the skin. On the fingertips, these ripples are called fingerprints. They are a person's most individual physical characteristic, and they rarely change.

Dermis

The dermis makes up the largest portion of the skin, providing strength and structure. It is composed of two layers: papillary and reticular. The papillary dermis lies directly beneath the epidermis and is composed primarily of fibroblast cells capable of producing one form of collagen, a component of connective tissue. The reticular layer lies beneath the papillary layer and also produces collagen and elastic bundles. The dermis is also made up of blood and lymph vessels, nerves, sweat and sebaceous glands, and hair roots. The dermis is often referred to as the "true skin."

Subcutaneous Tissue

The subcutaneous tissue, or hypodermis, is the innermost layer of the skin. It is primarily adipose tissue, which provides a cushion between the skin layers, muscles, and bones. It promotes skin mobility, molds body contours, and insulates the body. Fat is deposited and distributed according to the person's gender and in part accounts for the difference in body shape between men and women. Overeating results in increased deposition of fat beneath the skin. The subcutaneous tissues and the amount of fat deposited are important factors in body temperature regulation.

Hair

An outgrowth of the skin, hair is present over the entire body except for the palms and soles. The hair consists of a root formed in the dermis and a hair shaft that projects beyond the skin. It grows in a cavity called a hair follicle. Proliferation of cells in the bulb of the hair causes the hair to form (see Fig. 55-1).

Hair follicles undergo cycles of growth and rest. The rate of growth varies; beard growth is the most rapid, followed by hair on the scalp, axillae, thighs, and eyebrows. The growth or anagen phase may last up to 6 years for scalp hair, whereas the telogen or resting phase lasts approximately 4 months. During telogen, hair is shed from the body. The

hair follicle recycles into the growing phase spontaneously, or it can be induced by plucking hairs. Growing and resting hairs can be found side by side on all parts of the body. About 90% of the 100,000 hair follicles on a normal scalp are in the growing phase at any one time, and 50 to 100 scalp hairs are shed each day.

There is a small bulge on the side of the hair follicle that houses the stem cells that migrate down to the follicle root and begin the cycle of reproducing the hair shaft. These bulges also contain the stem cells that migrate upward to reproduce skin. The location of these cells on the side of the hair shaft, rather than at the base, is a factor in hair loss. In conditions in which inflammation causes damage to the root of the hair, regrowth is possible. However, if inflammation causes damage to the side of the hair follicle, stem cells are destroyed and the hair does not grow.

In certain locations on the body, hair growth is controlled by sex hormones. The most obvious example is the growth of hair on the face (ie, beard and mustache), chest, and back, which is controlled by the male hormones known as androgens. Some women with higher levels of testosterone have hair in the areas generally thought of as masculine, such as the face, chest, and lower abdomen. This is often a normal genetic variation, but if it appears along with irregular menses and weight changes, it may indicate a hormonal imbalance.

Hair in different parts of the body serves different functions. The hairs of the eyes (ie, eyebrows and lashes), nose, and ears filter out dust, bugs, and airborne debris. The hair of the skin provides thermal insulation in mammals with hair or fur. This function is enhanced during cold or fright by piloerection (ie, hairs standing on end), caused by contraction of the tiny erector muscles attached to the hair follicle. The piloerector response that occurs in humans is probably vestigial (ie, rudimentary).

Hair color is supplied by various amounts of melanin within the hair shaft. Gray or white hair reflects the loss of pigment. Hair quantity and distribution can be affected by endocrine conditions. For example, Cushing's syndrome causes **hirsutism**, especially in women, and hypothyroidism (ie, underactive thyroid) causes changes in hair texture. **Alopecia** is the general loss of hair caused by various factors. Chemotherapy and radiation therapy cause hair thinning or weakening of the hair shaft. Several autoimmune disorders, including systemic lupus erythematosus and alopecia areata, cause hair loss in smaller defined areas. Folliculitis of the scalp will cause inflammation of the hair roots and scarring alopecia.

Nails

On the dorsal surface of the fingers and toes, a hard, transparent plate of keratin, called the nail, overlies the skin. The nail grows from its root, which lies under a thin fold of skin called the cuticle. The nail protects the fingers and toes by preserving their highly developed sensory functions, such as for picking up small objects.

Nail growth is continuous throughout life, with an average growth of 0.1 mm daily. Growth is faster in fingernails than toenails and tends to slow with aging. Complete renewal of a fingernail takes about 170 days, whereas toenail renewal takes 12 to 18 months.

Glands of the Skin

There are two types of skin glands: sebaceous glands and sweat glands (see Fig. 55-1). The **sebaceous glands** are associated with hair follicles. The ducts of the sebaceous glands empty **sebum** onto the space between the hair follicle and the hair shaft, thus lubricating the hair and rendering the skin soft and pliable.

Sweat glands are found in the skin over most of the body surface, but they are most heavily concentrated in the palms of the hands and soles of the feet. Only the glans penis, the margins of the lips, the external ear, and the nail bed are devoid of sweat glands. Sweat glands are subclassified into two categories: eccrine and apocrine.

The eccrine sweat glands are found in all areas of the skin. Their ducts open directly onto the skin surface. The thin, watery secretion called sweat is produced in the basal coiled portion of the eccrine gland and is released into its narrow duct. Sweat is composed predominantly of water and contains about half of the salt content of blood plasma. Sweat is released from eccrine glands in response to elevated ambient temperature and elevated body temperature. The rate of sweat secretion is under the control of the sympathetic nervous system. Excessive sweating of the palms and soles, axillae, forehead, and other areas may occur in response to pain and stress.

The apocrine sweat glands are larger than eccrine sweat glands and are located in the axillae, anal region, scrotum, and labia majora. Their ducts generally open onto hair follicles. The apocrine glands become active at puberty. In women, they enlarge and recede with each menstrual cycle. Apocrine glands produce a milky sweat that is sometimes broken down by bacteria to produce the characteristic underarm odor. Specialized apocrine glands called ceruminous glands are found in the external ear, where they produce cerumen (ie, wax).

Functions of the Skin

Protection

The skin covering most of the body is no more than 1 mm thick, but it provides very effective protection against invasion by bacteria and other foreign matter. The thickened skin of the palms and soles protects against the effects of the constant trauma that occurs in these areas.

The stratum corneum, the outer layer of the epidermis, provides the most effective barrier to epidermal water loss and penetration of environmental factors such as chemicals, microbes, and insect bites.

Various lipids are synthesized in the stratum corneum and are the basis for the barrier function of this layer. These are long-chain lipids that are better suited than phospholipids for water resistance. The presence of these lipids in the stratum corneum creates a relatively impermeable barrier for water loss and for the entry of toxins, microbes, and other substances that come in contact with the surface of the skin.

Some substances do penetrate the skin but meet resistance in trying to move through the channels between the cell layers of the stratum corneum. Microbes and fungi, which are part of the body's normal flora, cannot penetrate unless there is a break in the skin barrier.

The dermis–epidermis junction is the basal layer, which is composed of collagen. The basal layer serves four functions. It acts as a scaffold for tissue organization and a template for regeneration; it provides selective permeability for filtration of serum; it is a physical barrier between different types of cells; and it binds the epithelium to underlying cell layers.

Sensation

The receptor endings of nerves in the skin allow the body to constantly monitor the conditions of the immediate environment. The primary functions of the receptors in the skin are to sense temperature, pain, light touch, and pressure (or heavy touch). Different nerve endings respond to each of the different stimuli. Although the nerve endings are distributed over the entire body, they are more concentrated in some areas than in others. For example, the fingertips are more densely innervated than the skin on the back.

Fluid Balance

The stratum corneum, the outermost layer of the epidermis, has the capacity to absorb water, thereby preventing an excessive loss of water and electrolytes from the internal body and retaining moisture in the subcutaneous tissues. When skin is damaged, as occurs with a severe burn, large quantities of fluids and electrolytes may be lost rapidly, possibly leading to circulatory collapse, shock, and death.

The skin is not completely impermeable to water. Small amounts of water continuously evaporate from the skin surface. This evaporation, called insensible perspiration, amounts to approximately 600 mL daily in a normal adult. Insensible water loss varies with the body and ambient temperature. In a person with a fever, the loss can increase. During immersion in water, the skin can accumulate water up to three or four times its normal weight, such as the swelling of the skin that occurs after prolonged bathing.

Temperature Regulation

The body continuously produces heat as a result of the metabolism of food, which produces energy. This heat is dissipated primarily through the skin. Three major physical processes are involved in loss of heat from the body to the environment. The first process, radiation, is the transfer of heat to another object of lower temperature situated at a distance. The second process, conduction, is the transfer of heat from the body to a cooler object in contact with it. The third process, convection, which consists of movement of warm air molecules away from the body, is the transfer of heat by conduction to the air surrounding the body.

Evaporation from the skin aids heat loss by conduction. Heat is conducted through the skin into water molecules on its surface, causing the water to evaporate. The water on the skin surface may be from insensible perspiration, sweat, or the environment.

Normally, all of these mechanisms for heat loss are used. However, when the ambient temperature is very high, radiation and convection are ineffective, and evaporation becomes the only means of heat loss.

Under normal conditions, metabolic heat production is balanced by heat loss, and the internal temperature of the

body is maintained constant at approximately 37°C (98.6°F). The rate of heat loss depends primarily on the surface temperature of the skin, which is a function of the skin blood flow. Under normal conditions, the total blood circulated through the skin is approximately 450 mL/min, or 10 to 20 times the amount of blood required to provide necessary metabolites and oxygen. Blood flow through these skin vessels is controlled primarily by the sympathetic nervous system. Increased blood flow to the skin results in more heat delivered to the skin and a greater rate of heat loss from the body. In contrast, decreased skin blood flow decreases the skin temperature and helps conserve heat for the body. When the temperature of the body begins to fall, as occurs on a cold day, the blood vessels of the skin constrict, thereby reducing heat loss from the body.

Sweating is another process by which the body can regulate the rate of heat loss. Sweating does not occur until the core body temperature exceeds 37°C, regardless of skin temperature. In extremely hot environments, the rate of sweat production may be as high as 1 L/h. Under some circumstances (eg, emotional stress), sweating may occur as a reflex and may be unrelated to the need to lose heat from the body.

Vitamin Production

Skin exposed to ultraviolet light can convert substances necessary for synthesizing vitamin D (cholecalciferol). Vitamin D is essential for preventing osteoporosis and rickets, a condition that causes bone deformities and results from a deficiency of vitamin D, calcium, and phosphorus.

Immune Response Function

Research has confirmed a definite action of Langerhans cells in facilitating the uptake of immunoglobulin E (IgE)-associated allergens. This action plays a pivotal role in the pathogenesis of atopic dermatitis and other allergic diseases such as asthma and allergic rhinitis. These findings support the concept of a systemic regulatory mechanism as a trigger for allergic diseases and suggest that this trigger can be aggravated by local inflammation of atopic eczema (Porth & Matfin, 2009).

Gerontologic Considerations

The skin undergoes many physiologic changes associated with normal aging. A lifetime of excessive sun exposure, systemic diseases, and poor nutrition can increase the range of skin conditions and the rapidity with which they appear. In addition, certain medications (eg, antihistamines, antibiotics, diuretics) are photosensitizing and increase the damage that results from sun exposure. The outcome is an increasing vulnerability to injury and to certain diseases. Therefore, skin conditions are common among older people.

The major changes in the skin of older people include dryness, wrinkling, uneven pigmentation, and various proliferative lesions. Cellular changes associated with aging include a thinning at the junction of the dermis and epidermis. The result of this thinning is fewer anchoring sites between the two skin layers, which means that even minor injury or stress to the epidermis can cause it to shear away from the dermis. This phenomenon may account for the increased

Figure 55-2 Hands with and overlapping folds common to aging skin.

vulnerability of aged skin to trauma. With increasing age, the epidermis and dermis thin and flatten, causing wrinkles, sags, and overlapping skin folds (Fig. 55-2).

Loss of the subcutaneous tissue substances of elastin, collagen, and fat diminishes the protection and cushioning of underlying tissues and organs, decreases muscle tone, and results in the loss of the insulating properties of fat.

Cellular replacement slows as a result of aging. As the dermal layers thin, the skin becomes fragile and transparent. The blood supply to the skin also changes with age. Vessels, especially the capillary loops, decrease in number and size. These vascular changes contribute to the delayed wound healing commonly seen in the elderly patient. Sweat and sebaceous glands decrease in number and functional capacity, leading to dry and scaly skin. Reduced hormonal levels of androgens are thought to contribute to declining sebaceous gland function.

Hair growth gradually diminishes, especially over the lower legs and dorsum of the feet. Thinning is common in the scalp, axilla, and pubic areas. Other functions affected by normal aging include the barrier function of skin, sensory perception, and thermoregulation.

Photoaging, or damage from excessive sun exposure, has detrimental effects on the normal aging of skin. A lifetime of outdoor work or outdoor activities (eg, construction work, lifeguarding, sunbathing) without prudent use of sunscreens can lead to profound wrinkling; increased loss of elasticity; mottled, pigmented areas; cutaneous atrophy; and benign or malignant lesions.

Many skin lesions are part of normal aging. Recognizing these lesions enables the examiner to assist the patient to feel less anxious about changes in skin. Chart 55-1 summarizes some skin lesions that are expected to appear as the skin ages. These are normal and require no special attention unless the skin becomes infected or irritated.

Assessment

When caring for patients with dermatologic disorders, the nurse obtains important information through the health history and direct observations. The nurse's skill in physical

CHART
55-1**Benign Changes in Elderly Skin**

- Cherry angiomas (bright red “moles”)
- Diminished hair, especially on scalp and pubic area
- Dyschromias (color variations)
 - Solar lentigo (liver spots)
 - Melasma (dark discoloration of the skin)
 - Lentiginos (freckles)
- Neurodermatitis (itchy spots)
- Seborrheic keratoses (crusty brown “stuck-on” patches)
- Spider angiomas
- Telangiectasias (red marks on skin caused by stretching of the superficial blood vessels)
- Wrinkles
- Xerosis (dryness)
- Xanthelasma (yellowish waxy deposits on upper and lower eyelids)

assessment and an understanding of the anatomy and function of the skin can ensure that deviations from normal are recognized, reported, and documented.

Health History

During the health history interview, the nurse asks about any family and personal history of skin allergies; allergic reactions to food, medications, and chemicals; previous skin conditions; and skin cancer. The names of cosmetics, soaps, shampoos, and other personal hygiene products are obtained if there have been any recent skin conditions noticed with the use of these products. If suspicious areas are noted, the patient is questioned about nonprescription or herbal preparations that are being used. The health history addresses the onset, signs and symptoms, location, and duration of any pain, itching, rash, or other discomfort experienced by the patient. Chart 55-2 lists selected questions useful in obtaining appropriate information and Chart 55-3 provides genetic factors influencing skin conditions.

Physical Assessment

Assessment of the skin involves the entire skin area, including the mucous membranes, scalp, hair, and nails. The skin is a reflection of a person’s overall health, and alterations commonly correspond to disease in other organ systems. Inspection and palpation are techniques commonly used in examining the skin. The room must be well lighted and warm. A penlight may be used to highlight lesions. The patient completely disrobes and is adequately draped. Gloves are worn during skin examination if a rash or lesions are to be palpated. However, it is important to avoid making the patient feel as if he or she cannot be touched.

The general appearance of the skin is assessed by observing color, temperature, moisture or dryness, skin texture (rough or smooth), lesions, vascularity, mobility, and the condition of the hair and nails. Skin turgor, possible edema, and elasticity are assessed by palpation.

Assessing Skin Color

The color gradations that occur in people with dark skin are largely determined by genetics; they may be described as light, medium, or dark. In people with dark skin, melanin is

CHART
55-2**Assessing for Skin Disorders**

Patient history relevant to skin disorders may be obtained by asking the following questions:

- When did you first notice this skin problem? (Also investigate duration and intensity.)
- Has it occurred previously?
- Are there any other symptoms?
- What site was first affected?
- What did the rash or lesion look like when it first appeared?
- Where and how fast did it spread?
- Do you have any itching, burning, tingling, or crawling sensations?
- Is there any loss of sensation?
- Is the problem worse at a particular time or season?
- How do you think it started?
- Do you have a history of hay fever, asthma, hives, eczema, or allergies?
- Who in your family has skin problems or rashes?
- Did the eruptions appear after certain foods were eaten? Which foods?
- When the problem occurred, had you recently consumed alcohol?
- What relation do you think there may be between a specific event and the outbreak of the rash or lesion?
- What medications are you taking?
- What topical medication (ointment, cream, salve) have you put on the lesion (including over-the-counter medications)?
- What skin products or cosmetics do you use?
- What is your occupation?
- What in your immediate environment (plants, animals, chemicals, infections) might be precipitating this disorder? Is there anything new, or are there any changes in the environment?
- Does anything touching your skin cause a rash?
- How has this affected you (or your life)?
- Is there anything else you wish to talk about in regard to this disorder?

produced at a faster rate and in larger quantities than in people with light skin. Healthy dark skin has a reddish base or undertone. The buccal mucosa, tongue, lips, and nails normally are pink. The skin of exposed portions of the body, especially in sunny, warm climates, tends to be more pigmented than the rest of the body. Almost every process that occurs on the skin causes some color change. For example, **hypopigmentation** may be caused by a fungal infection, eczema, or **vitiligo**; **hyperpigmentation** can occur after sun injury or as a result of aging. Dark pigment responds with discoloration after injury or inflammation, and patients with dark skin more often experience postinflammatory hyperpigmentation than those with lighter skin. The hyperpigmentation eventually fades but may require months to a year to do so.

Changes in skin color in people with dark skin are more noticeable and may cause more concern because the discoloration is more readily visible. Because of the increased number of melanocytes in darker skin, pigment changes can become quite obvious and cause great psychological discomfort. Some variation in skin pigment levels is considered normal. Examples include the pigmented crease across

CHART
55-3GENETICS IN NURSING PRACTICE
Integumentary Conditions

Integumentary conditions influenced by genetic factors include the following:

- Albinism
- Eczema
- Hypohidrotic ectodermal dysplasia
- Incontinentia pigmenti
- Neurofibromatosis type 1
- Pseudoxanthoma elasticum
- Psoriasis

Nursing Assessments**Family History Assessment**

- Assess for other closely related family members with integumentary impairment or abnormalities.
- Inquire about the nature and type of skin lesions and age at onset (eg, skin involvement with incontinentia pigmenti occurs in the first few weeks of life with blistering of the skin, whereas lesions of neurofibromatosis type 1 may appear in early childhood through adulthood).
- Note gender of affected individuals (eg, mostly females with incontinentia pigmenti, mostly males with hypohidrotic ectodermal dysplasia).
- Inquire about the presence of other clinical features, such as unusual hair, teeth, or nails; thrombocytopenia; recurrent infections.

Patient Assessment

- Assess for related clinical features, such as sparse eyebrows and eyelashes, abnormally shaped teeth, alopecia, nail abnormalities (eg, hypohidrotic ectodermal dysplasia).
- Assess for related alterations in vision, such as nystagmus or strabismus; albinism; retinal abnormalities (eg, pseudox-

anthoma elasticum); Lisch nodules and/or optic glioma (neurofibromatosis type 1).

Management Issues Specific to Genetics

- Inquire whether DNA mutation or other genetics testing has been performed on affected family members.
- If indicated, refer for further genetics counseling and evaluation so that family members can discuss inheritance, risk to other family members, availability of genetics testing, and gene-based interventions.
- Offer appropriate genetics information and resources.
- Assess patient's understanding of genetics information.
- Provide support to families with newly diagnosed genetics-related integumentary conditions.
- Participate in management and coordination of care for patients with genetic conditions and for individuals predisposed to develop or pass on a genetic condition.

the bridge of the nose, pigmented streaks in the nails, and pigmented spots on the sclera of the eye.

Table 55-1 provides an overview of color changes in light-skinned and dark-skinned people.

Cyanosis

Cyanosis is the bluish discoloration that results from a lack of oxygen in the blood (Fig. 55-3). It appears with shock or with respiratory or circulatory compromise. In people with light skin, cyanosis manifests as a bluish hue to the lips, fingertips, and nail beds. Other indications of decreased tissue perfusion include cold, clammy skin; a rapid, thready pulse; and rapid, shallow respirations. The conjunctivae of the eyelids are examined for pallor and **petechiae**.

In a person with dark skin, the skin usually assumes a grayish cast. To detect cyanosis, the areas around the mouth and lips and over the cheekbones and earlobes should be observed.

Erythema

Erythema is redness of the skin caused by the congestion of capillaries. In light-skinned people, it is easily observable. To determine possible inflammation, the skin is palpated for increased warmth and for smoothness (ie, edema) or hardness (ie, intracellular infiltration). Because dark skin tends to assume a purple-gray cast when an inflammatory process is present, it may be difficult to detect erythema.

Jaundice

Jaundice, a yellowing of the skin, is directly related to elevations in serum bilirubin and is often first observed in the sclerae and mucous membranes (see Fig. 55-3).

Assessing Rash

In instances of pruritus (ie, itching) the patient is asked to indicate which areas of the body are involved. The skin is then stretched gently to decrease the reddish tone and make the rash more visible. Pointing a penlight laterally across the skin may highlight the rash, making it easier to observe. The differences in skin texture are then assessed by running the tips of the fingers lightly over the skin. The borders of the rash may be palpable. The patient's mouth and ears are included in the examination (rubeola, or measles, causes a red cast to appear on the ears, and skin cancers are quite common on the crest of the ears). The patient's temperature is assessed, and the lymph nodes are palpated especially in the axilla, inguinal fold, and behind the knees (popliteal area).

Assessing Skin Lesions

Skin lesions are the most prominent characteristics of dermatologic conditions. They vary in size, shape, and cause and are classified according to their appearance and origin.

Table 55-1 COLOR CHANGES IN LIGHT AND DARK SKIN

Etiology	Light Skin	Dark Skin
Pallor		
Anemia—decreased hematocrit	Generalized pallor	Brown skin appears yellow-brown, dull; black skin appears ashen gray, dull. (Observe areas with least pigmentation: conjunctivae, mucous membranes.)
Shock—decreased perfusion, vasoconstriction		Ashen gray, dull; cool to palpation
Local arterial insufficiency	Marked localized pallor (lower extremities, especially when elevated)	
Albinism—total absence of pigment melanin	Whitish pink	Tan, cream, white
Vitiligo—a condition characterized by destruction of the melanocytes in circumscribed areas of the skin (may be localized or widespread)	Patchy, milky white spots, often symmetric bilaterally	Same
Cyanosis		
Increased amount of unoxygenated hemoglobin:	Dusky blue	Dark but dull, lifeless; only severe cyanosis is apparent in skin. (Observe conjunctivae, oral mucosa, nail beds.)
Central—chronic heart and lung diseases cause arterial desaturation		
Peripheral—exposure to cold, anxiety	Nail beds dusky	
Erythema		
Hyperemia—increased blood flow through engorged arterial vessels, as in inflammation, fever, alcohol intake, blushing	Red, bright pink	Purplish tinge, but difficult to see. (Palpate for increased warmth with inflammation, taut skin, and hardening of deep tissues.)
Polycythemia—increased red blood cells, capillary stasis	Ruddy blue in face, oral mucosa, conjunctivae, hands and feet	Well concealed by pigment. (Observe for redness in lips.)
Carbon monoxide poisoning	Bright, cherry red in face and upper torso	Cherry red nail beds, lips, and oral mucosa
Venous stasis—decreased blood flow from area, engorged venules	Dusky rubor of dependent extremities (a prelude to necrosis with pressure ulcer)	Easily masked. (Use palpation to identify warmth or edema.)
Jaundice		
Increased serum bilirubin concentration (>2–3 mg/100 mL) due to liver dysfunction or hemolysis, as after severe burns or some infections	Yellow first in sclerae, hard palate, and mucous membranes; then over skin	Check sclerae for yellow near limbus; do not mistake normal yellowish fatty deposits in the periphery under eyelids for jaundice. (Jaundice is best noted at junction of hard and soft palate, on palms.)
Carotenemia—increased level of serum carotene from ingestion of large amounts of carotene-rich foods	Yellow-orange tinge in forehead, palms and soles, and nasolabial folds, but no yellowing in sclerae or mucous membranes	Yellow-orange tinge in palms and soles
Uremia—renal failure causes retained urochrome pigments in the blood	Orange-green or gray overlying pallor of anemia; may also have ecchymoses and purpura	Easily masked. (Rely on laboratory and clinical findings.)
Brown-Tan		
Addison's disease—cortisol deficiency stimulates increased melanin production	Bronzed appearance, an “external tan”; most apparent around nipples, perineum, genitalia, and pressure points (inner thighs, buttocks, elbows, axillae)	Easily masked. (Rely on laboratory and clinical findings.)
Café-au-lait spots—caused by increased melanin pigment in basal cell layer	Tan to light brown, irregularly shaped, oval patch with well-defined borders often not visible in the very dark skinned person	

Figure 55-3 Examples of skin color changes: the bluish tint of cyanosis (*left*) and the yellow hue of jaundice (*right*).

Skin lesions can be described as primary or secondary. Primary lesions are the initial lesions and are characteristic of the disease itself. Secondary lesions result from changes in primary lesions resulting from external causes, such as scratching, trauma, infections, or changes caused by wound healing. Depending on the stage of development, skin lesions are further categorized by type and appearance (Table 55-2).

A preliminary assessment of the eruption or lesion helps identify the type of **dermatosis** and indicates whether the lesion is primary or secondary. At the same time, the anatomic distribution of the eruption or lesion

Table 55-2 PRIMARY AND SECONDARY SKIN LESIONS

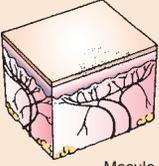

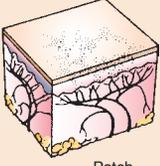

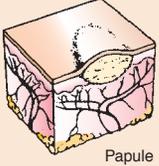

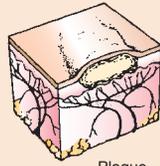

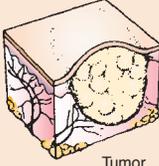

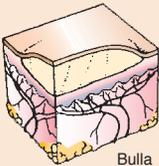

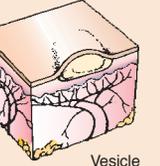

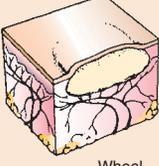

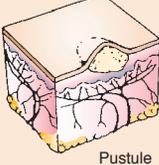

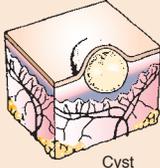

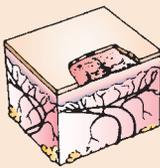

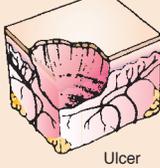

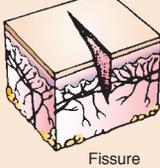

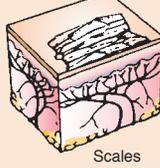

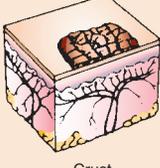

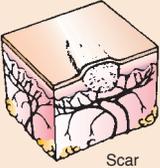

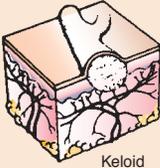

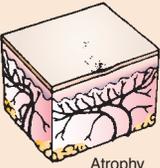

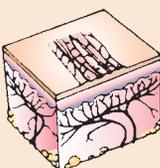

Lesion	Description	Examples
Primary Lesions		
<p>MACULE, PATCH</p>  <p>Macule</p>  <p>Patch</p>	<p>Flat, nonpalpable skin color change (color may be brown, white, tan, purple, red)</p> <ul style="list-style-type: none"> • <i>Macule</i>: less than 1 cm, circumscribed border • <i>Patch</i>: greater than 1 cm, may have irregular border 	<p>Freckles, flat moles, petechia, rubella, vitiligo, port wine stains, ecchymosis</p>
<p>PAPULE, PLAQUE</p>  <p>Papule</p>  <p>Plaque</p>	<p>Elevated, palpable, solid mass with a circumscribed border</p> <p>Plaque may be coalesced papules with flat top</p> <ul style="list-style-type: none"> • <i>Papule</i>: less than 0.5 cm • <i>Plaque</i>: greater than 0.5 cm 	<p><i>Papules</i>: Elevated nevi, warts, lichen planus</p> <p><i>Plaques</i>: Psoriasis, actinic keratosis</p>
<p>NODULE, TUMOR</p>  <p>Nodule</p>  <p>Tumor</p>	<p>Elevated, palpable, solid mass that extends deeper into the dermis than a papule</p> <ul style="list-style-type: none"> • <i>Nodule</i>: 0.5–2 cm; circumscribed • <i>Tumor</i>: greater than 1–2 cm; tumors do not always have sharp borders 	<p><i>Nodules</i>: Lipoma, squamous cell carcinoma, poorly absorbed injection, dermatofibroma</p> <p><i>Tumors</i>: Larger lipoma, carcinoma</p>
<p>VESICLE, BULLA</p>  <p>Vesicle</p>  <p>Bulla</p>	<p>Circumscribed, elevated, palpable mass containing serous fluid</p> <ul style="list-style-type: none"> • <i>Vesicle</i>: less than 0.5 cm • <i>Bulla</i>: greater than 0.5 cm 	<p><i>Vesicles</i>: Herpes simplex/zoster, chickenpox, poison ivy, second-degree burn (blister)</p> <p><i>Bulla</i>: Pemphigus, contact dermatitis, large burn blisters, poison ivy, bullous impetigo</p>
<p>WHEAL</p>  <p>Wheal</p>	<p>Elevated mass with transient borders; often irregular; size and color vary</p> <p>Caused by movement of serous fluid into the dermis; does not contain free fluid in a cavity (as, for example, a vesicle does)</p>	<p>Urticaria (hives), insect bites</p>
<p>PUSTULE</p>  <p>Pustule</p>	<p>Pus-filled vesicle or bulla</p>	<p>Acne, impetigo, furuncles, carbuncles</p>

Table 55-2 PRIMARY AND SECONDARY SKIN LESIONS (Continued)

Lesion	Description	Examples
<p>CYST</p>  <p>Cyst</p>	Encapsulated fluid-filled or semisolid mass in the subcutaneous tissue or dermis	Sebaceous cyst, epidermoid cysts
<p>Secondary Lesions</p>		
<p>EROSION</p>  <p>Erosion</p>	Loss of superficial epidermis that does not extend to dermis; depressed, moist area	Ruptured vesicles, scratch marks
<p>ULCER</p>  <p>Ulcer</p>	Skin loss extending past epidermis; necrotic tissue loss; bleeding and scarring possible	Stasis ulcer of venous insufficiency, pressure ulcer
<p>FISSURE</p>  <p>Fissure</p>	Linear crack in the skin that may extend to dermis	Chapped lips or hands, athlete's foot
<p>SCALES</p>  <p>Scales</p>	Flakes secondary to desquamated, dead epithelium that may adhere to skin surface; color varies (silvery, white); texture varies (thick, fine)	Dandruff, psoriasis, dry skin, pityriasis rosea
<p>CRUST</p>  <p>Crust</p>	Dried residue of serum, blood, or pus on skin surface Large, adherent crust is a scab	Residue left after vesicle rupture: impetigo, herpes, eczema

Continued on following page

Table 55-2 PRIMARY AND SECONDARY SKIN LESIONS (Continued)		
Lesion	Description	Examples
<p>SCAR (CICATRIX)</p>  <p>Scar</p>	<p>Skin mark left after healing of a wound or lesion; represents replacement by connective tissue of the injured tissue</p> <ul style="list-style-type: none"> • <i>Young scars</i>: red or purple • <i>Mature scars</i>: white or glistening 	Healed wound or surgical incision
<p>KELOID</p>  <p>Keloid</p>	<p>Hypertrophied scar tissue secondary to excessive collagen formation during healing; elevated, irregular, red</p> <p>Greater incidence among African Americans</p>	Keloid of ear piercing or surgical incision
<p>ATROPHY</p>  <p>Atrophy</p>	<p>Thin, dry, transparent appearance of epidermis; loss of surface markings; secondary to loss of collagen and elastin; underlying vessels may be visible</p>	Aged skin, arterial insufficiency
<p>LICHENIFICATION</p>  <p>Lichenification</p>	<p>Thickening and roughening of the skin or accentuated skin markings that may be secondary to repeated rubbing, irritation, scratching</p>	Contact dermatitis

should be observed because certain diseases affect certain sites of the body and are distributed in characteristic patterns and shapes (Figs. 55-4 and 55-5). To determine the extent of the regional distribution, the left and right sides of the body should be compared while the color and shape of the lesions are assessed. The degree of pigmentation of the patient's skin may affect the appearance of a lesion. Lesions may be black, purple, or gray on dark skin and tan or red in patients with light skin. A metric ruler is used to measure the size of the lesions so that any further extension can be compared with this baseline measurement. After observation, the lesions are palpated to determine their texture, shape, and border and to see if they are soft and filled with fluid or hard and fixed to the surrounding tissue.

Skin lesions are described clearly and in detail on the patient's health record, using precise terminology:

- Color of the lesion
- Any redness, heat, pain, or swelling
- Size and location of the involved area
- Pattern of eruption (eg, macular, papular, scaling, oozing, discrete, confluent)
- Distribution of the lesion (eg, bilateral, symmetric, linear, circular)

If acute open wounds or lesions are found on inspection of the skin, a comprehensive assessment should be made and documented. This assessment should address the following issues:

- **Wound bed:** Inspect for necrotic and granulation tissue, epithelium, exudate, color, and odor
- **Wound edges and margins:** Observe for undermining (ie, extension of the wound under the surface skin), and evaluate for condition
- **Wound size:** Measure in millimeters or centimeters, as appropriate, to determine diameter and depth of the wound and surrounding erythema
- **Surrounding skin:** Assess for color, suppleness and moisture, irritation, and scaling

Assessing Vascularity and Hydration

After the color of the skin has been evaluated and lesions have been inspected, an assessment of vascular changes in the skin is performed. A description of vascular changes includes location, distribution, color, size, and the presence of

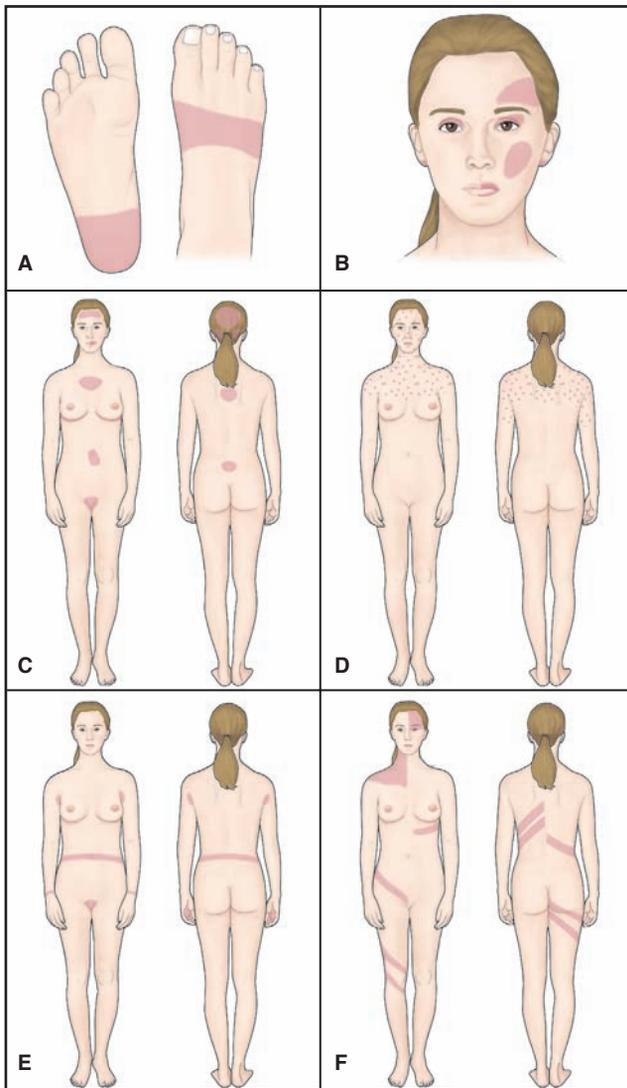

Figure 55-4 Anatomic distribution of common skin disorders. **A**, Contact dermatitis (shoes). **B**, Contact dermatitis (cosmetics, perfumes, earrings). **C**, Seborrheic dermatitis. **D**, Acne. **E**, Scabies. **F**, Herpes zoster (shingles).

pulsations. Common vascular changes include petechiae, ecchymoses, **telangiectases** (venous stars), and angiomas, (Table 55-3).

Skin moisture, temperature, and texture are assessed primarily by palpation. The turgor (ie, elasticity) of the skin, which decreases in normal aging, may be a factor in assessing the hydration status of a patient.

Assessing the Nails

A brief inspection of the nails includes observation of configuration, color, and consistency. Many alterations in the nail or nail bed reflect local or systemic abnormalities in progress or resulting from past events (Fig. 55-6). Transverse depressions known as Beau's lines in the nails may reflect retarded growth of the nail matrix because of severe illness or, more commonly, local trauma. Ridging, hypertrophy, and other changes may also be visible because of local trauma.

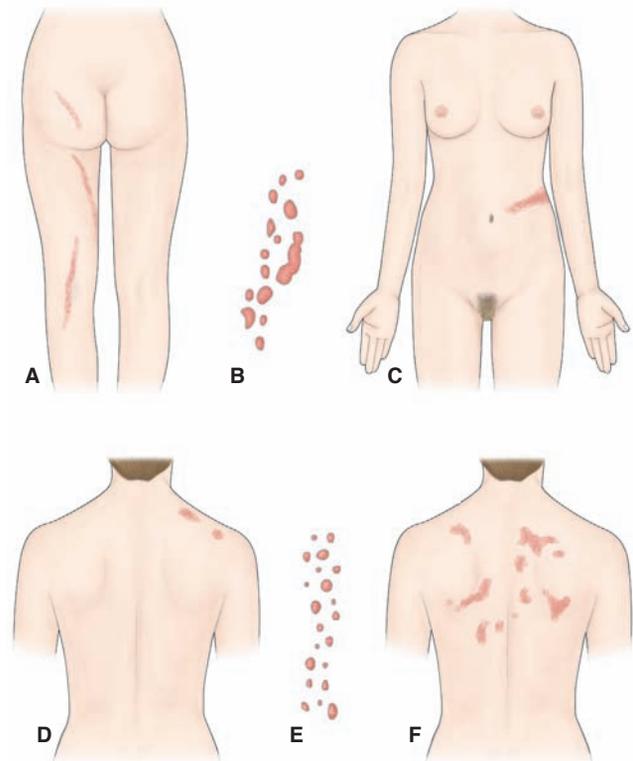

Figure 55-5 Skin lesion configurations. **A**, Linear (in a line). **B**, Annular and arciform (circular or arcing). **C**, Zosteriform (linear along a nerve route). **D**, Grouped (clustered). **E**, Discrete (separate and distinct). **F**, Confluent (merged).

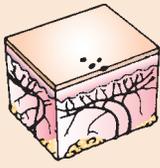

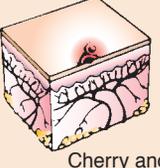

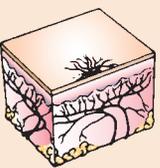

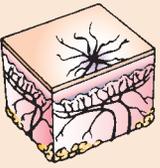

Paronychia, an inflammation of the skin around the nail, is usually accompanied by tenderness and erythema. Pitted surface of the nails is a definite indication of psoriasis. Spoon-shape nails can indicate a severe iron deficiency anemia. The angle between the normal nail and its base is 160 degrees. When palpated, the nail base is usually firm. Clubbing of the nails, which can occur from hypoxia, is manifested by a straightening of the normal angle (180 degrees or greater) and softening of the nail base. The softened area feels spongelike when palpated.

Assessing the Hair

The hair assessment is carried out by inspection and palpation. Gloves are worn by the examiner, and the examination room should be well lighted. Separating the hair so that the condition of the skin underneath can be easily seen, the nurse assesses color, texture, and distribution. The wooden end of a cotton swab can be used to make small parts in the hair so that the scalp can be inspected. Any abnormal lesions, evidence of itching, inflammation, scaling, or signs of infestation (ie, lice or mites) are documented.

Color and Texture

Natural hair color ranges from white to black. Hair begins to turn gray with age, initially during the third decade of life, when the loss of melanin begins to become apparent. However, it is not unusual for the hair of younger people to turn gray as a result of hereditary traits. The person with albinism (ie, partial or complete absence of pigmentation)

Table 55-3 VASCULAR LESIONS	
Lesion	Description
PETECHIA (PL. PETECHIAE)  <p>Petechiae</p>	Round red or purple macule Small: 1–2 mm Secondary to blood extravasation Associated with bleeding tendencies or emboli to skin
ECCHYMOSIS (PL. ECCHYMOSES)  <p>Ecchymoses</p>	Round or irregular macular lesion Larger than petechia Color varies and changes: black, yellow, and green hues Secondary to blood extravasation Associated with trauma, bleeding tendencies
CHERRY ANGIOMA  <p>Cherry angioma</p>	Papular and round Red or purple Noted on trunk, extremities May blanch with pressure Normal age-related skin alteration Usually not clinically significant
SPIDER ANGIOMA  <p>Spider angioma</p>	Red, arteriole lesion Central body with radiating branches Noted on face, neck, arms, trunk Rare below the waist May blanch with pressure Associated with liver disease, pregnancy, vitamin B deficiency
TELANGIECTASIA (VENOUS STAR)  <p>Telangiectasia</p>	Shape varies: spider-like or linear Color bluish or red Does not blanch when pressure is applied Noted on legs, anterior chest Secondary to superficial dilation of venous vessels and capillaries Associated with increased venous pressure states (varicosities)

has a genetic predisposition to white hair from birth. The natural state of the hair can be altered by using hair dyes, bleaches, and curling or relaxing products. The types of products used are identified in the assessment.

The texture of scalp hair ranges from fine to coarse, silky to brittle, oily to dry, and shiny to dull, and hair can be straight, curly, or kinky. Dry, brittle hair may result from overuse of hair dyes, hair dryers, and curling irons or from endocrine disorders, such as thyroid dysfunction. Oily hair is usually caused by increased secretion from the sebaceous glands close to the scalp. If the patient reports a recent change in hair texture, the underlying reason is pursued; the alteration may arise simply from the overuse of commercial hair products or from changing to a new shampoo.

Distribution

Body hair distribution varies with location. Hair over most of the body is fine, except in the axillae and pubic areas, where it is coarse. Pubic hair, which develops at puberty, forms a diamond shape extending up to the umbilicus in boys and men. Female pubic hair resembles an inverted triangle. If the pattern found is more characteristic of the opposite gender, it may indicate an endocrine disorder and further investigation is in order. Racial differences in hair are expected, such as straight hair in Asians and curly, coarser hair in people of African descent.

Men tend to have more body and facial hair than women. Alopecia can occur over the entire body or be confined to a specific area. Scalp hair loss may be localized to patchy areas or may range from generalized thinning to total baldness. When assessing scalp hair loss, it is important to investigate the underlying cause with the patient. Patchy hair loss may be from habitual hair pulling or twisting; excessive traction on the hair (eg, braiding too tightly); excessive use of dyes, straighteners, and oils; chemotherapeutic agents (eg, doxorubicin [Adriamycin], cyclophosphamide [Cytosan]); bacterial or fungal infection; or moles or lesions on the scalp. Regrowth may be erratic, and distribution may never attain the previous thickness.

Hair Loss

The most common cause of hair loss is male pattern baldness, which affects more than half of the male population and is believed to be related to heredity, aging, and androgen (male hormone) levels. Androgen is necessary for male pattern baldness to develop. The pattern of hair loss begins with receding of the hairline in the frontal-temporal area and progresses to gradual thinning and complete loss of hair over the top of the scalp and crown. Figure 55-7 illustrates the typical pattern of male hair loss. Though androgenic alopecia is considered a male disorder, millions of women also experience it. Women tend to retain some of the hair on the crown of the scalp and never go completely bald.

Other Changes

Male pattern hair distribution may be seen in some women at the time of menopause, when the hormone estrogen is no longer produced by the ovaries. In women with hirsutism, excessive hair may grow on the face, chest, shoulders, and pubic area. If menopause is ruled out as the underlying cause, other hormonal changes related to pituitary or adrenal dysfunction must be investigated.

Because patients with skin conditions may be viewed negatively by others, these patients may become distraught and avoid interaction with people. Skin conditions can lead to disfigurement, isolation, job loss, and economic hardship.

Some conditions may lead to feelings of depression, frustration, self-consciousness, poor self-image, and rejection. Itching and skin irritation, features of many skin diseases, may be constant annoyances. These discomforts may result in loss of sleep, anxiety, and depression, all of which reinforce the general distress and fatigue that frequently accompany skin disorders.

For patients experiencing physical and psychological discomforts, the nurse needs to provide understanding,

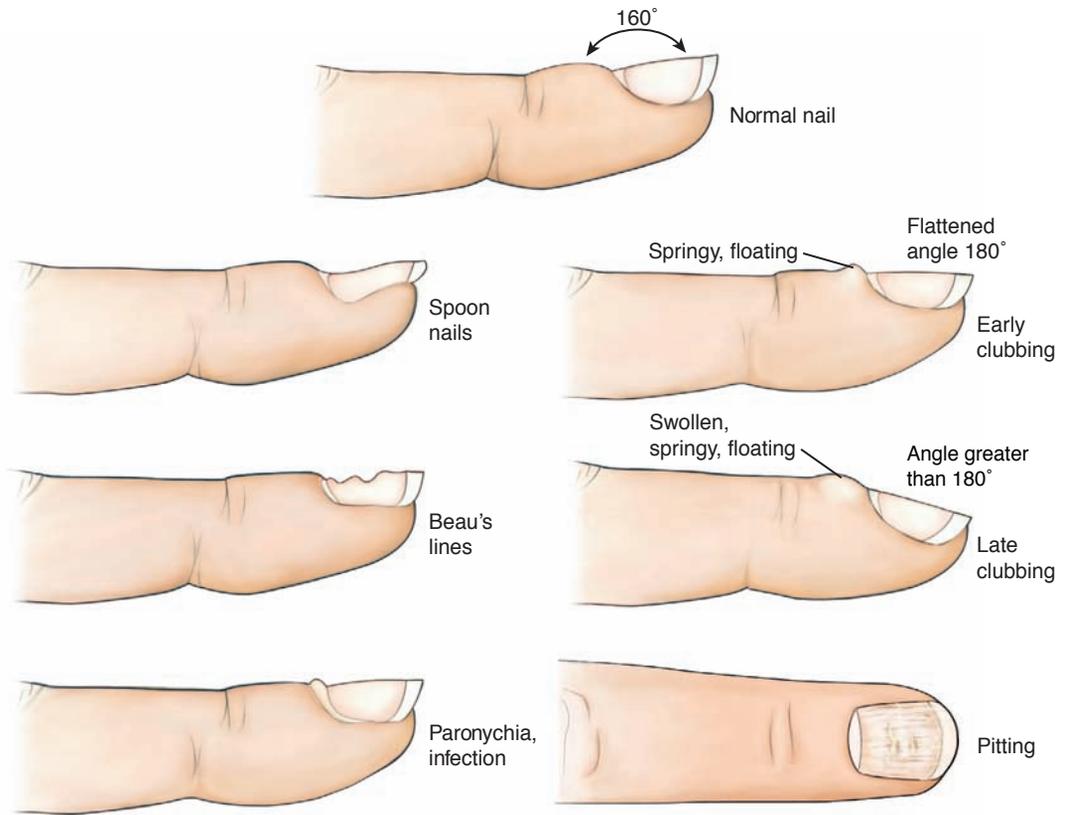

Figure 55-6 Common nail disorders.

explanations of the problem, appropriate instructions related to treatment, nursing support, and encouragement. It is imperative to overcome any aversion that may be felt when caring for patients with unattractive skin disorders. The nurse should show no sign of hesitancy when approaching patients with skin disorders. Such hesitancy only reinforces the psychological trauma of the disorder.

Skin Consequences of Selected Systemic Diseases

Diabetes Mellitus

Because diabetes causes changes in circulation and cell nutrition, it can have a great impact on skin status. Some of the more common skin conditions encountered in diabetes are discussed in this section. Further information can be found in Chapter 41.

Diabetic Dermopathy

Diabetic dermopathy (shin spots) occurs in about 50% of peoples with diabetes. These lesions are found on the lower anterior legs, forearms, and thighs and over other bony prominences. They are caused by breakdown of the small vessels that supply the skin. Each spot starts as a dull red bump, smaller than a pencil eraser. It slowly spreads to about one inch (the size of a quarter), becomes increasingly scaly, and eventually leaves a brownish scar on the skin. The lesions are usually bilateral and occur in linear clusters.

Stasis Dermatitis

Stasis dermatitis is not unique to diabetes, but because of the blood vessel damage that results from diabetes, it is very common in patients with diabetes. Large vessels are damaged, compromising circulation to the lower arms and legs.

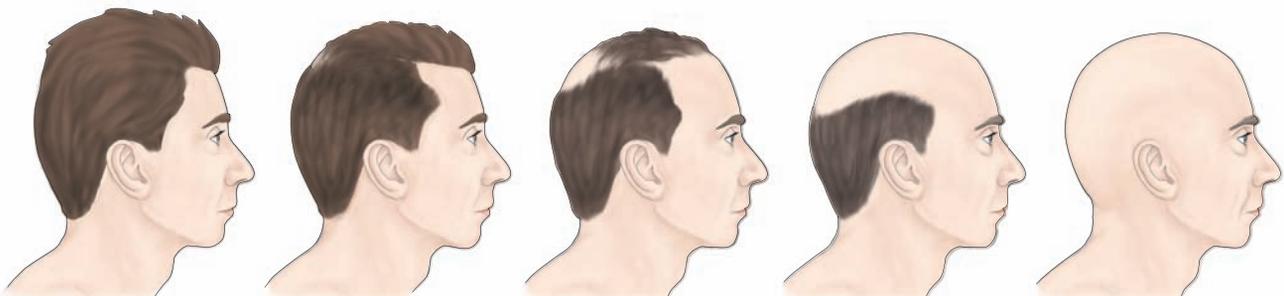

Figure 55-7 The progression of male pattern baldness.

The skin suffers from lack of nutrients, becoming very dry and fragile. Minor injuries heal slowly, and ulcers form easily. The skin takes on a thick leathery texture and a yellowish, waxy hue.

Skin Infections

The skin of patients with diabetes is prone to bacterial and fungal infections. Bacterial infections appear as small pimples around hair follicles. The most frequently affected sites include the lower legs, lower abdomen, and buttocks. Sometimes these lesions enlarge to become furuncles or carbuncles. If the blood glucose level is not well controlled, these infections may be very slow to heal.

Fungal infections are quite common in areas that remain moist all the time (under breasts, upper thighs, in axilla). *Candida* (ie, yeast) infections appear beefy red and have small pustules around the border of the area, with the skin appearing moist and raw.

Dermatophyte infections are dry and only minimally red, with more scale. Common sites are the toenails and feet.

Nurses must be alert to the signs of these common infections. If necessary, they should bring them to the attention of the physician and help the patient or family learn basic skin maintenance techniques.

Leg and Foot Ulcers

Because of changes in peripheral nerves, patients with diabetes do not always sense minor injuries to the lower legs and feet. Infections begin and if left untreated may lead to ulcerations. Ulcerations are often not noticed and become quite large before being treated. Ulcerations unresponsive to treatment are a leading cause of diabetic foot and leg amputations.

Human Immunodeficiency Virus Disease

Cutaneous signs may be the first manifestation of human immunodeficiency virus (HIV), appearing in more than 90% of HIV-infected people as immune function deteriorates. These skin signs correlate with low CD4 counts and may become very atypical in immunocompromised people. Some disorders such as Kaposi's sarcoma, oral hairy leukoplakia, facial molluscum contagiosum, and oral candidiasis may suggest that CD4 counts are less than 200 to 300 cell/ μ L. Being sensitive to these changes can alert the nurse so that early intervention can be initiated (Freytes, Arroyo-Novoa, Figueroa-Ramos, et al., 2007).

Diagnostic Evaluation

As previously discussed, it is important to inspect the primary and secondary lesions and their configuration and distribution. Certain diagnostic procedures may also be used to help identify skin conditions.

Skin Biopsy

Performed to obtain tissue for microscopic examination, a skin biopsy may be obtained by scalpel excision or by a skin punch instrument that removes a small core of tissue.

Biopsies are performed on skin nodules, plaques, blisters, and other lesions to rule out malignancy and to establish an exact diagnosis.

Immunofluorescence

Designed to identify the site of an immune reaction, immunofluorescence testing combines an antigen or antibody with a fluorochrome dye. Antibodies can be made fluorescent by attaching them to a dye. Direct immunofluorescence tests on skin are techniques to detect autoantibodies directed against portions of the skin. The indirect immunofluorescence test detects specific antibodies in the patient's serum.

Patch Testing

Performed to identify substances to which the patient has developed an allergy, patch testing involves applying the suspected allergens to normal skin under occlusive patches. The development of redness, fine elevations, or itching is considered a weak positive reaction; fine blisters, papules, and severe itching indicate a moderately positive reaction; and blisters, pain, and ulceration indicate a strong positive reaction.

Skin Scrapings

Tissue samples are scraped from suspected fungal lesions with a scalpel blade moistened with oil so that the scraped skin adheres to the blade. The scraped material is transferred to a glass slide, covered with a coverslip, and examined microscopically. The spores and hyphae of dermatophyte infections, as well as infestations such as scabies, can be visualized.

Tzanck Smear

The Tzanck smear is a test used to examine cells from blistering skin conditions, such as herpes zoster, varicella, herpes simplex, and all forms of pemphigus. The secretions from a suspected lesion are applied to a glass slide, stained, and examined.

Wood's Light Examination

Wood's light is a special lamp that produces long-wave ultraviolet rays, which result in a characteristic dark purple fluorescence. The color of the fluorescent light is best seen in a darkened room, where it is possible to differentiate epidermal from dermal lesions and hypopigmented and hyperpigmented lesions from normal skin. The patient is reassured that the light is not harmful to skin or eyes. Lesions that still contain melanin almost disappear under ultraviolet light, whereas lesions that are devoid of melanin increase in whiteness with ultraviolet light.

Clinical Photographs

Photographs are taken to document the nature and extent of the skin condition and are used to determine progress or improvement resulting from treatment. They are sometimes used to track the status of moles to document if the characteristics of the mole are changing.

CRITICAL THINKING EXERCISE

EBP You are volunteering at the skin cancer screening booth at a community health fair. A college student approaches you and asks about risk factors for skin cancer. He states that he lifeguards at a pool every summer and that he is on his school's golf team and plays golf year round. Identify the evidence to support the use of protection from the sun, including sunscreens, to prevent skin cancer. Discuss the strength of the evidence that supports the use of sunscreens. Identify the criteria used to evaluate the strength of the evidence for this practice.

Chapter 56

Management of Patients With Dermatologic Problems

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

- 1 Describe the general management of the patient with an abnormal skin condition.
- 2 Describe the health education needs of the patient with infections of the skin and parasitic skin diseases.
- 3 Describe the management and nursing care of the patient with psoriasis.
- 4 Use the nursing process as a framework for care of patients with blistering disorders.
- 5 Use the nursing process as a framework for care of patients with toxic epidermal necrolysis and Stevens-Johnson syndrome.
- 6 Describe the management and nursing care of the patient with skin cancer.
- 7 Use the nursing process as a framework for care of the patient with malignant melanoma.
- 8 Describe characteristics of the various types of Kaposi's sarcoma.
- 9 Compare the various types of dermatologic and plastic reconstructive procedures.
- 10 Describe the nursing care of patients undergoing dermatologic and plastic reconstructive procedures.

GLOSSARY

- acantholysis:** separation of epidermal cells from each other due to damage or abnormality of the intracellular substance
- balneotherapy:** a bath with therapeutic additives
- carbuncle:** localized skin infection involving several hair follicles
- cheilitis:** inflammation of the lips (when dry, cracking, inflamed skin occurs at the corners of the mouth it is called angular cheilitis; when caused by sun exposure it is called solar cheilitis)
- comedones:** the primary lesions of acne, caused by sebum blockage in the hair follicle
- cytotoxic:** destructive of cells
- débridement:** removal of necrotic or dead tissue by mechanical, surgical, or autolytic means
- dermatitis:** any inflammation of the skin
- dermatosis:** any abnormal skin lesion
- epidermopoiesis:** development of epidermal cells
- fibrinolytic:** a substance that acts to break up fibrin, the fine filaments of blood clots
- furuncle:** localized skin infection of a single hair follicle
- hydrophilic:** a material that absorbs moisture
- hydrophobic:** a material that repels moisture
- hygroscopic:** a material that absorbs moisture from the air
- lichenification:** thickening of the horny layer of the skin
- liniments:** lotions with added oil for increased softening of the skin
- mitogenic:** a substance that stimulates mitosis or cell division and reproduction
- plasmapheresis:** removal of whole blood from the body, separation of its cellular elements by centrifugation, and reinfusion of them suspended in saline or some other plasma substitute, thereby depleting the body's own plasma without depleting its cells
- pyoderma:** bacterial skin infections
- striae:** bandlike streaks on the skin, distinguished by color, texture, depression, or elevation from the tissue in which they are found; usually purplish or white
- suspensions:** liquid preparations in which powder is suspended, requiring shaking before use
- tinea:** a superficial fungal infection on the skin or scalp
- xerosis:** overly dry skin

Nursing care for patients with dermatologic problems includes administering topical and systemic medications, managing wet dressings and other special dressings, and providing therapeutic baths. The four major objectives of therapy are to prevent additional damage, prevent secondary infection, reverse the inflammatory process, and relieve the symptoms.

SKIN CARE FOR PATIENTS WITH SKIN CONDITIONS

Some skin problems are markedly aggravated by soap and water, and bathing routines are modified according to the condition. Denuded skin, whether the area of desquamation is large or small, is excessively prone to damage by chemicals and trauma. The friction of a towel, if applied with vigor, is sufficient to produce a brisk inflammatory response that causes any existing lesion to flare up and extend.

Protecting the Skin

Basic skin care in bathing a patient with skin problems is as follows:

- A mild, lipid-free soap or soap substitute is used.
- The area is rinsed completely and blotted dry with a soft cloth.
- Deodorant soaps and laundry detergents are avoided.

Special care is necessary when changing dressings. Use of pledgets saturated with oil, sterile saline, or another prescribed solution helps loosen crusts, remove exudates, or free an adherent dry dressing.

Preventing Secondary Infection

Skin lesions should be regarded as potentially infectious, and proper precautions should be observed until the diagnosis is established. Most lesions with purulent drainage contain infectious material. The nurse and physician must adhere to standard precautions and wear gloves when inspecting the skin or changing a dressing. Use of standard precautions and proper disposal of any contaminated dressing is carried out according to the Occupational Safety and Health Administration (OSHA) regulations.

Reversing the Inflammatory Process

The type of skin lesion (eg, oozing, infected, or dry) usually determines the type of local medication or treatment that is prescribed. As a rule, if the skin is acutely inflamed (ie, hot, red, and swollen) and oozing, it is best to apply wet dressings and soothing lotions. For chronic conditions in which the skin surface is dry and scaly, water-soluble emulsions, creams, ointments, and pastes are used. The therapy is modified as the responses of the skin indicate. The patient and the nurse should note whether the medication or dressings seem to irritate the skin. The success or failure of therapy usually depends on adequate instruction and motivation of the patient and family, and the support of health care personnel promotes adherence to instructions.

WOUND CARE FOR SKIN CONDITIONS

There are three types of wound dressings: passive, interactive, and active. *Passive* dressings have only a protective function and maintain a moist environment for natural healing. They include those that just cover the area (eg, DuoDERM, Tegaderm) and may remain in place for several days. *Interactive* dressings are capable of absorbing wound exudate while (1) maintaining a moist environment in the area of the wound and (2) allowing the surrounding skin to remain dry. They include hydrocolloids, alginates, and hydrogels. It is thought that interactive dressings are able to modify the physiology of the wound environment by modulating and stimulating cellular activity and by releasing growth factor (Fonder, Lazarus, Cowan, et al., 2008). *Active* dressings improve the healing process and decrease healing time. They include skin grafts and biologic skin substitutes. Both interactive and active dressings create a moist environment at the interface of the wound with the dressing.

Because so many wound care products are available, it is often difficult to select the most appropriate product for a specific wound. Selection of products should be made carefully because of their expense. Both clinical efficacy and health-related outcomes (eg, decreased pain, increased mobility) should be used to measure the success of a product for a wound. Even with the availability of a large variety of dressings, an appropriate selection can be made if certain principles are maintained. These principles are referred to as the five rules of wound care (Krasner, Rodeheaver & Sibbald, 2007):

- *Rule 1: Categorization.* The nurse learns about dressings by generic category and compares new products with those that already make up the category. The nurse becomes familiar with indications, contraindications, and side effects. The best dressing may be created by combining products in different categories to achieve several goals at the same time. These categories are discussed in subsequent sections.
- *Rule 2: Selection.* The nurse selects the safest and most effective, easy-to-use, and cost-effective dressing possible. In many cases, nurses carry out the physician's prescriptions for dressings, but they must be prepared to give the physician feedback about the dressing's effect on the wound, ease of use for the patient, and other considerations when applicable.
- *Rule 3: Change.* The nurse changes dressings based on patient, wound, and dressing assessments, not on standardized routines.

NURSING ALERT

The natural wound-healing process should not be disrupted. Unless the wound is infected or has a heavy discharge, it is common to leave chronic wounds covered for 48 to 72 hours and acute wounds for 24 hours.

- *Rule 4: Evolution.* As the wound progresses through the phases of wound healing, the dressing protocol

is altered to optimize wound healing. It is rare, especially in cases of chronic wounds, that the same dressing material is appropriate throughout the healing process. The nurse teaches the patient or family caregiver about wound care and ensures that the family has access to appropriate dressing choices.

- **Rule 5: Practice.** Practice with dressing material is required for the nurse to learn the performance parameters of the particular dressing. Refining the skills of applying appropriate dressings correctly and learning about new dressing products are essential nursing responsibilities. Dressing changes should not be delegated to unlicensed personnel; these techniques require the knowledge base and assessment skills of professional nurses.

Autolytic Débridement

Autolytic **débridement** is a process that uses the body's own digestive enzymes to break down necrotic tissue. The wound is kept moist with occlusive dressings. Eschar and necrotic debris are softened, liquefied, and separated from the bed of the wound.

Several commercially available products contain the same enzymes that the body produces naturally. These are called enzymatic débriding agents; examples include Accu-Zyme, collagenase (Santyl), Granulex, and Zymase. Application of these products speeds the rate at which necrotic tissue is removed. This method, although slower than surgi-

cal débridement, is more discriminating for tissue removal and does not damage healthy tissue surrounding the wound. When enzymatic débridement is being used under an occlusive dressing, a foul odor is produced by the breakdown of cellular debris. This odor does not indicate that the wound is infected. The nurse should expect this reaction and help the patient and family understand the reason for the odor.

Categories of Dressings

Table 56-1 is a guide to wound dressing functions and categories.

Occlusive Dressings

Occlusive dressings may be commercially produced or made inexpensively from sterile or nonsterile gauze squares or wrap. Occlusive dressings cover topical medication that is applied to a skin lesion. The area is kept airtight by using plastic film (eg, plastic wrap). Plastic film is thin and readily adapts to all sizes, body shapes, and skin surfaces. Generally, plastic wrap should be used no more than 12 hours each day. Plastic surgical tape containing a corticosteroid in the adhesive layer can be cut to size and applied to individual lesions.

Wet Dressings

Wet dressings (wet compresses applied to the skin) were traditionally used for acute, weeping, inflammatory lesions. They have become almost obsolete because of the many newer products available for wound care.

Table 56-1 QUICK GUIDE TO FUNCTION AND ACTION OF WOUND DRESSINGS

Function	Action	Example
Absorption	Absorbs exudate	Alginates, composite dressings, foams, gauze, hydrocolloids, hydrogels
Cleansing	Removes purulent drainage, foreign debris, and devitalized tissue	Wound cleansers
Débridement	<i>Autolytic</i> ; covers a wound and allows enzymes to self-digest sloughed skin	Absorption beads, pastes, powders; alginates; composite dressings; foams; hydrate gauze; hydrogels; hydrocolloids; transparent films; wound care systems
	<i>Chemical</i> or enzymatic; applied topically to break down devitalized tissue	Enzymatic débridement agents
	<i>Mechanical</i> ; removes devitalized tissue with mechanical force	Wound cleansers, gauze (wet to dry), whirlpool
Diathermy	Produces electrical current to promote warmth and new tissue growth	
Hydration	Adds moisture to a wound	Gauze (saturated with saline) solution, hydrogels, wound care systems
Maintain moist environment	Manages moisture levels in a wound and maintains a moist environment	Composites, contact layers, foams, gauze (impregnated or saturated), hydrogels, hydrocolloids, transparent films, wound care systems
Manage high-output wounds	Manages excessive quantities of exudate	Pouching systems
Pack or fill dead space	Prevents premature wound closure or fills shallow areas and provides absorption	Absorbent beads, powders, pastes; alginates, composites, foams, gauze (impregnated and nonimpregnated)
Protect and cover wound	Provides protection from the external environment	Composites, compression bandages/wraps, foams, gauze dressings, hydrogels, hydrocolloids, transparent film dressings
Protect periwound skin	Prevents moisture and mechanical trauma from damaging delicate tissue around wound	Composites, foams, hydrocolloids, pouching systems, skin sealants, transparent film dressings
Provide therapeutic compression	Provides appropriate levels of support to the lower extremities in venous stasis disease	Compression bandages, wraps, graduated compression stockings

Moisture-Retentive Dressings

Commercially produced moisture-retentive dressings can perform the same functions as wet dressings but are more efficient at removing exudate because of their higher moisture-vapor transmission rate; some have reservoirs that can hold excessive exudate. A number of moisture-retentive dressings are already impregnated with saline solution, petrolatum, zinc-saline solution, hydrogel, or antimicrobial agents, thereby eliminating the need to coat the skin to avoid maceration. The main advantages of moisture-retentive dressings over wet dressings are improved fibrinolysis, accelerated epidermal resurfacing, reduced pain, fewer infections, less scar tissue, gentle autolytic débridement, and decreased frequency of dressing changes. Depending on the product used and the type of dermatologic conditions encountered, most moisture-retentive dressings may remain in place from 12 to 24 hours; some can remain in place as long as a week.

Hydrogels

Hydrogels are polymers with 90% to 95% water content. They are available in impregnated sheets or as gel in a tube. Their high moisture content makes them ideal for autolytic débridement of wounds. They are semitransparent, allowing for wound inspection without dressing removal. They are comfortable and soothing for the painful wound. They require a secondary dressing to keep them in place. Hydrogels are appropriate for superficial wounds with high serous output, such as abrasions, skin graft sites, and draining venous ulcers.

Hydrocolloids

Hydrocolloids are composed of a water-impermeable, polyurethane outer covering separated from the wound by a hydrocolloid material. They are adherent and nonpermeable to water vapor and oxygen. As water evaporates over the wound, it is absorbed into the dressing, which softens and discolors with the increased water content. The dressing can be removed without damage to the wound. As the dressing absorbs water, it produces a foul-smelling, yellowish covering over the wound. This is a normal chemical interaction between the dressing and wound exudate and should not be confused with purulent drainage from the wound. Unfortunately, most of the hydrocolloid dressings are opaque, preventing inspection of the wound without removal of the dressing.

Available in sheets and in gels, hydrocolloids are a good choice for exudative wounds and for acute wounds. Easy to use and comfortable, hydrocolloid dressings promote débridement and formation of granulation tissue. Most can be left in place for as long as 7 days and can be submerged in water for bathing or showering. A recent consensus statement of wound experts suggested that hydrocolloid dressings are better than saline gauze or paraffin gauze dressings for complete healing of chronic wounds (Vaneau, Chaby, Guillot, et al., 2007).

Foam Dressings

Foam dressings consist of microporous polyurethane with an absorptive **hydrophilic** (water-absorbing) surface that covers the wound and a **hydrophobic** (water-resistant) backing to block leakage of exudate. They are nonadherent and require a secondary dressing to keep them in place. Moisture is absorbed into the foam layer, decreasing maceration of

surrounding tissue. A moist environment is maintained, and removal of the dressing does not damage the wound. The foams are opaque and must be removed for wound inspection. Foams are a good choice for exudative wounds. They are especially helpful over bony prominences because they provide contoured cushioning.

Calcium Alginates

Calcium alginates are derived from seaweed and consist of very absorbent calcium alginate fibers. They are hemostatic and bioabsorbable and can be used as sheets or mats of absorbent material. As the exudate is absorbed, the fibers turn into a viscous hydrogel. They are useful in areas where the tissue is more irritated or macerated. The alginate dressing forms a moist pocket over the wound while the surrounding skin stays dry. The dressing also reacts with wound fluid, which forms a foul-smelling coating. Alginates work well when packed into a deep cavity, wound, or sinus tract with heavy drainage (Krasner, et al., 2007). They are nonadherent and require a secondary dressing. A recent consensus statement of wound experts suggests that alginates are superior to other modern dressings for débriding necrotic wounds (Vaneau, et al., 2007).

Advances in Wound Treatment

Increasing understanding of how skin heals has led to several advances in therapy. Growth factors are cytokines or proteins that have potent **mitogenic** activity (Vaneau, et al., 2007). Low levels of cytokines circulate in the blood continuously and control key factors involved in wound healing. Many investigators believe that a deficit of cytokines contributes to poor wound healing. Regranex gel, which contains becaplermin, a recombinant human platelet-derived growth factor, promotes chemotactic recruitment and proliferation of the cells involved in wound healing (Fonder, et al., 2008).

Bioengineered skin substitutes have emerged in the past 25 years as the most effective method for management of chronic wounds. Most of these skin substitutes are cultures of keratinocytes delivered on a petrolatum gauze. They work by maintaining wound moisture, providing a structure for regeneration of cells, and supplying beneficial cytokines. These substitutes include AlloDerm, Apligraf, Dermagraft, Epicel, and Laserskin.

Some oral medications are being investigated for their benefits in healing chronic venous ulcers of the lower legs. Pentoxifylline (Trental) increases peripheral blood flow by decreasing the viscosity of blood. It has some **fibrinolytic** action and decreases leukocyte adhesion to the wall of the blood vessels. Enteric-coated aspirin was thought to be of value, but a more recent study suggests that aspirin inhibits the tensile strength of skin and prolongs the healing time (Fonder, et al., 2008).

A recent study (Jones, Fennie & Lenihan, 2007) found several surprising results related to healing of chronic wounds:

- Mechanical débridement is contraindicated because it may increase the possibility of infection and because there may be inadvertent damage to healthy tissue.
- The use of a commercial cleansing agent rather than water, normal saline, or povidone-iodine is related to faster healing.

- Initial selection of the dressing type to be used is critical to success. Wounds heal faster when the type of dressing is not changed during treatment. If the type of dressing was changed four or five times, healing times were more likely to be prolonged.
- Documenting the presence of bacteria is critical. Bacteria slow healing time. However, antibiotics are often overused; thus, it is important to check for the presence of bacteria before initiating antibiotic therapy.

Medical Management

Therapeutic Baths (Balneotherapy)

Baths or soaks, known as **balneotherapy**, are useful when large areas of skin are affected. The baths remove crusts, scales, and previously applied topical medications and relieve the inflammation and pruritus (itching) that accompany acute dermatoses. Additional information about therapeutic baths is given in Chart 56-1.

Pharmacologic Therapy

Because skin is easily accessible, topical medications are often used. High concentrations of some medications can be applied directly to the affected site with little systemic absorption and therefore with few systemic side effects. However, some medications are readily absorbed through the skin and can produce systemic effects. Because topical preparations may induce allergic contact **dermatitis** in sensitive patients, any untoward response should be reported immediately and the medication discontinued.

Chart 56-1 • Therapeutic Baths

Types of Therapeutic Baths	
Bath Solution	Effects and Uses
Water	Same effect as wet dressings
Saline	Used for widely disseminated lesions
Colloidal (Aveeno, oatmeal)	Antipruritic, soothing
Sodium bicarbonate (baking soda)	Cooling
Starch	Soothing
Medicated tars	Psoriasis and chronic eczema
Bath oils	Antipruritic and emollient action; acute and subacute generalized eczematous eruptions

Nursing Interventions	
•	Fill the tub half full.
•	Keep the water at a comfortable temperature.
•	Do not allow the water to cool excessively.
•	Use a bath mat, because <i>medications added to the bath can cause the tub to be slippery</i> .
•	Apply an emollient cream to damp skin after the bath if lubrication is desired.
•	Because tars are volatile, the bath area should be well ventilated.
•	Maintain a constant room temperature without drafts.
•	Encourage the patient to wear light, loose clothing after the bath.

Medicated lotions, creams, ointments, and powders are frequently used to treat skin lesions. In general, moisture-retentive dressings, with or without medication, are used in the acute stage; lotions and creams are reserved for the subacute stage; and ointments are used when inflammation has become chronic and the skin is dry with scaling or **lichenification**.

With all types of topical medication, the patient is taught to apply the medication gently but thoroughly and, when necessary, to cover the medication with a dressing to protect clothing. Table 56-2 lists commonly used topical preparations.

Lotions

Lotions are frequently used to replenish lost skin oils or to relieve pruritus. They are usually applied directly to the skin, but a dressing soaked in the lotion can be placed on the affected area. Lotions must be applied every 3 or 4 hours for sustained therapeutic effect. If left in place for a longer period, they may crust and cake on the skin.

Lotions are of two types: suspensions and liniments. **Suspensions**, consist of a powder in water that requires shaking before application, and clear solutions, contain completely dissolved active ingredients. A suspension such as calamine lotion provides a rapid cooling and drying effect as it evaporates, leaving a thin, medicinal layer of powder on the affected skin. **Liniments** are lotions with oil added to prevent crusting. Because lotions are easy to use, therapeutic compliance is generally high.

Powders

Powders usually have a talc, zinc oxide, bentonite, or cornstarch base and are dusted on the skin with a shaker or with cotton sponges. Although their therapeutic action is brief, powders act as **hygroscopic** agents that absorb and retain moisture from the air and reduce friction between skin surfaces and clothing or bedding.

Creams

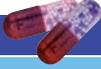

Creams may be suspensions of oil in water or emulsions of water in oil, with additional ingredients to prevent bacterial and fungal growth. Both may cause an allergic reaction such as contact dermatitis. Oil-in-water creams are easily applied and usually are the most cosmetically acceptable to the patient. Although they can be used on the face, they tend to have a drying effect. Water-in-oil emulsions are greasier and are preferred for drying and flaking dermatoses. Creams usually are rubbed into the skin by hand. They are used for their moisturizing and emollient effects.

Gels

Gels are semisolid emulsions that become liquid when applied to the skin or scalp. They are cosmetically acceptable to the patient because they are not visible after application, and they are greaseless and nonstaining. The newer water-based gels appear to penetrate the skin more effectively and cause less stinging on application. They are especially useful for acute dermatitis in which there is weeping exudate (eg, poison ivy).

Pastes

Pastes are mixtures of powders and ointments and are used in inflammatory blistering conditions. They adhere to the

Table 56-2 COMMON TOPICAL PREPARATIONS AND MEDICATIONS

Preparation	Product Name
Bath preparations	
With tar	Balnetar, Doak Oil, Lavatar
With colloidal oatmeal	Aveeno Oilated Bath Powder
With oatmeal and mineral oil	Aveeno Bath Oil, Nutra Soothe
With mineral oil	Nutraderm Bath Oil, Lubath, Alpha-Keri Bath Oil
Moisturizer creams	Acid Mantle Cream, Curel Cream, Dermasil, Eucerin, Lubriderm, Noxzema Skin Cream
Moisturizer ointments	Aquaphor Ointment, Eutra Swiss Skin Cream, Vaseline Ointment
Topical anesthetics	lidocaine (Xylocaine) of various strengths in the form of spray, ointment, gel; EMLA cream (lidocaine 2.5% and prilocaine 2.5%)
Topical antibiotics	bacitracin, Polysporin (bacitracin and polymixin B), Bactroban ointment or cream (mupirocin 2%), erythromycin 2% (Emgel, Eryderm Solution), clindamycin phosphate 1% (Cleocin cream, gel, solution), gentamicin sulfate 1% (Garamycin cream or ointment), 1% silver sulfadiazine cream (Silvadene)

skin and may be difficult to remove without using an oil (eg, olive oil, mineral oil). Pastes are applied with a wooden tongue depressor or gloved hand.

Ointments

Ointments retard water loss and lubricate and protect the skin. They are the preferred vehicle for delivering medication to chronic or localized dry skin conditions, such as eczema or psoriasis. Ointments are applied with a wooden tongue depressor or gloved hand.

Sprays and Aerosols

Spray and aerosol preparations may be used on any widespread dermatologic condition. They evaporate on contact and are used infrequently.

Corticosteroids

Corticosteroids are widely used in treating dermatologic conditions to provide anti-inflammatory, antipruritic, and vasoconstrictive effects. The patient is taught to apply this medication according to strict guidelines, using it sparingly but rubbing it into the prescribed area thoroughly. Absorption of topical corticosteroids is enhanced when the skin is hydrated or the affected area is covered by an occlusive or moisture-retentive dressing. Inappropriate use of topical corticosteroids can result in local and systemic side effects, especially when the medication is absorbed through inflamed and excoriated skin, is used under occlusive dressings, or is used for long periods on sensitive areas. Local side effects may include skin atrophy and thinning, **striae** (bandlike streaks), and telangiectasia (small, red lesions caused by dilation of blood vessels). Thinning of the skin results from the ability of corticosteroids to inhibit skin collagen synthesis. The thinning process can be reversed by discontinuing the medication, but striae and telangiectasia are permanent. Systemic side effects may include hyperglycemia and symptoms of Cushing's syndrome. Caution is required when applying corticosteroids around the eyes for two reasons: (1) long-term use may cause glaucoma or

cataracts, and (2) the anti-inflammatory effect of corticosteroids may mask existing viral or fungal infections.

Concentrated (fluorinated) corticosteroids are never applied on the face or intertriginous areas (ie, axilla and groin) because these areas have a thinner stratum corneum and absorb the medication much more quickly than areas such as the forearm or legs. Persistent use of concentrated topical corticosteroids in any location may produce acne-like dermatitis, known as steroid-induced acne, and hypertrichosis (excessive hair growth). Because some topical corticosteroid preparations are available without prescription, patients should be cautioned about prolonged and inappropriate use. Table 56-3 lists topical corticosteroid preparations according to potency.

Intralesional Therapy

Intralesional therapy consists of injecting a sterile suspension of medication (usually a corticosteroid) into or just below a lesion. Although this treatment may have an anti-inflammatory effect, local atrophy may result if the medication is injected into subcutaneous fat. Skin lesions treated with intralesional therapy include psoriasis, keloids, and cystic acne. Occasionally, immunotherapeutic and antifungal agents are administered as intralesional therapy.

Systemic Medications

Systemic medications are also prescribed for skin conditions. These include corticosteroids for short-term therapy for contact dermatitis or for long-term treatment of a chronic **dermatosis**, such as pemphigus vulgaris. Other frequently used systemic medications include antibiotics, antifungals, antihistamines, sedatives, tranquilizers, analgesics, and **cytotoxic** (destructive of cells) agents.

Nursing Management

Management begins with a health history, direct observation, and a complete physical examination. (Chapter 55 provides a description of integumentary assessment.) Because of its visibility, a skin condition is usually difficult to ignore or conceal from others and may therefore cause the patient

Table 56-3 POTENCY: TOPICAL CORTICOSTEROIDS

Potency	Topical Corticosteroid	Preparations
OTC	0.5–1.0% hydrocortisone	cr, lot, oint
Lowest	dexamethasone 0.1% (Decaderm)	cr, oint, aerosol, gel
	alclometasone 0.05% (Aclovate)	cr, oint
	hydrocortisone 2.5% (Hytone)	cr, lot, oint
Low–medium	desonide 0.05% (DesOwen, Tridesilon)	cr, lot, oint
	fluocinolone acetonide 0.025% (Synalar)	cr, solution
	hydrocortisone valerate 0.2% (Westcort)	cr, solution
	betamethasone valerate 0.1% (Valisone)	cr, oint
	fluticasone propionate 0.05% (Cutivate)	cr, oint
	triamcinolone acetonide 0.1–0.5% (Aristocort)	cr, oint, lot
Medium–high	fluocinonide 0.05% (Lidex)	cr, oint, gel
	desoximetasone 0.05–0.25% (Topicort)	cr, oint, gel
	fluocinolone 0.2% (Synalar)	cr, oint
	diflorasone diacetate 0.05% (Psorcon)	cr, oint
	clobetasol propionate 0.05% (Temovate)	cr, oint, gel
Very high	betamethasone dipropionate 0.05% (Diprolene)	cr, oint, gel
	halobetasole propionate 0.05% (Ultravate)	cr, oint

cr, cream; lot, lotion; oint, ointment; OTC, over the counter.

emotional distress. The major goals for the patient may include maintenance of skin integrity, relief of discomfort, promotion of restful sleep, self-acceptance, knowledge about skin care, and avoidance of complications.

Nursing management for patients who must perform self-care for skin problems, such as applying medications and dressings, focuses mainly on teaching the patient how to wash the affected area and pat it dry, apply medication to the lesion while the skin is moist, cover the area with plastic (eg, Telfa pads, plastic wrap, vinyl gloves, plastic bag) if recommended, and cover it with an elastic bandage, dressing, or paper tape to seal the edges. Dressings that contain or cover a topical corticosteroid should be removed for 12 of every 24 hours to prevent skin thinning, striae, and telangiectasia.

Other forms of dressings, such as those used to cover topical medications, include soft cotton cloth and stretchable cotton dressings (eg, Surgitube, TubeGauz) that can be used for fingers, toes, hands, and feet. The hands can be covered with disposable polyethylene or vinyl gloves sealed at the wrists; the feet can be wrapped in plastic bags covered by cotton socks. Gloves and socks that are already impregnated with emollients, making application to the hands and feet more convenient, are also available. When large areas of the body must be covered, cotton cloth topped by an expandable stockinette can be used. Disposable diapers or cloths folded in diaper fashion are useful for dressing the groin and the perineal areas. Axillary dressings can be made of cotton cloth, or a commercially prepared dressing may be used and taped in place or held by dress shields. A turban or plastic shower cap is useful for holding dressings on the scalp. A face mask, made from gauze with holes cut out for the eyes, nose, and mouth, may be held in place with gauze ties looped through holes cut in the four corners of the mask.

PRURITUS

General Pruritus

Pruritus (itching) is one of the most common symptoms of patients with dermatologic disorders. Itch receptors are unmyelinated, penicillate (brushlike) nerve endings that are

found exclusively in the skin, mucous membranes, and cornea. Although pruritus is usually caused by primary skin disease with resultant rash or lesions, it may occur without a rash or lesion. This is referred to as essential pruritus, which generally has a rapid onset, may be severe, and interferes with normal daily activities.

Pruritus may be the first indication of a systemic internal disease such as diabetes mellitus, blood disorders, or cancer (occult malignancy of the breast or colon; lymphoma). It may also accompany renal, hepatic, and thyroid diseases (Chart 56-2). Some common oral medications such as aspirin, antibiotics, hormones (ie, estrogens, testosterone, or oral contraceptives), and opioids (ie, morphine or cocaine) may cause pruritus directly or by increasing sensitivity to ultraviolet light. Certain soaps and chemicals, radiation therapy, prickly heat (miliaria), and contact with woolen garments are also associated with pruritus. Pruritus may also be

Chart 56-2 • Systemic Disorders Associated With Generalized Pruritus

- Chronic renal disease
- Obstructive biliary disease (primary biliary cirrhosis, extrahepatic biliary obstruction, drug-induced cholestasis)
- Endocrine disease (thyrotoxicosis, hypothyroidism, diabetes mellitus)
- Psychiatric disorders (emotional stress, anxiety, neurosis, phobias)
- Malignancies (polycythemia vera, Hodgkin's lymphoma, lymphoma, leukemia, multiple myeloma, mycosis fungoides, and cancers of the lung, breast, central nervous system, and gastrointestinal tract)
- Neurologic disorders (multiple sclerosis, brain abscess, brain tumor)
- Infestations (scabies, lice, other insects)
- Pruritus of pregnancy (pruritic urticarial papules of pregnancy [PUPPI], cholestasis of pregnancy, pemphigoid of pregnancy)
- Folliculitis (bacterial, candidiasis, dermatophyte)
- Skin conditions (seborrheic dermatitis, folliculitis, iron deficiency anemia, atopic dermatitis)

caused by psychological factors, such as excessive stress in family or work situations.

Gerontologic Considerations

Pruritus occurs frequently in elderly people as a result of dry skin. Elderly people are also more likely to have a systemic illness that triggers pruritus, are at higher risk for occult malignancy, and are more likely to be taking multiple medications than younger people. All of these factors increase the incidence of pruritus in elderly people.

Pathophysiology

Scratching the pruritic area causes the inflamed cells and nerve endings to release histamine, which produces more pruritus, generating a vicious itch–scratch cycle. If the patient responds to an itch by scratching, the integrity of the skin may be altered, and excoriation, redness, raised areas (ie, wheals), infection, or changes in pigmentation may result. Pruritus usually is more severe at night and is less frequently reported during waking hours, probably because the person is distracted by daily activities. At night, when there are fewer distractions, the slightest pruritus cannot be easily ignored. Severe itching can be debilitating.

Medical Management

A thorough history and physical examination usually provide clues to the underlying cause of the pruritus, such as hay fever, allergy, recent administration of a new medication, or a change of cosmetics or soaps. After the cause has been identified, treatment of the condition should relieve the pruritus. Signs of infection and environmental clues, such as warm, dry air or irritating bed linens, should be identified. In general, washing with soap and hot water is avoided. Bath oils containing a surfactant that allows the oil to mix with bath water (eg, Lubath, Alpha-Keri) may be sufficient for cleaning. However, an elderly patient or a patient with unsteady balance should avoid adding oil because it increases the danger of slipping in the bathtub. A warm bath with a mild soap followed by application of a bland emollient to moist skin can control **xerosis** (dry skin). Applying a cold compress, ice cube, or cool agents that contain menthol and camphor (which constrict blood vessels) may also help relieve pruritus.

Pharmacologic Therapy

Topical corticosteroids may be beneficial as anti-inflammatory agents to decrease itching. Oral antihistamines are even more effective because they can overcome the effects of histamine release from damaged mast cells. An antihistamine, such as diphenhydramine (Benadryl) or hydroxyzine (Atarax), prescribed in a sedative dose at bedtime is often effective in producing a restful and comfortable sleep. Nonsedating antihistamine medications such as fexofenadine (Allegra) are more appropriate to relieve daytime pruritus. Tricyclic antidepressants, such as doxepin (Sinequan), may be prescribed for pruritus of neuropsychogenic origin. If pruritus continues, further investigation of a systemic problem is advised.

Nursing Management

The nurse reinforces the reasons for the prescribed therapeutic regimen and counsels the patient on specific points of care. If baths have been prescribed, the patient is

reminded to use tepid (not hot) water and to shake off the excess water and blot between intertriginous areas (body folds) with a towel. Rubbing vigorously with the towel is avoided because this overstimulates the skin and causes more itching. It also removes water from the stratum corneum. Immediately after bathing, the skin should be lubricated with an emollient to trap moisture.

The patient is instructed to avoid situations that cause vasodilation. Examples include exposure to an overly warm environment and ingestion of alcohol or hot foods and liquids. All can induce or intensify pruritus. Using a humidifier is helpful if environmental air is dry. Activities that result in perspiration should be limited because perspiration may irritate and promote pruritus. If the patient is troubled at night with itching that interferes with sleep, the nurse can advise wearing cotton clothing next to the skin rather than synthetic materials. The room should be kept cool and humidified. Vigorous scratching should be avoided and nails kept trimmed to prevent skin damage and infection. When the underlying cause of pruritus is unknown and further testing is required, the nurse explains each test and the expected outcome.

Perineal and Perianal Pruritus

Pruritus of the genital and anal regions may be caused by small particles of fecal material lodged in the perianal crevices or attached to anal hairs. Alternatively, it may result from perianal skin damage caused by scratching, moisture, and decreased skin resistance as a result of corticosteroid or antibiotic therapy. Other possible causes of perianal itching include local irritants such as scabies and lice, local lesions such as hemorrhoids, fungal or yeast infections, and pinworm infestation. Conditions such as diabetes mellitus, anemia, hyperthyroidism, and pregnancy may also result in pruritus. Occasionally, no cause can be identified.

Management

The patient is instructed to follow proper hygiene measures and to discontinue home and over-the-counter remedies. The perineal or anal area should be rinsed with lukewarm water and blotted dry with cotton balls. Premoistened tissues may be used after defecation. Cornstarch can be applied in the skinfold areas to absorb perspiration.

As part of health teaching, the nurse instructs the patient to avoid bathing in water that is too hot and to avoid using bubble baths, sodium bicarbonate, and detergent soaps, all of which aggravate dryness. To keep the perineal or perianal skin as dry as possible, patients should avoid wearing underwear made of synthetic fabrics. Local anesthetic agents should not be used because of possible allergic effects. The patient should also avoid vasodilating agents or stimulants (eg, alcohol, caffeine) and mechanical irritants such as rough or woolen clothing. A diet that includes adequate fiber may help maintain soft stools and prevent minor trauma to the anal mucosa.

SECRETORY DISORDERS

The main secretory function of the skin is performed by the sweat glands, which help regulate body temperature. These glands excrete perspiration that evaporates, thereby cooling

the body. The sweat glands are located in various parts of the body and respond to different stimuli. Those on the trunk generally respond to thermal stimulation; those on the palms and soles respond to nervous stimulation; and those in the axillae and on the forehead respond to both kinds of stimulation. Normal perspiration has no odor. Body odor is produced by the increase in bacteria on the skin and the interaction of bacterial waste products with the chemicals of perspiration. As a rule, moist skin is warm, and dry skin is cool, but this is not always true. It is not unusual to observe warm, dry skin in a dehydrated patient and very hot, dry skin in some febrile states.

Normally, sweat can be controlled with the use of antiperspirants and deodorants. Most antiperspirants are aluminum salts that block the opening to the sweat duct. Pure deodorants inhibit bacterial growth and block the metabolism of sweat; they have no antiperspirant effect. Fragrance-free deodorants are available for those with sensitive skin.

Hidradenitis Suppurativa

Hidradenitis suppurativa is a chronic suppurative folliculitis of the perianal, axillary, and genital areas or under the breasts. It develops after puberty and can produce abscesses or sinuses with scarring. The cause is unknown, but it appears to have a genetic basis.

Pathophysiology

Abnormal blockage of the sweat glands causes recurring inflammation, nodules, and draining sinus tracts. Eventually, hypertrophic bands of scar tissue form in the area of the sweat glands.

Clinical Manifestations

The condition occurs more frequently in the axilla but also appears in inguinal folds, on the mons pubis, and around the buttocks. The patient can be extremely uncomfortable with multiple suppurative lesions within a small area.

Management

Management is often difficult. Hot compresses and oral antibiotics are used frequently. Isotretinoin (Accutane, Sotret) or acitretin (Soriatane) can be tried; careful monitoring for side effects is important. Incision and drainage of large suppurating areas with gauze packs inserted to facilitate drainage are often necessary. Rarely, the entire area is excised, removing the scar tissue and any infection. This surgery is drastic and performed only as a last resort.

Seborrheic Dermatoses

Seborrhea is excessive production of sebum (secretion of sebaceous glands) in areas where sebaceous glands are normally found in large numbers, such as the face, scalp, eyebrows, eyelids, sides of the nose and upper lip, malar regions (cheeks), ears, axillae, under the breasts, groin, and gluteal crease of the buttocks. Seborrheic dermatitis is a chronic inflammatory disease of the skin with a predilection for areas

that are well supplied with sebaceous glands or lie between skin folds, where the bacteria count is high.

Clinical Manifestations

Two forms of seborrheic dermatoses can occur: an oily form and a dry form. Either form may start in childhood and continue throughout life. The oily form appears moist or greasy. There may be patches of sallow, greasy skin, with or without scaling, and slight erythema, predominantly on the forehead, nasolabial fold, beard area, scalp, and between adjacent skin surfaces in the regions of the axillae, groin, and breasts. Small pustules or papulopustules resembling acne may appear on the trunk. The dry form, consisting of flaky desquamation of the scalp with a profuse amount of fine, powdery scales, is commonly called dandruff. The mild forms of the disease are asymptomatic. When scaling occurs, it is often accompanied by pruritus, which may lead to scratching and secondary infections and excoriation.

Seborrheic dermatitis has a genetic predisposition. Hormones, nutritional status, infection, and emotional stress influence its course. The remissions and exacerbations of this condition should be explained to the patient. If a person has not previously been diagnosed with this condition and suddenly appears with a severe outbreak, a complete history and physical examination should be conducted.

Medical Management

Because there is no known cure for seborrhea, the objectives of therapy are to control the disorder and allow the skin to repair itself. Seborrheic dermatitis of the body and face may respond to a topically applied corticosteroid cream, which allays the secondary inflammatory response. However, this medication should be used with caution near the eyelids because it can lead to glaucoma and cataracts. Patients with seborrheic dermatitis may develop a secondary candidal (yeast) infection in body creases or folds. To avoid this, patients should be advised to ensure maximum aeration of the skin and to clean areas where there are creases or folds in the skin carefully. Patients with persistent candidiasis should be evaluated for diabetes.

The mainstay of dandruff treatment is proper, frequent shampooing (at least three times weekly) with medicated shampoos. Two or three different types of shampoo should be used in rotation to prevent the seborrhea from becoming resistant to a particular shampoo. The shampoo is left on at least 5 to 10 minutes. As the condition of the scalp improves, the treatment can be less frequent. Antiseborrheic shampoos include those containing selenium sulfide suspension, zinc pyrithione, salicylic acid or sulfur compounds, and tar shampoo that contains sulfur or salicylic acid.

Nursing Management

A person with seborrheic dermatitis is advised to avoid external irritants, excessive heat, and perspiration; rubbing and scratching prolong the disorder. To avoid secondary infection, the patient should air the skin and keep skin folds clean and dry.

Instructions for using medicated shampoos are reinforced for people with dandruff who require treatment. Frequent shampooing is contrary to some cultural practices; the nurse

should be sensitive to these differences when teaching the patient about home care.

The patient is cautioned that seborrheic dermatitis is a chronic condition that tends to reappear. The goal is to keep it under control. Patients need to be encouraged to adhere to the treatment program. Those who become discouraged and disheartened by the effect on body image should be treated with sensitivity and encouraged to express their feelings.

Acne Vulgaris

Acne vulgaris is a common disorder affecting susceptible hair follicles, most commonly on the face, neck, and upper trunk. It is characterized by **comedones** (primary acne lesions), both closed and open, and by papules, pustules, nodules, and cysts.

Acne is the most commonly encountered skin condition in adolescents and young adults between 12 and 35 years. It accounts for at least 15% of all dermatology visits. Both males and females are affected equally, although onset is slightly earlier in females, because they reach puberty at a younger age than males. Acne becomes more marked during adolescence because the endocrine glands that influence the secretions of the sebaceous glands are functioning at peak activity. Acne appears to stem from an interplay of genetic, hormonal, and bacterial factors. In most cases, there is a family history of acne.

Pathophysiology

During puberty, androgens stimulate the sebaceous glands, causing them to enlarge and secrete a natural oil, sebum, which rises to the top of the hair follicle and flows out onto the skin surface. In adolescents who develop acne, androgenic stimulation produces a heightened response in the sebaceous glands so that acne occurs when accumulated sebum plugs the pilosebaceous ducts.

Clinical Manifestations

The primary lesions of acne are comedones. Closed comedones (whiteheads) form from impacted lipids or oils and keratin that plug the dilated follicle. Closed comedones may evolve into open comedones, in which the contents of the ducts are in open communication with the external environment. The color of open comedones (blackheads) results from an accumulation of lipid, bacterial, and epithelial debris. Some closed comedones may rupture, resulting in an inflammatory reaction caused by leakage of follicular contents (eg, sebum, keratin, bacteria) into the dermis. The resultant inflammation is seen clinically as erythematous papules, inflammatory pustules, and inflammatory cysts. Mild papules and cysts drain and heal without treatment. Deeper papules and cysts cause scarring of the skin. Acne is usually graded as mild, moderate, or severe based on the number and type of lesions.

Assessment and Diagnostic Findings

The diagnosis of acne is based on the history and physical examination, evidence of lesions characteristic of acne, and age. Women may report a history of flare-ups a few days before

menses. The presence of the typical comedones along with excessively oily skin is characteristic. Oiliness is more prominent in the midfacial area; other parts of the face may appear dry. When there are numerous lesions, some of which are open, the person may exude a distinct sebaceous odor. Biopsy of lesions is seldom necessary for a definitive diagnosis.

Medical Management

The goals of management are to reduce bacterial colonies, decrease sebaceous gland activity, prevent the follicles from becoming plugged, reduce inflammation, combat secondary infection, minimize scarring, and eliminate factors that predispose the person to acne. The therapeutic regimen depends on the type of lesion (eg, comedones, papule, pustule, cyst). The duration of treatment depends on the extent and severity of the acne. In severe cases, treatment may extend over years.

There is no predictable cure for the disease, but combinations of therapies are available that can effectively control its activity. Table 56-4 summarizes the treatment modalities for acne vulgaris.

Nutrition and Hygiene Therapy

Diet is not believed to play a major role in therapy. However, the elimination of a specific food or food product

Table 56-4

TYPE OF TREATMENTS COMMONLY USED FOR ACNE VULGARIS

Type of Therapy	Prescribed Treatment Agent
Topical	benzoyl peroxide wash, gel benzoyl peroxide and erythromycin (Benzamycin gel) benzoyl peroxide and sulfur (Benzulfoid cream) resorcinol (as ingredient in other preparations) salicylic acid (as ingredient in other preparations) sulfur (as ingredient in other preparations) tretinoin (Retin A, Avita) other comedogenics (adapalene [Differin], azelaic acid [Azelex], tazorotene [Tazorac]) topical antibiotics
Systemic	oral antibiotics (erythromycin, tetracycline, clindamycin, doxycycline, minocin, penicillins) isotretinoin (Accutane) hormones: corticosteroids high dose for anti-inflammatory action low dose to suppress androgenic action intralesional for anti-inflammatory action antiandrogens oral contraceptives (women only)
Surgical	extraction of comedo contents drainage of pustules and cysts excision of sinus tracts and cysts intralesional corticosteroids for anti-inflammatory action cryotherapy dermabrasion for scars laser resurfacing of scars

Treatments listed are common but do not include all available forms of therapy.

associated with a flare-up of acne, such as chocolate, cola, fried foods, or milk products, should be promoted. Maintenance of good nutrition equips the immune system for effective action against bacteria and infection.

For mild cases of acne, washing twice each day with a cleansing soap may be all that is required. Oil-free cosmetics and creams should be chosen. These products are usually designated as useful for acne-prone skin.

Pharmacologic Therapy

Topical Therapy

Over-the-counter acne medications contain either salicylic acid or benzoyl peroxide, both of which are very effective at removing the sebaceous follicular plugs. However, the skin of some people is sensitive to these products, which can cause irritation or excessive dryness, especially when used with some prescribed topical medications. The patient should be instructed to discontinue use of the product if severe irritation occurs.

Benzoyl peroxide preparations are widely used because they produce a rapid and sustained reduction of inflammatory lesions. They depress sebum production and promote breakdown of comedo plugs and have an antibacterial effect. Initially, benzoyl peroxide causes redness and scaling, but the skin usually adjusts quickly to its use. Typically, the patient applies a gel of benzoyl peroxide once daily. In many instances, this is the only treatment needed. Benzoyl peroxide, benzoyl erythromycin (Benzamycin), and benzoyl sulfur (Sulfoyl) are available over the counter and by prescription.

Vitamin A acid (tretinoin) applied topically is used to clear the keratin plugs from the pilosebaceous ducts. The patient should be informed that symptoms may worsen during early weeks of therapy because inflammation, erythema, and peeling may occur. The patient is cautioned against sun exposure while using this topical medication because it may cause an exaggerated sunburn. Package insert directions should be followed carefully. Improvement may take 8 to 12 weeks.

Topical antibiotic treatment for acne is common. Topical antibiotics suppress bacterial growth; reduce superficial free fatty acid levels; decrease comedones, papules, and pustules; and produce no systemic side effects.

Systemic Therapy

Oral antibiotics administered in small doses over a long period are very effective in treating moderate and severe acne, especially when the acne is inflammatory and results in pustules, abscesses, and scarring. Therapy may continue for months to years. The tetracycline family of antibiotics is contraindicated in children younger than 12 years and in pregnant women. Administration during pregnancy can affect the development of teeth, causing enamel hypoplasia and permanent discoloration of teeth in infants. Side effects of tetracyclines include photosensitivity, nausea, diarrhea, cutaneous infection in either gender, and vaginitis in women. In some women, broad-spectrum antibiotics may suppress normal vaginal bacteria and predispose the patient to candidiasis, a fungal infection.

Synthetic vitamin A compounds (ie, retinoids) are used with dramatic results in patients with nodular cystic acne

unresponsive to conventional therapy. One compound is isotretinoin, which is used for active inflammatory papular pustular acne that has a tendency to scar. Isotretinoin reduces sebaceous gland size and inhibits sebum production. It also causes the epidermis to shed (epidermal desquamation), thereby unseating and expelling existing comedones.

The most common side effect, experienced by almost all patients, is **cheilitis** (inflammation of the lips). Dry and chafed skin and mucous membranes are frequent side effects. These changes are reversible with the withdrawal of the medication. Most important, isotretinoin, like other vitamin A metabolites, is teratogenic in humans, meaning that it can have an adverse effect on a fetus. Effective contraceptive measures for women of childbearing age are mandatory during treatment and for about 4 to 8 weeks thereafter. To avoid additive toxic effects, patients are cautioned not to take vitamin A supplements while taking isotretinoin.

Estrogen therapy (including progesterone–estrogen preparations) suppresses sebum production and reduces skin oiliness. It is usually reserved for young women when the acne begins somewhat later than usual and tends to flare up at certain times in the menstrual cycle. Estrogen-dominant oral contraceptive compounds may be administered on a prescribed cyclic regimen. Estrogen is not administered to male patients because of undesirable side effects such as enlargement of the breasts and decrease in body hair.

Surgical Management

Treatment includes comedo extraction, injections of corticosteroids into the inflamed lesions, and incision and drainage of large, fluctuant (moving in palpable waves), nodular cystic lesions. Cryosurgery (freezing with liquid nitrogen) may be used for nodular and cystic forms of acne. Patients with deep scars may be treated with deep abrasive therapy (dermabrasion), in which the epidermis and some superficial dermis are removed down to the level of the scars.

Comedones may be removed with a comedo extractor. The site is first cleaned with alcohol. The opening of the extractor is then placed over the lesion, and direct pressure is applied to cause extrusion of the plug through the extractor. Removal of comedones leads to erythema, which may take several weeks to subside. Recurrence of comedones after extraction is common.

Nursing Management

Nursing care of patients with acne consists largely of monitoring and managing potential complications of skin treatments. Major nursing activities include patient education, particularly in proper skin care techniques, and managing potential problems related to the skin disorder or therapy. Providing positive reassurance, listening attentively, and being sensitive to the feelings of the patient with acne are essential for the patient's psychological well-being and understanding of the disease and treatment plan.

Preventing Scarring

Prevention of scarring is the ultimate goal of therapy. The chance of scarring increases with the severity of the grade of acne. Severe acne (25 to more than 50 comedones, papules,

or pustules) usually requires longer-term therapy with systemic antibiotics or isotretinoin. Patients should be warned that discontinuing these medications can lead to more flare-ups and increase the chance of deep scarring. Furthermore, manipulation of the comedones, papules, and pustules increases the potential for scarring.

When acne surgery is prescribed to extract deep-seated comedones or inflamed lesions or to incise and drain cystic lesions, the intervention itself may result in further scarring. Dermabrasion, which levels existing scar tissue, can also increase scar formation. Hyperpigmentation or hypopigmentation also may affect the tissue involved. The patient should be informed of these potential outcomes before choosing surgical intervention for acne.

Promoting Home and Community-Based Care

Teaching Patients Self-Care

In addition to instructions for taking prescribed medications, patients are instructed to wash the face and other affected areas with mild soap and water twice each day to remove surface oils and prevent obstruction of the oil glands. Mild abrasive soaps and drying agents are prescribed to eliminate the oily feeling that troubles many patients. At the same time, patients are cautioned to avoid excessive abrasion because it makes acne worse.

All forms of friction and trauma are avoided, including propping the hands against the face, rubbing the face, and wearing tight collars and helmets. Patients are instructed to avoid manipulation of pimples or blackheads. Squeezing merely worsens the problem, because a portion of the blackhead is pushed down into the skin, which may cause the follicle to rupture. Because cosmetics, shaving creams, and lotions can aggravate acne, these substances are best avoided unless the patient is advised otherwise.

INFECTIOUS DERMATOSES

Bacterial Skin Infections

Also called **pyodermas**, pus-forming bacterial infections of the skin may be primary or secondary. Primary skin infections originate in previously normal-appearing skin and are usually caused by a single organism. Secondary skin infections arise from a preexisting skin disorder or from disruption of the skin integrity from injury or surgery. In either case, several microorganisms may be implicated (eg, *Staphylococcus aureus*, group A streptococci). The most common primary bacterial skin infections are impetigo and folliculitis. Folliculitis may lead to furuncles or carbuncles.

IMPETIGO

Impetigo is a superficial infection of the skin caused by staphylococci, streptococci, or multiple bacteria. Bullous impetigo, a more deep-seated infection of the skin caused by *S. aureus*, is characterized by the formation of bullae (large, fluid-filled blisters) from original vesicles. The bullae rupture, leaving raw, red areas.

The exposed areas of the body, face, hands, neck, and extremities are most frequently involved. Impetigo is contagious

and may spread to other parts of the patient's skin or to other members of the family who touch the patient or use towels or combs that are soiled with the exudate of the lesions.

Impetigo is seen in people of all ages. It is particularly common in children living in poor hygienic conditions. It often follows pediculosis capitis (head lice), scabies (itch mites), herpes simplex, insect bites, poison ivy, or eczema. Chronic health problems, poor hygiene, and malnutrition may predispose an adult to impetigo. There is some indication that excessive use of antibacterial soaps may create resistant bacteria and contribute to the problem.

Clinical Manifestations

The lesions of impetigo begin as small, red macules, which quickly become discrete, thin-walled vesicles that rupture and become covered with a loosely adherent honey-yellow crust (Fig. 56-1). These crusts are easily removed to reveal smooth, red, moist surfaces on which new crusts soon develop. If the scalp is involved, the hair is matted, which distinguishes the condition from ringworm.

Medical Management

Systemic antibiotic therapy is the usual treatment. It reduces contagious spread, treats deep infection, and prevents acute glomerulonephritis (kidney infection), which may occur as a consequence of streptococcal skin diseases. In non-bullous impetigo, benzathine penicillin or oral penicillin may be prescribed. In bullous impetigo, a penicillinase-resistant penicillin (eg, cloxacillin [Cloxapen], dicloxacillin [Dycill]) may be used. In penicillin-allergic patients, erythromycin is an effective alternative.

Topical antibacterial therapy (eg, mupirocin [Bactroban]) may be prescribed when the disease is limited to a small area. The medication must be applied to the lesions several times daily for a week; this treatment regimen may be impossible for some patients or their caregivers to follow. Topical antibiotics generally are not as effective as systemic therapy in eradicating or preventing the spread of streptococci from the respiratory tract, thereby increasing the risk of developing glomerulonephritis.

When topical therapy is prescribed, lesions are soaked or washed with soap solution to remove the central site of bacterial growth, giving the topical antibiotic an opportunity to reach the infected site. After the crusts are removed, a topical antibiotic cream is applied. Gloves are worn when providing patient care. An antiseptic solution, such as povidone iodine (Betadine), may be used to clean the skin,

Figure 56-1 Impetigo of the nostril.

reduce bacterial content in the infected area, and prevent spread.

Nursing Management

The nurse instructs the patient and family members to bathe at least once daily with bactericidal soap. Cleanliness and good hygiene practices help prevent the spread of the lesions from one skin area to another and from one person to another. Each person should have a separate towel and washcloth. Because impetigo is a contagious disorder, infected people should avoid contact with other people until the lesions heal.

FOLLICULITIS, FURUNCLES, AND CARBUNCLES

Folliculitis is an infection of bacterial or fungal origin that arises within the hair follicles. Lesions may be superficial or deep. Single or multiple papules or pustules appear close to the hair follicles. Folliculitis commonly affects the beard area of men who shave, as well as women's legs, if they shave. Other areas include the axillae, trunk, and buttocks. Follicular disorders are usually caused by staphylococci, although if the immune system is impaired, the causative organisms may be gram-negative bacilli.

Pseudofolliculitis barbae (shaving bumps) occur predominantly on the faces of African American and other curly haired men as a result of shaving. The sharp ingrowing hairs have a curved root that grows at a more acute angle and pierces the skin, provoking an irritative reaction. The only entirely effective treatment is to avoid shaving. Other treatments include using special lotions or antibiotics or using a hand brush to dislodge the hairs mechanically. If the patient must remove facial hair, a depilatory cream or electric razor may be used.

A **furuncle** (boil) is an acute inflammation arising deep in one or more hair follicles and spreading into the surrounding dermis. This inflammation is a deep form of folliculitis. Furunculosis refers to multiple or recurrent lesions. Furuncles may occur anywhere on the body but are more prevalent in areas subjected to irritation, pressure, friction, and excessive perspiration, such as the back of the neck, the axillae, and the buttocks.

A furuncle may start as a small, red, raised, painful pimple. Frequently, the infection progresses and involves the skin and subcutaneous fatty tissue, causing tenderness, pain, and surrounding cellulitis. The area of redness and induration represents an effort of the body to keep the infection localized. The bacteria (usually staphylococci) produce necrosis of the invaded tissue. The characteristic pointing of a boil follows in a few days. When this occurs, the center becomes yellow or black, and the boil is said to have "come to a head."

A **carbuncle** is an abscess of the skin and subcutaneous tissue that represents an extension of a furuncle that has invaded several follicles and is large and deep seated. It is usually caused by a staphylococcal infection. Carbuncles appear most commonly in areas where the skin is thick and inelastic; the back of the neck and the buttocks are common sites. The extensive inflammation frequently prevents a complete walling off of the infection; purulent material

may be absorbed, resulting in high fever, pain, leukocytosis, and even extension of the infection to the bloodstream.

Furuncles and carbuncles are more likely to occur in patients with underlying systemic diseases, such as diabetes or hematologic malignancies, and in those receiving immunosuppressive therapy for other diseases. Both are more prevalent in hot climates, especially on skin beneath occlusive clothing.

Medical Management

In treating staphylococcal infections, it is important not to rupture or destroy the protective wall of induration that localizes the infection. The boil or pimple should never be squeezed. Systemic antibiotic therapy, selected by culture and sensitivity study, is generally indicated. Oral cloxacillin and dicloxacillin are first-line medications. Cephalosporins and erythromycin are also effective. To promote comfort, bed rest is advised for patients who have boils on the perineum or in the anal region, and a course of systemic antibiotic therapy is indicated to prevent the spread of the infection.

When the pus has localized and is fluctuant, a small incision with a scalpel can speed resolution by relieving the tension and ensuring direct evacuation of the pus and debris. The patient is instructed to keep the draining lesion covered with a dressing.

Nursing Management

Intravenous (IV) fluids, fever reduction, and other supportive treatments are indicated for patients who are acutely ill from infection. Warm, moist compresses hasten resolution of the furuncle or carbuncle. The surrounding skin may be cleaned gently with antibacterial soap, and an antibacterial ointment may be applied. Soiled dressings are handled according to standard precautions. Nursing personnel should carefully follow standard precautions to avoid becoming carriers of staphylococci. Disposable gloves are worn when caring for these patients.

NURSING ALERT

Nurses must take special precautions in caring for boils on the face because the skin area drains directly into the cranial venous sinuses. Sinus thrombosis with fatal pyemia can develop after manipulating a boil in this location. The infection can travel through the sinus tract and penetrate the brain cavity, causing a brain abscess.

Promoting Home And Community-Based Care

Teaching Patients Self-Care

To prevent and control staphylococcal skin infections such as boils and carbuncles, the staphylococcal pathogen must be eliminated from the skin and environment. Efforts must be made to increase the patient's resistance and provide a hygienic environment. If lesions are actively draining, the mattress and pillow should be covered with plastic material and wiped with disinfectant daily; the bed linens, towels, and clothing should be laundered after each use; and the

patient should use an antibacterial soap and shampoo for an indefinite period, often several months.

Recurrent infection is prevented with the use of long-term antibiotic therapy (longer than about 3 months). The patient must take the full dose for the time prescribed. The purulent exudate is a source of reinfection or transmission of infection to caregivers. If the patient has a history of recurrent infections, a carrier state may exist, which should be investigated and treated with an antibacterial cream such as mupirocin (Bactroban).

Viral Skin Infections

HERPES ZOSTER

Herpes zoster, also called shingles, is an infection caused by the varicella-zoster viruses (VZVs), members of a group of DNA viruses. The viruses that cause chickenpox (varicella) and herpes zoster are indistinguishable, hence the two-part name. The disease is characterized by a painful vesicular eruption along the area of distribution of the sensory nerves from one or more posterior ganglia. After a case of chickenpox runs its course, the VZV responsible for the outbreak lies dormant inside nerve cells near the brain and spinal cord. Later, when these latent viruses are reactivated because of declining cellular immunity, they travel by way of the peripheral nerves to the skin, where the viruses multiply and create a red rash of small, fluid-filled blisters.

It is thought that during the aging process, natural immunity to the varicella wanes, allowing the virus to reactivate and maintaining it in the population. Herpes zoster develops in about 10% of adults during their lifetimes, usually after 50 years of age; the disease develops in as many as 50% of people by 85 years of age. These episodes tend to be localized and have few sequelae. Compared with Caucasians, African Americans are affected by herpes zoster much less frequently; however, if they do develop the disease, they often have it at a younger age. There is an increased frequency of herpes zoster infections in patients with weakened immune systems, including those with human immunodeficiency virus (HIV) infection and in those with cancer. In these patients, the infection can become widespread and cause significant complications.

Clinical Manifestations

The eruption is usually accompanied or preceded by pain, which may radiate over the entire region supplied by the affected nerves. The pain may be burning, lancinating (tearing or sharply cutting), stabbing, or aching. Some patients have no pain, but itching and tenderness may occur over the area. Malaise and gastrointestinal disturbances may precede the eruption. The patches of grouped vesicles appear on the red and swollen skin. The early vesicles, which contain serum, later may become purulent, rupture, and form crusts. The inflammation is usually unilateral, involving the thoracic, cervical, or cranial nerves in a bandlike configuration. The blisters are usually confined to a narrow region of the face or trunk (Fig. 56-2). The clinical course varies from 1 to 3 weeks. If an ophthalmic nerve is involved, the patient may have eye pain. Inflammation and a rash on the trunk

Figure 56-2 Herpes zoster (shingles).

may cause pain with the slightest touch. The healing time varies from 7 to 26 days.

The most common complication of herpes zoster is postherpetic neuralgia, which occurs in approximately 20% of cases, becoming more common in the elderly. Fifty percent of patients older than 60 years of age have persistent pain that lasts longer than 6 months (High, 2005).

Medical Management

Herpes zoster infection can be arrested if oral antiviral agents such as acyclovir (Zovirax), valacyclovir (Valtrex), or famciclovir (Famvir) are administered within 24 hours of the initial eruption. IV acyclovir, if started early, is effective in significantly reducing the pain and halting the progression of the disease. In older patients, the pain from herpes zoster may persist as postherpetic neuralgia for months after the skin lesions disappear.

The goals of herpes zoster management are to relieve the pain and to reduce or avoid complications, which include infection, scarring, and postherpetic neuralgia and eye complications. Pain is controlled with analgesics because adequate pain control during the acute phase helps prevent persistent pain patterns. Systemic corticosteroids may be prescribed for patients older than 50 years of age to reduce the incidence and duration of postherpetic neuralgia (persistent pain of the affected nerve after healing). Healing usually occurs more quickly in those who have been treated with corticosteroids. Triamcinolone (Aristocort, Kenacort, Kenalog) injected subcutaneously under painful areas is effective as an anti-inflammatory agent.

Ophthalmic herpes zoster occurs when an eye is involved. This is considered an ophthalmic emergency, and the patient should be referred to an ophthalmologist immediately to prevent the possible sequelae of keratitis, uveitis, ulceration, and blindness.

People who have been exposed to varicella by primary infection or by vaccination are not at risk for infection after exposure to patients with herpes zoster.

A vaccination for childhood varicella developed in the 1970s has been used successfully to decrease the incidence of childhood disease. A more potent formulation of the vaccine was developed to boost VZV cellular immunity in people older than 55 years of age. Studies have shown favorable results with very few side effects. One large study by the Veterans Administration showed a reduction in incidence of VZV infections by almost 50% in 60- to 69-year-old participants. This vaccination is now being recommended as part of prevention strategies in older adults (High, 2005).

Nursing Management

The patient and family members are instructed about the importance of taking antiviral agents as prescribed and in keeping follow-up appointments with the health care provider. The nurse assesses the patient's discomfort and response to medication and collaborates with the physician to make necessary adjustments to the treatment regimen. The patient is taught how to apply wet dressings or medication to the lesions and to follow proper hand hygiene techniques to avoid spreading the virus.

Diversions activities and relaxation techniques are encouraged to ensure restful sleep and to alleviate discomfort. A caregiver may be required to assist with dressings, particularly if the patient is elderly and unable to apply them. Food preparation for patients who cannot care for themselves or prepare nourishing meals must be arranged.

HERPES SIMPLEX

Herpes simplex is a common skin infection. There are two types of the causative virus, which are identified by viral typing. Generally, herpes simplex type 1 occurs on the mouth and type 2 occurs in the genital area, but both viral types can be found in both locations. About 85% of adults worldwide are seropositive for herpes type 1. The prevalence of type 2 is lower; type 2 usually appears at the onset of sexual activity. Serologic testing shows that many more people are infected than have a history of clinical disease.

Herpes simplex is classified as a true primary infection, a nonprimary initial episode, or a recurrent episode. True primary infection is the initial exposure to the virus. A nonprimary initial episode is the initial episode of either type 1 or type 2 in a person previously infected with the other type. Recurrent episodes are subsequent episodes of the same viral type.

Types of Herpes Simplex

Orolabial Herpes

Orolabial herpes, also called fever blisters or cold sores, consists of erythematous-based clusters of grouped vesicles on the lips. A prodrome of tingling or burning with pain may precede the appearance of the vesicles by up to 24 hours. Certain triggers, such as sunlight exposure or increased stress, may cause recurrent episodes. Fewer than 1% of people with primary orolabial herpes infections develop herpetic gingivostomatitis. This complication occurs more often in children and young adults than in people of other ages. The onset is often accompanied by high fever, regional lymphadenopathy, and generalized malaise. Another com-

plication of orolabial herpes is the development of erythema multiforme, an acute inflammation of the skin and mucous membranes with characteristic lesions that have the appearance of targets (ie, concentric red rings with white bands between the red rings).

Genital Herpes

Genital herpes, or type 2 herpes simplex, manifests with a broad spectrum of clinical signs. Minor infections may produce no symptoms at all; severe primary infections with type 1 can cause systemic flulike illness. Lesions appear as grouped vesicles on an erythematous base initially involving the vagina, rectum, or penis. New lesions can continue to appear for 7 to 14 days. Lesions are symmetric and usually cause regional lymphadenopathy. Fever and flulike symptoms are common. Typical recurrences begin with a prodrome of burning, tingling, or itching about 24 hours before the vesicles appear. As the vesicles rupture, erosions and ulcerations begin to appear. Severe infections can cause extensive erosions of the vaginal or anal canal. For further information, see Chapter 47.

Assessment and Diagnostic Findings

Herpes simplex infections are confirmed in several ways. Generally, the appearance of the skin eruption is strongly suggestive. Viral cultures and rapid assays are available, and the type of test used depends on lesion morphology. Acute vesicular lesions are more likely to react positively to the rapid assay, whereas older, crusted patches are better diagnosed with viral culture. In all cases, it is imperative to obtain enough viral cells for testing, and careful collection methods are therefore important. All crusts should be gently removed or vesicles gently unroofed. A sterile cotton swab premoistened in viral culture preservative is used to swab the base of the vesicle to obtain a specimen for analysis.

Complications

Eczema herpeticum is a condition in which patients with eczema contract herpes that spreads throughout the eczematous areas. The same type of spread of herpes can occur in severe seborrhea, scabies, and other chronic skin conditions. Eczema herpeticum is managed with oral or IV acyclovir.

Herpetic whitlow is an infection of the pulp of a fingertip with herpes type 1 or 2. There is tenderness and erythema of the cuticle. Deep-seated vesicles appear within 24 hours.

In mothers who have primary infections during pregnancy, intrauterine neonatal infections can occur. Most cases of neonatal infection with herpes occur during delivery by contact of the infant with the mother's active ulcerations. Fetal anomalies include skin lesions, microcephaly, encephalitis, and intracerebral calcifications.

Medical Management

In many patients, recurrent orolabial herpes represents more of a nuisance than a disease. Because sun exposure is a common trigger, people with recurrent orolabial herpes should use a sunscreen liberally on the lips and face. Topical treatment with drying agents may accelerate healing. In

more severe outbreaks or in patients with identified triggers, intermittent treatment with 200 mg acyclovir administered five times each day for 5 days is often started as soon as the earliest symptoms occur.

Treatment of genital herpes depends on the severity, the frequency, and the psychological impact of recurrences and on the infectious status of the sexual partner. For people who have mild or rare outbreaks, no treatment may be required. For those who have more severe outbreaks, but for whom outbreaks are still infrequent, intermittent treatment as described for oral lesions can be used. Use of intermittent oral medication has been shown to reduce the duration of herpes genital infections by only 24 to 36 hours. If a patient is using intermittent treatment for infrequent episodes, the medication should be initiated within the first 24 hours after the infection is identified.

Patients who have more than six recurrences per year may benefit from suppressive therapy. Use of acyclovir, valacyclovir, or famciclovir suppresses 85% of recurrences, and 20% of patients are free of recurrences during suppressive therapy. Suppressive therapy also reduces viral shedding by almost 95%, making the person less contagious. Treatment with suppressive doses of oral antiviral medications prevents recurrent erythema multiforme (acute eruption of macules, papules, and vesicles with a multiform appearance).

Management of genital herpes in pregnancy differs among clinicians. Routine prenatal cultures do not predict shedding at the time of delivery. The use of scalp electrodes during delivery should be avoided because they increase the risk of infection in the newborn. Because the risk of

neonatal herpes is greater in women with their initial episode during pregnancy, suppression therapy should be started in affected women to reduce outbreaks during the third trimester. All women with active lesions at the time of delivery undergo cesarean section.

In immunocompromised patients, suppression therapy should be considered. In severe infections of hospitalized patients, IV acyclovir is prescribed.

Fungal (Mycotic) Skin Infections

Fungi, tiny members of a subdivision of the plant kingdom that thrive on organic matter, cause various common skin infections. In some cases, they affect only the skin and its appendages (hair and nails). In other cases, internal organs are involved, and the diseases may be life-threatening. However, superficial infections rarely cause even temporary disability and respond readily to treatment. Secondary infection with bacteria, *Candida*, or both organisms may occur.

The most common fungal skin infection is **tinea**, which is also called ringworm because of its characteristic appearance of a ring or rounded tunnel under the skin. Tinea infections affect the head, body, groin, feet, and nails. Table 56-5 summarizes the tinea infections.

To obtain a specimen for diagnosis, the lesion is cleaned and a scalpel or glass slide is used to remove scales from the margin of the lesion. The scales are dropped onto a slide to which potassium hydroxide has been added. The diagnosis is made by examination of the infected scales microscopically for spores and hyphae or by isolating the organism in

Table 56-5 TINEA (RINGWORM) INFECTIONS

Type and Location	Clinical Manifestations	Treatment
Tinea capitis (head) Contagious fungal infection of the hair shaft	<ul style="list-style-type: none"> • Common in children • Oval, scaling, erythematous patches • Small papules or pustules on the scalp • Brittle hair that breaks easily 	<ul style="list-style-type: none"> • Griseofulvin for 6 weeks • Shampoo hair two or three times with Nizoral or selenium sulfide shampoo
Tinea corporis (body)	<ul style="list-style-type: none"> • Begins with red macule, which spreads to a ring of papules or vesicles with central clearing • Lesions found in clusters • Many spread to the hair, scalp, or nails • Very pruritic • An infected pet may be the source 	<ul style="list-style-type: none"> • Mild conditions: topical antifungal creams • Severe conditions: griseofulvin or terbinafine
Tinea cruris (groin area; "jock itch")	<ul style="list-style-type: none"> • Begins with small, red scaling patches, which spread to form circular elevated plaques • Very pruritic • Clusters of pustules may be seen around borders 	<ul style="list-style-type: none"> • Mild conditions: topical antifungal creams • Severe conditions: griseofulvin or terbinafine
Tinea pedis (foot; "athlete's foot")	<ul style="list-style-type: none"> • Soles of one or both feet have scaling and mild redness with maceration in the toe webs • More acute infections may have clusters of clear vesicles on dusky base 	<ul style="list-style-type: none"> • Soak feet in vinegar and water solution • Resistant infections: griseofulvin or terbinafine • Terbinafine (Lamisil) daily for 3 months
Tinea unguum (toenails; affects about 50% of adults)	<ul style="list-style-type: none"> • Nails thicken, crumble easily, and lack luster • Whole nail may be destroyed 	<ul style="list-style-type: none"> • Itraconazole (Sporanox) in pulses of 1 week a month for 3 months in cases of terbinafine failure

culture. Under Wood's light, a specimen of infected hair appears fluorescent; this may be helpful in diagnosing some cases of tinea capitis.

Parasitic Skin Infestations

These conditions include infestations of the skin by lice (pediculosis) and the itch mite (scabies).

PEDICULOSIS: LICE INFESTATION

Lice infestation affects people of all ages. Three varieties of lice infest humans: *Pediculus humanus capitis* (head louse), *Pediculus humanus corporis* (body louse), and *Phthirus pubis* (pubic louse or crab louse). Lice are called ectoparasites because they live on the outside of the host's body. They depend on the host for their nourishment, feeding on human blood approximately five times each day. They inject their digestive juices and excrement into the skin, which causes severe itching.

Types of Pediculosis

Pediculosis Capitis

Pediculosis capitis is an infestation of the scalp by the head louse. The female louse lays her eggs (nits) close to the scalp. The nits become firmly attached to the hair shafts with a tenacious substance. The young lice hatch in about 10 days and reach maturity in 2 weeks. Head lice may be transmitted directly by physical contact or indirectly by infested combs, brushes, wigs, hats, and bedding.

Pediculosis Corporis and Pubis

Pediculosis corporis is an infestation of the body by the body louse. This is a disease of unwashed people or those who live in close quarters and do not change their clothing (eg, survivors of natural disasters such as hurricanes, floods, and earthquakes who must live with others in temporary housing without access to running water and clean clothes). Pediculosis pubis is extremely common. The infestation is generally localized in the genital region and is transmitted chiefly by sexual contact.

Clinical Manifestations

Head lice are found most commonly along the back of the head and behind the ears. To the naked eye, the eggs look like silvery, glistening oval bodies. The bite of the insect causes intense pruritus, and the resultant scratching often leads to secondary bacterial infection, such as impetigo or furunculosis. The infestation is more common in children and people with long hair.

With body lice, the areas of the skin that come in closest contact with the underclothing (ie, neck, trunk, and thighs) are chiefly involved. The body louse lives primarily in the seams of underwear and clothing, to which it clings as it pierces the skin with its proboscis. Its bites cause characteristic minute hemorrhagic points. Widespread excoriation may appear as a result of intense pruritus and scratching, especially on the trunk and neck. Among the secondary lesions produced are parallel linear scratches and a slight degree of eczema. In long-standing cases, the skin may become thick, dry, and scaly, with dark pigmented areas.

Pruritus, particularly at night, is the most common symptom of pediculosis pubis. Reddish-brown dust (ie, excretions of the insects) may be found in the patient's underclothing. The pubic area should be examined with a magnifying glass for lice crawling down a hair shaft or nits cemented to the hair or at the junction with the skin. Infestation by pubic lice may coexist with sexually transmitted diseases such as gonorrhea, herpes, or syphilis. There may also be infestation of the hairs of the chest, axillae, beard, and eyelashes. Gray-blue macules may sometimes be seen on the trunk, thighs, and axillae as a result of either the reaction of the insects' saliva with bilirubin (converting it to biliverdin) or an excretion produced by the salivary glands of the louse.

Medical Management

Treatment of head lice involves washing the hair with a shampoo containing lindane (Kwell) or pyrethrin compounds with piperonyl butoxide (RID or R&C Shampoo). The patient is instructed to shampoo the scalp and hair according to the product directions. After the hair is rinsed thoroughly, it is combed with a fine-toothed comb dipped in vinegar to remove any remaining nits or nit shells freed from the hair shafts. They are extremely difficult to remove and may have to be picked off one by one.

All articles, clothing, towels, and bedding that may have lice or nits should be washed in hot water—at least 54°C (130°F)—or dry cleaned to prevent reinfestation. Upholstered furniture, rugs, and floors should be vacuumed frequently. Combs and brushes are also disinfected with the shampoo. All family members and close contacts are treated. Complications such as severe pruritus, pyoderma, and dermatitis are treated with antipruritics, systemic antibiotics, and topical corticosteroids.

The patient with body lice is instructed to bathe with soap and water, after which a prescription scabicide (lindane or 5% permethrin [Elimite]) is applied to affected areas of the skin and to hairy areas, according to the product directions. An alternative topical therapy is an over-the-counter strength of permethrin (1% Nix). If the eyelashes are involved, petrolatum may be thickly applied twice daily for 8 days, followed by mechanical removal of any remaining nits.

Complications, such as severe pruritus, pyoderma, and dermatitis, are treated with antipruritics, systemic antibiotics, and topical corticosteroids. Body lice can transmit epidemic rickettsial disease (eg, epidemic typhus, relapsing fever, and trench fever) to humans. The causative organism may be in the gastrointestinal tract of the insect and may be excreted on the skin surface of the infested person.

Nursing Management

The nurse informs the patient that head lice may infest anyone and are not a sign of uncleanliness. Because the condition spreads rapidly, treatment must be started immediately. School epidemics may be managed by having all of the students shampoo their hair on the same night. Students should be warned not to share combs, brushes, and hats. Each family member should be inspected for head lice daily for at least 2 weeks. The patient should be instructed that lindane may be toxic to the central nervous system when used more frequently or for longer periods of time than specified in the package insert.

Treatment is necessary for all family members and sexual contacts of patients with body and/or pubic lice. The nurse instructs them about personal hygiene and methods to prevent or control infestation. The patient and partner must also be scheduled for a diagnostic workup for coexisting sexually transmitted disease.

SCABIES

Scabies is an infestation of the skin by the itch mite *Sarcoptes scabiei*. The disease may be found in people living in substandard hygienic conditions, but it can occur in anyone. Infestations may or may not be associated with sexual activity. The mites frequently involve the fingers, and hand contact may produce infection. In children, overnight stays with friends or the exchange of clothes may be a source of infection. Health care personnel who have prolonged hands-on physical contact with an infected patient may become infected.

Clinical Manifestations

It takes approximately 4 weeks from the time of contact for the patient's symptoms to appear. The patient complains of severe itching caused by a delayed type of immunologic reaction to the mite or its fecal pellets. During examination, the patient is asked where the pruritus is most severe. A magnifying glass and a penlight are held at an oblique angle to the skin while a search is made for the small, raised burrows created by the mites. The burrows may be multiple, straight or wavy, brown or black, threadlike lesions, most commonly observed between the fingers and on the wrists. Other sites are the extensor surfaces of the elbows, the knees, the edges of the feet, the points of the elbows, around the nipples, in the axillary folds, under pendulous breasts, and in or near the groin or gluteal fold, penis, or scrotum. Red, pruritic eruptions usually appear between adjacent skin areas. However, the burrow is not always visible. Any patient with a rash may have scabies.

One classic sign of scabies is the increased itching that occurs during the overnight hours, perhaps because the increased warmth of the skin has a stimulating effect on the parasite. Hypersensitivity to the organism and its products of excretion also may contribute to the pruritus. If the infection has spread, other members of the family and close friends also complain of pruritus about 1 month later.

Secondary lesions are quite common and include vesicles, papules, excoriations, and crusts. Bacterial superinfection may result from constant excoriation of the burrows and papules.

Gerontologic Considerations

Elderly patients living in long-term care facilities are susceptible to outbreaks of scabies because of close living quarters, poor hygiene due to limited physical ability, and the potential for incidental spread of the organisms by staff members. Although pruritus may be severe in the older patient, the vivid inflammatory reaction seen in younger people seldom occurs. Scabies may not be recognized in the elderly person; the pruritus may erroneously be attributed to the dry skin of old age or to anxiety.

Health care personnel in extended-care facilities should wear gloves when providing hands-on care for a patient sus-

pected of having scabies until the diagnosis is confirmed and treatment completed. It is advisable to treat all residents, staff, and families of patients at the same time to prevent reinfection. Because geriatric patients may be more sensitive to side effects of the scabicides, they should be closely observed for reactions.

Assessment and Diagnostic Findings

The diagnosis is confirmed by recovering *S. scabiei* or the mites' byproducts from the skin. A sample of superficial epidermis is scraped from the top of the burrows or papules with a small scalpel blade. The scrapings are placed on a microscope slide and examined through a microscope at low power to demonstrate evidence of the mite.

Medical Management

The patient is instructed to take a warm, soapy bath or shower to remove the scaling debris from the crusts and then to dry thoroughly and allow the skin to cool. A prescription scabicide, such as lindane, crotamiton (Eurax), or 5% permethrin, is applied thinly to the entire skin from the neck down, sparing only the face and scalp (which are not affected in scabies). The medication is left on for 12 to 24 hours, after which the patient is instructed to wash thoroughly. One application may be curative, but it is advisable to repeat the treatment in 1 week.

NURSING ALERT

The patient must understand medication instructions because application of a scabicide immediately after bathing and before the skin dries and cools increases percutaneous absorption of the scabicide and the potential for central nervous system abnormalities such as seizures.

Nursing Management

The patient should wear clean clothing and sleep between freshly laundered bed linens. All bedding and clothing should be washed in hot water and dried on the hot dryer cycle. If bed linens or clothing cannot be washed in hot water, dry cleaning is advised.

After treatment is completed, the patient should apply an ointment, such as a topical corticosteroid, to skin lesions because the scabicide may irritate the skin. The patient's hypersensitivity does not cease on destruction of the mites. Pruritus may continue for several weeks as a manifestation of hypersensitivity, particularly in atopic (allergic) people. This is not a sign that the treatment has failed. The patient is instructed (1) not to apply more scabicide, because it will cause more irritation and increased itching, and (2) not to take frequent hot showers, because they can dry the skin and produce pruritus. Oral antihistamines such as diphenhydramine or hydroxyzine can help control the pruritus.

All family members and close contacts should be treated simultaneously to eliminate the mites. Some scabicides are approved for use in infants and pregnant women. If scabies is sexually transmitted, the patient may require treatment for coexisting sexually transmitted disease. Scabies may also coexist with pediculosis.

CONTACT DERMATITIS

Contact dermatitis is an inflammatory reaction of the skin to physical, chemical, or biologic agents. The epidermis is damaged by repeated physical and chemical irritations. Contact dermatitis may be of the primary irritant type, in which a nonallergic reaction results from exposure to an irritating substance, or it may be an allergic reaction resulting from exposure of sensitized people to contact allergens. Allergic dermatoses are discussed in Chapter 53. Common causes of irritant dermatitis are soaps, detergents, scouring compounds, and industrial chemicals. Predisposing factors include extremes of heat and cold, frequent contact with soap and water, and a preexisting skin disease (Chart 56-3).

Clinical Manifestations

The eruptions begin when the causative agent contacts the skin. The first reactions include pruritus, burning, and erythema, followed closely by edema, papules, vesicles, and oozing or weeping. In the subacute phase, these vesicular changes are less marked, and they alternate with crusting, drying, fissuring, and peeling. If repeated reactions occur or if the patient continually scratches the skin, lichenification and pigmentation occur. Secondary bacterial invasion may follow.

Medical Management

The objectives of management are to soothe and heal the involved skin and protect it from further damage. The distribution pattern of the reaction is identified to differentiate between allergic and irritant contact dermatitis. A detailed history is obtained. If possible, the offending irritant is removed. Local irritation should be avoided, and soap is not generally used until healing occurs.

Many preparations are advocated for relieving dermatitis. In general, a bland, unmedicated lotion is used for small

patches of erythema. Cool, wet dressings also are applied over small areas of vesicular dermatitis. Finely cracked ice added to the water often enhances its antipruritic effect.

Wet dressings usually help clear the oozing eczematous lesions. A thin layer of cream or ointment containing a corticosteroid then may be used. Medicated baths at room temperature are prescribed for larger areas of dermatitis. For severe, widespread conditions, a short course of systemic corticosteroids may be prescribed.

NONINFECTIOUS INFLAMMATORY DERMATOSES

Psoriasis

Considered one of the most common skin diseases, psoriasis affects approximately 2% of the population, appearing more often in people of European ancestry. It is thought that this chronic disease stems from a hereditary defect that causes overproduction of keratin. Onset may occur at any age, but psoriasis is most common in people between 15 and 35 years of age. Psoriasis has a tendency to improve and then recur periodically throughout life (Porth & Matfin, 2009).

Pathophysiology

Current evidence supports an immunologic basis for psoriasis (Porth & Matfin, 2009). Periods of emotional stress and anxiety aggravate the condition, and trauma, infections, and seasonal and hormonal changes also are trigger factors.

In this disease, the cells in the basal layer of the skin divide too quickly, and the newly formed cells move so rapidly to the skin surface that they become evident as profuse scales or plaques of epidermal tissue. As a result of the increased number of basal cells and rapid cell passage, the normal events of cell maturation and growth cannot occur, which prevent formation of the normal protective layers of the skin.

Clinical Manifestations

Psoriasis may range in severity from a cosmetic source of annoyance to a physically disabling and disfiguring disorder. Lesions appear as red, raised patches of skin covered with silvery scales. The scaly patches are formed by the buildup of living and dead skin (Fig. 56-3). If the scales are scraped away, the dark-red base of the lesion is exposed, producing multiple bleeding points. The patches are not moist and may be pruritic. In approximately one fourth to one half of patients, the nails are also involved, with pitting, discoloration, crumbling beneath the free edges, and separation of the nail plate.

Bilateral symmetry is a feature of psoriasis. Particular sites of the body affected most by this condition include the scalp, the extensor surface of the elbows and knees, the lower part of the back, and the genitalia, as well as the nails.

Complications

Asymmetric rheumatoid factor–negative arthritis of multiple joints occurs in about 5% of people with psoriasis, before or after the skin lesions appear. Psoriatic arthritis is discussed in more detail later in this chapter.

Erythrodermic psoriasis, an exfoliative psoriatic state, involves disease progression that involves the total body

CHART
56-3

PATIENT EDUCATION Strategies for Avoiding Contact Dermatitis

The following precautions may help prevent repeated cases of contact dermatitis. Follow these instructions for at least 4 months after your skin appears to be completely healed.

- Study the pattern and location of your dermatitis and think about which things have touched your skin and which things may have caused the problem.
- Try to avoid contact with these materials.
- Avoid heat, soap, and rubbing, all of which are external irritants.
- Choose bath soaps, laundry detergents, and cosmetics that do not contain fragrance.
- Avoid using a fabric softener dryer sheet (Bounce, Cling Free). Fabric softeners that are added to the washer may be used.
- Avoid topical medications, lotions, or ointments, except those specifically prescribed for your condition.
- Wash your skin thoroughly immediately after exposure to possible irritants.
- When wearing gloves (for example, for washing dishes or general cleaning), be sure they are cotton-lined. Do not wear them more than 15 or 20 minutes at a time.

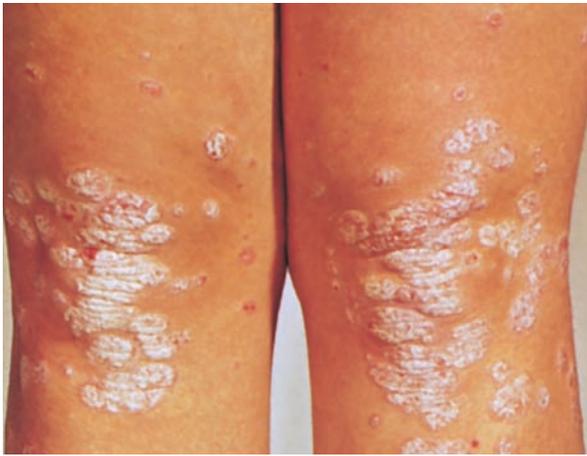

Figure 56-3 Psoriasis. Courtesy of Roche Laboratories.

surface. The patient is acutely ill. Erythrodermic psoriasis often appears in people with chronic psoriasis after infections, after exposure to certain medications, or following withdrawal of systemic corticosteroids.

Assessment and Diagnostic Findings

The presence of the classic plaque-type lesions generally confirms the diagnosis of psoriasis. If in doubt, the health care provider should assess for signs of nail and scalp involvement and for a positive family history. Biopsy of the skin is of little diagnostic value.

Medical Management

The goals of management are to slow the rapid turnover of epidermis, to promote resolution of the psoriatic lesions, and to control the natural cycles of the disease. There is no known cure.

The therapeutic approach should be one that the patient understands; it should be cosmetically acceptable and minimally disruptive of lifestyle. Treatment involves the commitment of time and effort by the patient and possibly the family. Any precipitating or aggravating factors are addressed. An assessment is made of lifestyle because psoriasis is significantly affected by stress. Management of emotional factors should be addressed as part of the overall treatment of psoriasis. Disruption of self-image and depression have been reported in up to 50% of patients with severe psoriasis. The patient is informed that treatment of severe psoriasis can be time-consuming, expensive, and aesthetically unappealing at times. More than 50% of patients report difficulty complying with treatment plans, either for time reasons or lack of response to the treatment.

The most important principle of psoriasis treatment is gentle removal of scales. This can be accomplished with baths. Oils (eg, olive oil, mineral oil, Aveeno Oilated Oatmeal Bath) or coal tar preparations (eg, Balnetar) can be added to the bath water and a soft brush used to scrub the psoriatic plaques gently. After bathing, the application of emollient creams containing alpha-hydroxy acids (eg, Lac-Hydrin, Penederm) or salicylic acid continues to soften thick scales. The patient and family should be encouraged to establish a regular skin care routine that can be maintained even when the psoriasis is not in an acute stage.

Pharmacologic Therapy

With the recent addition of biologic medications, three types of therapy are now commonly used: topical, systemic, and phototherapy (Table 56-6).

Topical Agents

Topically applied agents are used to slow the overactive epidermis. Topical corticosteroids may be applied for their

Table 56-6 CURRENT PHARMACOLOGIC TREATMENT FOR PSORIASIS		
Topical Agents	Use	Selected Agents
Biologicals	Moderate to severe lesions	Cyclosporine (Neoral), alefacept (Amevive), etanercept (Enbrel), infliximab (Remicade)
Topical corticosteroids	Mild to moderate lesions	Triamcinolone acetonide (Aristocort, Kenalog), bethamethasone valerate (Valisone, Diprosone)
	Moderate to severe lesions	Fluocinonide (Lidex)
	Severe lesions	Clobetasol (Temovate), betamethosone dipropionate (Diprolene), halobetasol (Ultravate)
	Lesions on face and groin	Alclometasome (Aclovate), desonide (DesOwen), hydrocortisone (Hytone 2.5%)
Topical nonsteroidals	Mild to severe	Retinoids such as tazarotene (Tazorac) Vitamin D ₃ derivative calcipotriene (Dovonex)
Coal tar products	Mild to moderate lesions	Coal tar and salicylic acid ointment (Aquatar, Estar gel, Fototar, Zetar); anthralin (AnthraDerm, Dritho-Cream); Neutrogena T-Derm, Psori Gel
Medicated shampoos	Scalp lesions	Neutrogena T-Gel, T-Sal, Zetar, Head & Shoulders, Desenex, Selsun Blue, Bakers P&S (emulsifying agent with phenol, saline solution, and mineral oil)
Intralesional therapy	Thick plaques and nails	Kenalog, Cordran-impregnated tape, Fluoroplex
Systemic therapy	Extensive lesions and nails	Methotrexate (Folex, Mexate); hydrourea (Hydrea); retinoic acid (Tegison) (not to be used in women of childbearing age)
Photochemotherapy	Psoriatic arthritis	Oral gold (auranofin), etrentinate, methotrexate
	Moderate to severe lesions	UVA or UVB light with or without topical medications PUVA (combines UVA light with oral psoralens, or topical tripsoralen)

anti-inflammatory effect. Choosing the correct strength of corticosteroid for the involved site and choosing the most effective vehicle base are important aspects of topical treatment. In general, high-potency topical corticosteroids should not be used on the face and intertriginous areas, and their use on other areas should be limited to a 4-week course of twice-daily applications. A 2-week break should be taken before repeating treatment with the high-potency corticosteroids. For long-term therapy, moderate-potency corticosteroids are used. On the face and intertriginous areas, only low-potency corticosteroids are appropriate for long-term use (see Table 56-3).

Occlusive dressings may be applied to increase the effectiveness of the corticosteroid. Large plastic bags may be used—one for the upper body with openings cut for the head and arms and one for the lower body with openings for the legs. Large rolls of tubular plastic can be used to cover the arms and legs. Another option is a vinyl jogging suit. The medication is applied, and the suit is put on over it. The hands can be wrapped in gloves, the feet in plastic bags, and the head in a shower cap. Occlusive dressings should not remain in place longer than 8 hours. The skin should be inspected carefully for the appearance of atrophy, hypopigmentation, striae, and telangiectasias, all side effects of corticosteroids.

NURSING ALERT

When plastic substances are used, the nurse needs to check for flammability. Some thin plastic films burn slowly (if touched by a lighted cigarette), whereas others burst rapidly into flame. The patient should be cautioned not to smoke while wrapped in a plastic dressing.

When psoriasis involves large areas of the body, topical corticosteroid treatment can be expensive and involve some systemic risk. The more potent corticosteroids, when applied to large areas of the body, have the potential to cause adrenal suppression through percutaneous absorption of the medication. In this event, other treatment modalities (eg, nonsteroidal topical medications, ultraviolet light) may be used instead or in combination to decrease the need for corticosteroids.

Two relatively new topical nonsteroidal treatments are calcipotriene (Dovonex) and tazarotene (Tazorac). Treatment with these agents tends to suppress **epidermopoiesis** (ie, development of epidermal cells) and cause sloughing of the rapidly growing epidermal cells. Calcipotriene 0.05% is a derivative of vitamin D₂. It works by decreasing the mitotic turnover of the psoriatic plaques. Its most common side effect is local irritation. The intertriginous areas and face should be avoided when using this medication. The patient should be monitored for symptoms of hypercalcemia. Calcipotriene is available as a cream for use on the body and a solution for the scalp. It is not recommended for use by elderly patients because of their more fragile skin or by pregnant or lactating women.

Tazarotene, a retinoid, causes sloughing of the scales covering psoriatic plaques. As with other retinoids, it causes increased sensitivity to sunlight by loss of the outermost layer of skin, so the patient should be cautioned to use an effective

sunscreen and avoid other photosensitizers (eg, tetracycline, antihistamines). Tazarotene is listed as a Category X drug in pregnancy; reports indicate evidence of fetal risk, and the risk of use in pregnant women clearly outweighs any possible benefits. A negative result on a pregnancy test should be obtained before initiating this medication in women of childbearing age, and an effective contraceptive should be continued during treatment. Side effects include burning, erythema, or irritation at the site of application and worsening of psoriasis.

Intralesional injections of the corticosteroid triamcinolone acetonide (Aristocort, Kenalog-10, Trymex) can be administered directly into highly visible or isolated patches of psoriasis that are resistant to other forms of therapy. Care must be taken to ensure that the medication is not injected into normal skin.

Systemic Agents

Although systemic corticosteroids may cause rapid improvement of psoriasis, the usual risks and the possibility of triggering a severe flare-up on withdrawal limit their use. Systemic cytotoxic preparations, such as methotrexate, have been used in treating extensive psoriasis that fails to respond to other forms of therapy.

Biological Agents. The newest line of treatments for psoriasis includes a group called biologics because of their derivation from immunomodulators and bioengineered proteins (such as antibodies or recombinant cytokines) and their targeted action directly on the T cells. These agents act by inhibiting activation and migration, eliminating the T cells completely, slowing postsecretory cytokines or inducing immune deviation. Five biologics are approved by the U.S. Food and Drug Administration (FDA) for treatment of moderate to severe psoriasis with or without psoriatic arthritis. They are administered either intravenously or subcutaneously, and patients must have the ability and motivation to self-administer injections.

Because of suppressed immune status, live vaccines could trigger full-blown disease in susceptible patients. Discussion with an infectious disease specialist is recommended. Some biological agents are designated as pregnancy Category B; all are secreted in breast milk (Pirzada, Tomi & Gulliver, 2007).

Infliximab (Remicade) is a monoclonal antibody that binds to tumor necrosis factor- α (TNF- α) and can only be administered by IV infusion. Etanercept (Enbrel) is a fusion protein that binds to soluble TNF- α and blocks its interaction with cell surface receptors. Efalizumab (Raptiva) is a murine antibody that inhibits T-cell activation and adherence to keratinocytes. Alefacept (Amevive) is a fusion protein that inhibits T-cell proliferation. Adalimumab (Humira) is a recombinant human immunoglobulin G1 (IgG1) monoclonal antibody against TNF- α . These biological agents have significant side effects, making close monitoring essential.

Oral Agents. Methotrexate appears to inhibit DNA synthesis in epidermal cells, thereby reducing the turnover time of the psoriatic epidermis. However, the medication can be toxic, especially to the liver, kidneys, and bone marrow. Laboratory studies must be monitored to ensure that

the hepatic, hematopoietic, and renal systems are functioning adequately. The patient should avoid drinking alcohol while taking methotrexate because alcohol ingestion increases the possibility of liver damage. The medication is teratogenic (produces physical defects in the fetus) and thus should not be administered to pregnant women.

Cyclosporine A, a cyclic peptide used to prevent rejection of transplanted organs, has shown some success in treatment of severe, therapy-resistant cases of psoriasis. However, its use is limited by side effects such as hypertension and nephrotoxicity.

Oral retinoids (ie, synthetic derivatives of vitamin A and its metabolite, vitamin A acid) modulate the growth and differentiation of epithelial tissue. Etretinate (Tegison, Tigason) is especially useful for severe pustular or erythrodermic psoriasis. Etretinate is a teratogen with a very long half-life; it cannot be used in women with childbearing potential.

Photochemotherapy

When psoriasis becomes widespread (defined as too many plaques to count or as involving more than 50% of the body surface), another treatment option involves combining a photosensitizing oral medication with exposure to ultraviolet-A light (PUVA). The patient takes a photosensitizing medication (usually 8-methoxypsoralen [8-mop, Houva-caps, meladinine, meloxine]) in a standard dose and is subsequently exposed to long-wave ultraviolet light as the medication plasma levels peak. It is thought that when psoralen-treated skin is exposed to UVA light, the psoralen binds with DNA and decreases cellular proliferation. PUVA has been associated with long-term risks of skin cancer, cataracts, and premature aging of the skin (Porth & Matfin, 2009).

The patient is usually treated two or three times each week until the psoriasis clears. An interim period of 48 hours between treatments is necessary to allow any burns resulting from PUVA therapy to become evident. After the psoriasis clears, the patient begins a maintenance program. Once little or no disease is active, less potent therapies are used to keep minor flare-ups under control.

Very often, phototherapy in the ultraviolet-B (UVB) spectrum is used as a single therapy modality. Research has shown that the most effective UVB range for therapeutic response is the range of 310 to 312 nm; therapy in this range precludes many of the negative side effects that can be experienced with broader range light. UVB is used alone or in combination with topical coal tar, emollients, and mild topical corticosteroids. Side effects are similar to those of PUVA therapy. A new therapy unit provides UVB in the narrow range of 311 to 312 nm, which decreases the harmful effects of UVB while providing more intense therapy. Response to treatment can be improved if narrow-band UVB is combined with the topical cream, calcipotriol (Dovonex). This cream induces synthesis of vitamin D in the skin and decreases the need for ultraviolet exposure (Lui & Mamelak, 2007).

If access to a light treatment unit is not feasible, the patient can expose himself or herself to sunlight. The risks of all light treatments are similar and include acute sunburn; exacerbation of photosensitive disorders such as lupus and

rosacea; as well as other skin changes such as increased wrinkles, thickening, and an increased risk for skin cancer.

Excimer lasers have come into use in treating psoriasis. These lasers function at 308 nm. Studies show that medium-size psoriatic plaques clear in four to six treatments and remain clear for up to 9 months. A laser can be more effective on the scalp or on other hard-to-treat areas because it can be aimed very specifically on the plaque (Taibjee, 2005).

Nursing Management

Assessment

The nursing assessment focuses on the appearance of the normal skin, the appearance of the skin lesions, and how the patient is coping with the psoriatic skin condition. It is important to examine the areas especially prone to psoriasis: elbows, knees, scalp, gluteal cleft, and all nails (for small pits).

Psoriasis may cause despair and frustration for the patient; observers may stare, comment, ask embarrassing questions, or even avoid the person. The disease can eventually exhaust the patient's resources, interfere with his or her job, and negatively affect many aspects of life. Teenagers are especially vulnerable to the psychological effects of this disorder.

The nurse assesses the impact of the disease on the patient and the coping strategies used for conducting normal activities and interactions with family and friends. Many patients need reassurance that the condition is not infectious, is not a reflection of poor personal hygiene, and is not skin cancer. The nurse can create an environment in which the patient feels comfortable discussing important quality-of-life issues related to his or her psychosocial and physical response to this chronic illness.

Nursing Interventions

Promoting Understanding

The nurse explains with sensitivity that although there is no cure for psoriasis and lifetime management is necessary, the condition can usually be controlled. The pathophysiology of psoriasis is reviewed, as are the factors that provoke it—irritation or injury to the skin (eg, cut, abrasion, sunburn), current illness (eg, pharyngeal streptococcal infection), and emotional stress. It is emphasized that repeated trauma to the skin and an unfavorable environment (eg, cold) or a specific medication (eg, lithium, beta-blockers, indomethacin [Indocin]) may exacerbate psoriasis. The patient is cautioned about taking any nonprescription medications because some may aggravate mild psoriasis.

Reviewing and explaining the treatment regimen are essential to ensure compliance. For example, if the patient has a mild condition confined to localized areas, such as the elbows or knees, application of an emollient to maintain softness and minimize scaling may be all that is required. Most patients need a comprehensive plan of care that ranges from using topical medications and shampoos to more complex and lengthy treatment with systemic medications and photochemotherapy, such as PUVA therapy. Patient education materials that include a description of the therapy and specific guidelines are helpful but cannot replace face-to-face discussions of the treatment plan.

Increasing Skin Integrity

To avoid injuring the skin, the patient is advised not to pick at or scratch the affected areas. Measures to prevent dry skin are encouraged because dry skin worsens psoriasis. Too-frequent washing produces more soreness and scaling. Water should be warm, not hot, and the skin should be dried by patting with a towel rather than by rubbing. Emollients have a moisturizing effect, providing an occlusive film on the skin surface so that normal water loss through the stratum corneum. A bath oil or emollient cleansing agent can comfort sore and scaling skin. Softening the skin can prevent fissures.

Improving Self-Concept and Body Image

A therapeutic relationship between health care professionals and the patient with psoriasis includes education and support. Introducing the patient to successful coping strategies used by others with psoriasis and making suggestions for reducing or coping with stressful situations at home, school, and work can facilitate a more positive outlook and acceptance of the chronicity of the disease.

Monitoring and Managing Potential Complications

The diagnosis of psoriasis, especially when it is accompanied by the complication of arthritis, is usually difficult to make. Psoriatic arthritis involving the sacroiliac and distal joints of the fingers may be overlooked, especially if the patient has the typical psoriatic lesions. However, patients who complain of mild joint discomfort and some pitting of the fingernails may not be diagnosed with psoriasis until the more obvious cutaneous lesions appear. The patient requires education about the care and treatment of the involved joints and the need for compliance with therapy. However, when the psoriasis is extensive and a family history of inflammatory arthritis is elicited, the chance that the patient will develop psoriatic arthritis increases substantially. It is recommended that a rheumatologist be consulted to assist in the diagnosis and treatment of the arthropathy.

Promoting Home and Community-Based Care

Teaching Patients Self-Care. Printed patient education materials may be provided to reinforce face-to-face discussions about treatment guidelines and other considerations.

Patients using topical corticosteroid preparations repeatedly on the face and around the eyes should be aware that cataract development is possible. Strict guidelines for applying these medications should be emphasized because overuse can result in skin atrophy, striae, and medication resistance.

PUVA, which is reserved for moderate to severe psoriasis, produces photosensitization. If exposure to the sun is unavoidable, the skin must be protected with sunscreen and clothing. Gray-tinted or green-tinted wraparound sunglasses should be worn to protect the eyes during and after treatment, and ophthalmologic examinations should be performed on a regular basis. Contraceptives should be used by sexually active women of reproductive age because the teratogenic effect of PUVA has not been determined.

If indicated, referral may be made to a mental health professional who can help to ease emotional strain and give support. Belonging to a support group may also help patients recognize that they are not alone in experiencing life adjustments in response to a visible, chronic disease. The National Psoriasis Foundation publishes periodic bulletins and reports about new and relevant developments in this condition.

Chart 56-4 is a Home Care Checklist for the patient with psoriasis.

Exfoliative Dermatitis

Exfoliative dermatitis is a serious condition characterized by progressive inflammation in which generalized erythema and scaling occur. It may be associated with chills, fever, prostration, severe toxicity, and a pruritic scaling of the skin. There is a profound loss of stratum corneum (ie, outermost layer of the skin), which causes capillary leakage, hypoproteinemia, and negative nitrogen balance. Because of widespread dilation of cutaneous vessels, large amounts of body heat are lost, and exfoliative dermatitis has a marked effect on the entire body.

Exfoliative dermatitis has a variety of causes. It is considered to be a secondary or reactive process to an underlying skin or systemic disease. It may appear as a part of the lymphoma group of diseases and may precede the clinical manifestations of lymphoma. Preexisting skin disorders

CHART
56-4

HOME CARE CHECKLIST The Patient With Psoriasis

At the completion of the home care instruction, the patient or caregiver will be able to:	PATIENT	CAREGIVER
• Describe the etiology of psoriasis.	✓	✓
• Describe optimal skin maintenance practices to maintain moisture of skin and prevent infection.	✓	✓
• Demonstrate correct application of prescribed topical medications.	✓	✓
• Describe common side effects of oral medication, if prescribed.	✓	✓
• Demonstrate appropriate therapeutic bath technique, if prescribed.	✓	✓
• Verbalize optimism about condition.	✓	
• Identify a support person with whom to discuss feelings and concerns.	✓	

that have been implicated include psoriasis, atopic dermatitis, and contact dermatitis. It also appears as a severe reaction to many medications, including penicillin and phenylbutazone (Butazolidin). The cause is unknown in approximately 25% of cases (James, Berger & Elston, 2005).

Clinical Manifestations

This condition starts acutely as a patchy or generalized erythematous eruption accompanied by fever, malaise, and occasionally gastrointestinal symptoms. The skin color changes from pink to dark red. After a week, the characteristic exfoliation (ie, scaling) begins, usually in the form of thin flakes that leave the underlying skin smooth and red, with new scales forming as the older ones come off. Hair loss may accompany this disorder. Relapses are common. The systemic effects include high-output heart failure, other gastrointestinal disturbances, breast enlargement, elevated levels of uric acid in the blood (ie, hyperuricemia), and temperature disturbances.

Medical Management

The objectives of management are to maintain fluid and electrolyte balance and to prevent infection. The treatment is individualized and supportive and should be initiated as soon as the condition is diagnosed.

The patient may be hospitalized and placed on bed rest. All medications that may be implicated are discontinued. A comfortable room temperature should be maintained because the patient does not have normal thermoregulatory control as a result of temperature fluctuations caused by vasodilation and evaporative water loss. Fluid and electrolyte balance must be maintained because there is considerable water and protein loss from the skin surface. Administration of plasma volume expanders may be indicated.

Nursing Management

Continual nursing assessment is carried out to detect infection. The disrupted, erythematous, moist skin is susceptible to infection and becomes colonized with pathogenic organisms, which produce more inflammation. Antibiotics, which are prescribed if infection is present, are selected on the basis of culture and sensitivity.

NURSING ALERT

The nurse observes the patient for signs and symptoms of heart failure because hyperemia and increased cutaneous blood flow can produce high-output cardiac failure.

Hypothermia may occur because increased blood flow in the skin, coupled with increased water loss through the skin, leads to heat loss by radiation, conduction, and evaporation. Changes in vital signs are closely monitored and reported.

Topical therapy is used to provide symptomatic relief. Soothing baths, compresses, and lubrication with emollients are used to treat the extensive dermatitis. The patient is likely to be extremely irritable because of the severe pruritus. Oral or parenteral corticosteroids may be prescribed

when the disease is not controlled by more conservative therapy. When a specific cause is known, more specific therapy may be used. The patient is advised to avoid all irritants in the future, particularly medications that are known to cause the disease.

BLISTERING DISEASES

Blisters of the skin have many origins, including bacterial, fungal, or viral infections; allergic contact reactions; burns; metabolic disorders; and immunologically mediated reactions. Some of these have been discussed previously (eg, herpes simplex and zoster infections, contact dermatitis). Immunologically mediated diseases are autoimmune reactions and represent a defect of IgM, IgE, IgG, and complement, C3. Some of these conditions are life-threatening; others become chronic.

The diagnosis is always made by histologic examination of a biopsy specimen, usually by a dermatopathologist. A specimen from the blister and surrounding skin demonstrates **acantholysis** (separation of epidermal cells from each other because of damage to or an abnormality of the intracellular substance). Circulating antibodies may be detected by immunofluorescent studies of the patient's serum.

Pemphigus

Pemphigus is a group of serious diseases of the skin characterized by the appearance of bullae (blisters) of various sizes on apparently normal skin (Fig. 56-4) and mucous membranes. Pemphigus is an autoimmune disease involving IgG. It is thought that the pemphigus antibody is directed against a specific cell-surface antigen in epidermal cells. A blister forms from the antigen-antibody reaction. The level of serum antibody is predictive of disease severity. Genetic factors may also have a role in its development, with the highest incidence in people of Jewish or Mediterranean descent. This disorder usually occurs in men and women in middle and late adulthood. The condition may be associated with penicillins and captopril (Capoten) and with myasthenia gravis.

Figure 56-4 Vesicles on the chin (in pemphigus). From Hall, J. C. (2006). *Sauer's manual of skin diseases*. Philadelphia: Lippincott Williams & Wilkins.

Clinical Manifestations

Most patients present with oral lesions appearing as irregularly shaped erosions that are painful, bleed easily, and heal slowly. The skin bullae enlarge, rupture, and leave large, painful eroded areas that are accompanied by crusting and oozing. A characteristic odor emanates from the bullae and the exuding serum. There is blistering or sloughing of uninvolved skin when minimal pressure is applied (Nikolsky's sign). The eroded skin heals slowly, and large areas of the body eventually are involved. Bacterial superinfection is common.

Complications

The most common complications arise when the disease process is widespread. Before the advent of corticosteroid and immunosuppressive therapy, patients were very susceptible to secondary bacterial infection. Skin bacteria have relatively easy access to the bullae as they ooze, rupture, and leave denuded areas exposed to the environment. Fluid and electrolyte imbalance results from fluid and protein loss as the bullae rupture. Hypoalbuminemia is common when the disease process includes extensive areas of the body skin surface and mucous membranes.

Management

The goals of therapy are to bring the disease under control as rapidly as possible, to prevent loss of serum and the development of secondary infection, and to promote re-epithelization (ie, renewal of epithelial tissue).

Corticosteroids are administered in high doses to control the disease and keep the skin free of blisters. The high dosage level is maintained until remission is apparent. In some cases, corticosteroid therapy must be maintained for life. High-dose corticosteroid therapy has serious toxic effects (see Chapter 42).

Immunosuppressive agents (eg, azathioprine [Azasan], cyclophosphamide [Cytosan], gold [Aurasol]) may be prescribed to help control the disease and reduce the corticosteroid dose. **Plasmapheresis** temporarily decreases the serum antibody level and has been used with variable success, although it is generally reserved for life-threatening cases.

Bullous Pemphigoid

Bullous pemphigoid is an acquired disease of flaccid blisters appearing on normal or erythematous skin. It appears more often on the flexor surfaces of the arms, legs, axilla, and groin. Oral lesions, if present, are usually transient and minimal. When the blisters break, the skin has shallow erosions that heal fairly quickly. Pruritus can be intense, even before the appearance of the blisters. Bullous pemphigoid is common in the elderly, with a peak incidence at about 60 years of age. There is no gender or racial predilection, and the disease can be found throughout the world.

Management

Medical treatment includes topical corticosteroids for localized eruptions and systemic corticosteroids for widespread involvement. Systemic corticosteroids (eg, prednisone [Delta-

son]) may be continued for months, in alternate-day doses. The patient needs to understand the implications of long-term corticosteroid therapy (see Chapter 42).

Dermatitis Herpetiformis

Dermatitis herpetiformis is an intensely pruritic, chronic disease that manifests with small, tense blisters that are distributed symmetrically over the elbows, knees, buttocks, and nape of the neck. It most commonly occurs between 20 and 40 years of age but can appear at any age. Most patients with dermatitis herpetiformis have a subclinical defect in gluten metabolism.

Management

Most patients respond to Dapsone and to a gluten-free diet. All patients should be screened for glucose-6-phosphate dehydrogenase (G6PD) deficiency because dapsone can induce severe hemolysis in those with this deficiency. Patients benefit from dietary counseling because the dietary restrictions are lifelong, and a gluten-free diet is often difficult to follow. They need emotional support as they deal with the process of learning new habits and accepting major changes in their lives.

NURSING PROCESS

CARE OF THE PATIENT WITH BLISTERING DISEASES

Assessment

Patients with blistering disorders may experience significant disability. There is constant itching and possible pain in the denuded areas of skin. There may be drainage from the denuded areas, which may be malodorous. Effective assessment and nursing management become a challenge.

Disease activity is monitored clinically by examining the skin for the appearance of new blisters. Areas where healing has occurred may show signs of hyperpigmentation. Particular attention is given to assessing for signs and symptoms of infection.

Diagnosis

Nursing Diagnoses

Based on nursing assessment data, the patient's major nursing diagnoses may include the following:

- Acute pain of skin and oral cavity related to blistering and erosions
- Impaired skin integrity related to ruptured bullae and denuded areas of the skin
- Anxiety and ineffective coping related to the appearance of the skin and no hope of a cure
- Deficient knowledge about medications and side effects

Collaborative Problems/Potential Complications

Based on the assessment data, potential complications include the following:

- Infection and sepsis related to loss of protective barrier of skin and mucous membranes
- Fluid volume deficit and electrolyte imbalance related to loss of tissue fluids

Planning and Goals

The major goals for the patient may include relief of discomfort from lesions, skin healing, reduced anxiety and improved coping capacity, and absence of complications.

Nursing Interventions

Relieving Oral Discomfort

The patient's entire oral cavity may be affected with erosions and denuded surfaces. Necrotic tissue may develop over these areas, adding to the patient's discomfort and interfering with eating. Weight loss and hypoproteinemia may result. Meticulous oral hygiene is important to keep the oral mucosa clean and allow the epithelium to regenerate. Frequent rinsing of the mouth with a solution of salt and baking soda is prescribed to rid the mouth of debris and to soothe ulcerated areas. Commercial mouthwashes are avoided. The lips are kept moist with lanolin, petrolatum, or lip balm. Cool mist therapy helps humidify environmental air.

Enhancing Skin Integrity and Relieving Discomfort

Cool, wet dressings or baths are protective and soothing. The patient with painful and extensive lesions should be premedicated with analgesics before skin care is initiated. Patients with large areas of blistering have a characteristic odor that decreases when secondary infection is controlled. After the patient's skin is bathed, it is dried carefully and dusted liberally with nonirritating powder (eg, cornstarch), which enables the patient to move about freely in bed. Fairly large amounts are necessary to keep the patient's skin from adhering to the sheets. Tape should never be used because it may produce more blisters. Hypothermia is common, and measures to keep the patient warm and comfortable are priority nursing activities. The nursing management of patients with bullous skin conditions is similar to that for patients with extensive burns (see Chapter 57).

Reducing Anxiety

Attention to the psychological needs of the patient requires listening to the patient, being available, providing expert nursing care, and educating the patient and the family. The patient is encouraged to express anxieties, discomfort, and feelings of hopelessness. Arranging for a family member or a close friend to spend more time with the patient can be supportive. When patients receive information about the disease and its treatment, uncertainty and anxiety often decrease, and the patient's capacity to act on his or her own behalf is enhanced. Psychological counseling may assist the patient in dealing with fears, anxiety, and depression.

Monitoring and Managing Potential Complications

INFECTION AND SEPSIS. The patient is susceptible to infection because the barrier function of the skin is compromised. Bullae are also susceptible to infection, and sepsis

may follow. The skin is cleaned to remove debris and dead skin and to prevent infection.

Secondary infection may be accompanied by an unpleasant odor from skin or oral lesions. *C. albicans* of the mouth (ie, thrush) commonly affects patients receiving high-dose corticosteroid therapy. The oral cavity is inspected daily, and any changes are reported. Oral lesions are slow to heal.

Infection is the leading cause of death in patients with blistering diseases. Particular attention is given to assessment for signs and symptoms of local and systemic infection. Seemingly trivial complaints or minimal changes are investigated because corticosteroids can mask or alter typical signs and symptoms of infection. The patient's vital signs are monitored, and temperature fluctuations are documented. The patient is observed for chills, and all secretions and excretions are monitored for changes suggesting infection. Results of culture and sensitivity tests are monitored. Antimicrobial agents are administered as prescribed, and response to treatment is assessed. Health care personnel must perform effective hand hygiene and wear gloves.

In hospitalized patients, environmental contamination is reduced as much as possible. Protective isolation measures and standard precautions are warranted.

FLUID AND ELECTROLYTE IMBALANCE. Extensive denudation of the skin leads to fluid and electrolyte imbalance because of significant loss of fluids and sodium chloride from the skin. This sodium chloride loss is responsible for many of the systemic symptoms associated with the disease and is treated by IV administration of saline solution.

A large amount of protein and blood is also lost from the denuded skin areas. Blood component therapy may be prescribed to maintain the blood volume, hemoglobin level, and plasma protein concentration. Serum albumin, protein, hemoglobin, and hematocrit values are monitored.

The patient is encouraged to maintain adequate oral fluid intake. Cool, nonirritating fluids are encouraged to maintain hydration. Small, frequent meals or snacks of high-protein, high-calorie foods (eg, oral nutritional supplements, eggnog, milk shakes) help maintain nutritional status. Parenteral nutrition is considered if the patient cannot eat an adequate diet.

Evaluation

Expected Patient Outcomes

Expected patient outcomes may include the following:

1. Reports relief from pain of oral lesions
 - a. Identifies therapies that reduce pain
 - b. Uses mouthwashes and anesthetic or antiseptic aerosol mouth spray
 - c. Drinks chilled fluids at 2-hour intervals
2. Achieves skin healing
 - a. States purpose of therapeutic regimen
 - b. Cooperates with soaks and bath regimen
 - c. Reminds caregivers to use liberal amounts of nonirritating powder on bed linens
3. Reports that anxiety and ability to cope with the condition have improved
 - a. Verbalizes concerns about condition, self, and relationships with others

- b. Participates in self-care
- 4. Experiences no complications
 - a. Has cultures from bullae, skin, and orifices that are negative for pathogenic organisms
 - b. Has no purulent drainage
 - c. Shows signs that skin is clearing
 - d. Has normal body temperature
 - e. Keeps intake record to ensure adequate fluid intake and normal fluid and electrolyte balance
 - f. Verbalizes the rationale for IV infusion therapy
 - g. Has urine output within normal limits
 - h. Has serum chemistry and hemoglobin and hematocrit values within normal limits

Toxic Epidermal Necrolysis and Stevens-Johnson Syndrome

Toxic epidermal necrolysis (TEN) and Stevens-Johnson syndrome (SJS) are potentially fatal skin disorders and the most severe forms of erythema multiforme. These diseases are mucocutaneous reactions that constitute a spectrum of reactions, with TEN being the most severe. The mortality rate from TEN is 30% to 35%. TEN and SJS are triggered by a reaction to medications. Antibiotics, especially sulfonamides, antiseizure agents, nonsteroidal anti-inflammatory drugs (NSAIDs), and sulfonamides are the most frequent medications implicated (Porth & Maffin, 2009).

TEN and SJS occur in all ages and both genders. The incidence is increased in older people because of their use of many medications. People who are immunosuppressed, including those with HIV infection and acquired immunodeficiency syndrome (AIDS), have a high risk of TEN and SJS. Although the incidence of these diseases in the general population is about two to three cases per 1 million people in the United States, the risk associated with sulfonamides in HIV-positive people may approach 1 case per 1000 (Porth & Maffin, 2009). Most patients with TEN have an abnormal metabolism of the medication; the mechanism leading to TEN seems to be a cell-mediated cytotoxic reaction.

Clinical Manifestations

TEN and SJS are characterized initially by conjunctival burning or itching, cutaneous tenderness, fever, cough, sore throat, headache, extreme malaise, and myalgias (ie, aches and pains). These signs are followed by a rapid onset of erythema involving much of the skin surface and mucous membranes, including the oral mucosa, conjunctiva, and genitalia. In severe cases of mucosal involvement, there may be danger of damage to the larynx, bronchi, and esophagus from ulcerations. Large, flaccid bullae develop in some areas; in other areas, large sheets of epidermis are shed, exposing the underlying dermis. Fingernails, toenails, eyebrows, and eyelashes may be shed along with the surrounding epidermis. The skin is excruciatingly tender, and the loss of skin leaves a weeping surface similar to that of a total-body, partial-thickness burn; hence, the condition is also referred to as “scalded skin syndrome.”

Complications

Sepsis and keratoconjunctivitis are complications of TEN and SJS. Unrecognized and untreated sepsis can be life-threatening. Keratoconjunctivitis can impair vision and result in conjunctival retraction, scarring, and corneal lesions.

Assessment and Diagnostic Findings

Histologic studies of frozen skin cells from a fresh lesion and cytodiagnosis of collections of cellular material from a freshly denuded area are conducted. A history of use of medications known to precipitate TEN or SJS may confirm medication reaction as the underlying cause.

Immunofluorescent studies may be performed to detect atypical epidermal autoantibodies. A genetic predisposition to erythema multiforme has been suggested but has not been confirmed in all cases.

Medical Management

The goals of treatment include control of fluid and electrolyte balance, prevention of sepsis, and prevention of ophthalmic complications. Supportive care is the mainstay of treatment.

All nonessential medications are discontinued immediately. If possible, the patient is treated in a regional burn center because aggressive treatment similar to that for severe burns is required. Skin loss may approach 100% of the total body surface area. Surgical débridement or hydrotherapy in a Hubbard tank (large steel tub) may be performed to remove involved skin.

Tissue samples from the nasopharynx, eyes, ears, blood, urine, skin, and unruptured blisters are obtained for culture to identify pathogenic organisms. IV fluids are prescribed to maintain fluid and electrolyte balance, especially in the patient who has severe mucosal involvement and who cannot easily take oral nourishment. Because an indwelling IV catheter may be a site of infection, fluid replacement is carried out by nasogastric tube and then orally as soon as possible.

Initial treatment with systemic corticosteroids is controversial. Some experts argue for early high-dose corticosteroid treatment. However, in most cases, the risk of infection, fluid and electrolyte imbalance, delayed healing, and difficulty in initiating oral corticosteroids early in the course of the disease outweigh its benefits. In patients with TEN thought to be due to a medication reaction, corticosteroids may be administered; however, the patient should be closely monitored for adverse effects.

Administration of IV immunoglobulin (IVIG) may provide rapid improvement and skin healing. This response is dramatically better than that obtained with immunosuppressives, and IVIG may become the treatment of choice (Mittmann, Chan, Knowles, et al., 2007).

Protecting the skin with topical agents is crucial. Various topical antibacterial and anesthetic agents are used to prevent wound sepsis and to assist with pain management. Systemic antibiotic therapy is used with extreme caution. Temporary biologic dressings (eg, pigskin, amniotic membrane) or plastic semipermeable dressings (eg, Vigilon) may be used to reduce pain, decrease evaporation, and

prevent secondary infection until the epithelium regenerates. Meticulous oropharyngeal and eye care is essential when there is involvement of the mucous membranes and the eyes.

NURSING PROCESS

CARE OF THE PATIENT WITH TOXIC EPIDERMAL NECROLYSIS OR STEVENS-JOHNSON SYNDROME

Assessment

A careful inspection of the skin is made, including its appearance and the extent of involvement. The normal skin is closely observed to determine if new areas of blisters are developing. Drainage from blisters is monitored for amount, color, and odor. The oral cavity is inspected daily for blistering and erosive lesions; the patient is assessed daily for itching, burning, and dryness of the eyes. The patient's ability to swallow and drink fluids, as well as speak normally, is determined.

The patient's vital signs are monitored, and special attention is given to the presence and character of fever and the respiratory rate, depth, rhythm, and cough. The characteristics and amount of respiratory secretions are observed. Assessment for high fever, tachycardia, and extreme weakness and fatigue is essential because these factors indicate the process of epidermal necrosis, increased metabolic needs, and possible gastrointestinal and respiratory mucosal sloughing. Urine volume, specific gravity, and color are monitored. The insertion sites of IV lines are inspected for signs of local infection. Body weight is recorded daily.

The patient is asked to describe fatigue and pain levels. An attempt is made to evaluate the patient's level of anxiety. The patient's basic coping mechanisms are assessed, and effective coping strategies are identified.

Diagnosis

Nursing Diagnoses

Based on the assessment data, the patient's major nursing diagnoses may include the following:

- Impaired tissue integrity (ie, oral, eye, and skin) related to epidermal shedding
- Deficient fluid volume and electrolyte losses related to loss of fluids from denuded skin
- Risk for imbalanced body temperature (ie, hypothermia) related to heat loss secondary to skin loss
- Acute pain related to denuded skin, oral lesions, and possible infection
- Anxiety related to the physical appearance of the skin and prognosis

Collaborative Problems/Potential Complications

Based on the assessment data, potential complications include the following:

- Sepsis
- Conjunctival retraction, scars, and corneal lesions

Planning and Goals

The major goals for the patient may include skin and oral tissue healing, fluid balance, prevention of heat loss, relief of pain, reduced anxiety, and absence of complications.

Nursing Interventions

Maintaining Skin and Mucous Membrane Integrity

The local care of the skin is an important area of nursing management. The skin denudes easily, especially when the patient is lifted and turned. The nursing staff must take special care to avoid friction involving the skin when moving the patient in bed. The skin should be checked after each position change to ensure that no new denuded areas have appeared. The nurse applies the prescribed topical agents to reduce the bacterial population of the wound surface. Warm compresses, if prescribed, should be applied gently to denuded areas. The topical antibacterial agent may be used in conjunction with hydrotherapy in a tank, bathtub, or shower. The nurse monitors the patient's condition during the treatment and encourages the patient to exercise the extremities during hydrotherapy.

The painful oral lesions make oral hygiene difficult. Careful oral hygiene is performed to keep the oral mucosa clean. Prescribed mouthwashes, anesthetics, or coating agents are used frequently to rid the mouth of debris, soothe ulcerative areas, and control foul mouth odor. The oral cavity is inspected several times each day, and any changes are documented and reported. Petrolatum or a prescribed ointment is applied to the lips.

Attaining Fluid Balance

The vital signs, urine output, and sensorium are observed for indications of hypovolemia. Mental changes from fluid and electrolyte imbalance, sensory overload, or sensory deprivation may occur. Laboratory test results are evaluated, and abnormal results are reported. The patient is weighed daily (with a bed scale if necessary).

Oral lesions may result in dysphagia, making tube feeding or parenteral nutrition necessary until oral ingestion can be tolerated. A daily calorie count and accurate recording of all intake and output are essential.

Preventing Hypothermia

The patient with TEN is prone to chilling. Dehydration may be made worse by exposing the denuded skin to a continuous current of warm air. The patient is usually sensitive to changes in room temperature. Measures similar to those implemented for a burn patient, such as cotton blankets, ceiling-mounted heat lamps, and heat shields, are useful in maintaining body temperature. To minimize shivering and heat loss, the nurse should work rapidly and efficiently when large wounds are exposed for wound care. The patient's temperature is monitored frequently.

Relieving Pain

The nurse assesses the patient's pain, its characteristics, factors that influence the pain, and the patient's behavioral responses. Prescribed analgesics are administered on a regular schedule, and the nurse documents pain relief and any side effects. Analgesics are administered before painful

treatments are performed. Providing thorough explanations and speaking calmly to the patient during treatments can allay the anxiety that may intensify pain. Offering emotional support and reassurance and implementing measures that promote rest and sleep are basic in achieving pain control. As the pain diminishes and the patient has more physical and emotional energy, self-management techniques for pain relief, such as progressive muscle relaxation and imagery, may be taught.

Reducing Anxiety

Because the lifestyle of the patient with TEN has been abruptly changed to one of complete dependence, an assessment of his or her emotional state may reveal anxiety, depression, and fear of dying. The patient can be reassured that these reactions are normal. The patient also needs nursing support, honest communication, and hope that the situation can improve. The patient is encouraged to express his or her feelings. Listening to the patient's concerns and being readily available with skillful and compassionate care are important anxiety-relieving interventions. Emotional support by a psychiatric nurse, spiritual advisor, psychologist, or psychiatrist may be helpful to promote coping during the long recovery period.

Monitoring and Managing Potential Complications

SEPSIS. The major cause of death from TEN is infection, and the most common sites of infection are the skin and mucosal surfaces, lungs, and blood. The organisms most often involved are *S. aureus*, *Pseudomonas*, *Klebsiella*, *Escherichia coli*, *Serratia*, and *Candida*. Monitoring vital signs closely and noticing changes in respiratory, renal, and gastrointestinal function may quickly detect the beginning of an infection. Strict asepsis is always maintained during routine skin care measures. Hand hygiene and wearing sterile gloves when carrying out procedures are essential. When the condition involves a large portion of the body, the patient should be in a private room to prevent possible cross-infection from other patients. Visitors should wear protective garments and wash their hands before and after coming into contact with the patient. People with any infections or infectious disease should not visit the patient until they are no longer a danger to the patient. The nurse is critical in identifying early signs and symptoms of infection and notifying the physician. Antibiotics are not generally begun until there is indication for their use.

CONJUNCTIVAL RETRACTION, SCARS, AND CORNEAL LESIONS. The eyes are inspected daily for signs of pruritus, burning, and dryness, which may indicate progression to keratoconjunctivitis, the principal eye complication. Applying a cool, damp cloth over the eyes may relieve burning sensations. The eyes are kept clean and observed for signs of discharge or discomfort, and the progression of symptoms is documented and reported. Administering an eye lubricant, when prescribed, may alleviate dryness and prevent corneal abrasion. Using eye patches or reminding the patient to blink periodically may also counteract dryness. The patient is instructed to avoid rubbing the eyes or putting any medication into the eyes that has not been prescribed or approved by the physician.

Promoting Home and Community-Based Care

TEACHING PATIENTS SELF-CARE. Patients with TEN or SJS with involvement of large areas of the skin require care that is similar to that of patients with thermal burns. As the patient completes the acute inpatient stage of illness, the focus is directed toward rehabilitation and outpatient care or care in a rehabilitation center. Throughout this care, the patient and family members are involved in the care and are instructed in the procedures, such as wound care and dressing changes, that will need to be continued at home. The patient and family members are assisted in acquiring dressing supplies that will be needed at home.

The patient and family members are also provided with instructions about pain management, nutrition, measures to increase mobility, and prevention of complications, including prevention of infection. They are taught the signs and symptoms of complications and instructed when to notify the health care provider. When appropriate, instructions are provided in writing to the patient and family so they can refer to these instructions when necessary at later times.

CONTINUING CARE. Interdisciplinary follow-up care is imperative to ensure that the patient's progress continues. Some patients will require care in a rehabilitation center before returning home. Others will require outpatient physical and occupational therapy for an extended period. When the patient returns home, the home care nurse coordinates the care provided by the various members of the health care team (eg, physician, physical therapist, occupational therapist, dietician). The nurse also monitors the patient's progress, provides ongoing assessment to identify complications, and monitors the patient's adherence to the plan of care. The patient's adaptation to the home care environment and the patient's and family's needs for support and assistance are also assessed. Referrals to community agencies are made as appropriate.

Evaluation

Expected Patient Outcomes

Expected patient outcomes may include the following:

1. Achieves increasing skin and oral tissue healing
 - a. Demonstrates areas of healing skin
 - b. Swallows fluids and speaks clearly
2. Attains fluid balance
 - a. Demonstrates laboratory values within normal ranges
 - b. Maintains urine volume and specific gravity within acceptable range
 - c. Shows stable vital signs
 - d. Increases intake of oral fluids without discomfort
 - e. Maintains weight or gains weight, if appropriate
3. Attains thermoregulation
 - a. Registers body temperature within normal range
 - b. Reports no chills
4. Achieves pain relief
 - a. Uses analgesics as prescribed
 - b. Uses self-management techniques for relief of pain
5. Appears less anxious
 - a. Discusses concerns freely
 - b. Sleeps for progressively longer periods

6. Absence of complications, such as sepsis and impaired vision
 - a. Has body temperature within normal range
 - b. Laboratory values within normal ranges
 - c. Has no abnormal discharges or signs of infection
 - d. Continues to see objects at baseline acuity level
 - e. Shows no signs of keratoconjunctivitis

ULCERATIONS

Superficial loss of surface tissue as a result of death of cells is called an ulceration. A simple ulcer, such as the kind found in a small, superficial, partial-thickness burn, tends to heal by granulation if kept clean and protected from injury. If exposed to the air, the serum that escapes dries and forms a scab, under which the epithelial cells grow and cover the surface completely. Certain diseases cause characteristic ulcers (eg, tuberculous ulcers, syphilitic ulcers).

Ulcers related to problems with arterial circulation are seen in patients with peripheral vascular disease, arteriosclerosis, Raynaud's disease, and frostbite. In these patients, treatment of the ulcers is concurrent with treatment of the arterial disease (see Chapter 31). Nursing management includes the use of the dressings discussed at the beginning of this chapter. If nursing interventions are instituted early in the progression of an ulcer, the condition can often be effectively improved. Surgical amputation of an affected limb is a last resort.

Pressure ulcers involve breakdown of the skin due to prolonged pressure, friction and shear forces, and insufficient blood supply, usually at bony prominences. Information about these ulcers is presented in Chapter 11.

SKIN TUMORS

Benign Skin Tumors

Cysts

Cysts of the skin are epithelium-lined cavities that contain fluid or solid material. Epidermal cysts (epidermoid cysts) occur frequently and may be described as slow-growing, firm, elevated tumors found most frequently on the face, neck, upper chest, and back. Removal of the cysts provides a cure.

Pilar cysts (trichilemmal cysts), formerly called sebaceous cysts, are most frequently found on the scalp. They originate from the middle portion of the hair follicle and from the cells of the outer hair root sheath. Treatment is surgical removal.

Seborrheic and Actinic Keratoses

Seborrheic keratoses are benign, wartlike lesions of various sizes and colors, ranging from light tan to black. They are usually located on the face, shoulders, chest, and back and are the most common skin tumors seen in middle-age and elderly people. They may be cosmetically unacceptable to the patient. A black keratosis may be erroneously diagnosed as malignant melanoma. Treatment is removal of the tumor

tissue by excision, electrodesiccation (destruction of the skin lesions by monopolar high-frequency electric current) and curettage, or application of carbon dioxide or liquid nitrogen. However, there is no harm in allowing these growths to remain because there is no medical significance to their presence.

Actinic keratoses are premalignant skin lesions that develop in chronically sun-exposed areas of the body. They appear as rough, scaly patches with underlying erythema. A small percentage of these lesions gradually transform into cutaneous squamous cell carcinoma; they are usually removed by cryotherapy or shave excision.

Verrucae: Warts

Warts are common, benign skin tumors caused by infection with the human papillomavirus, which belongs to the DNA virus group. People of all ages may be affected, but the warts occur most frequently between the ages of 12 and 16 years. There are many types of warts.

As a rule, warts are asymptomatic, except when they occur on weight-bearing areas, such as the soles of the feet. They may be treated with locally applied laser therapy, liquid nitrogen, salicylic acid plasters, or electrodesiccation.

Warts occurring on the genitalia and perianal areas are known as condylomata acuminata. They may be transmitted sexually and are treated with liquid nitrogen, cryosurgery, electrosurgery, topically applied trichloroacetic acid, and curettage. Condylomata that affect the uterine cervix predispose the patient to cervical cancer (see Chapter 47).

Angiomas

Angiomas are benign vascular tumors that involve the skin and the subcutaneous tissues. They are present at birth and may occur as flat, violet-red patches (port-wine angiomas) or as raised, bright-red, nodular lesions (strawberry angiomas). The latter tend to involute spontaneously within the first few years of life, but port-wine angiomas usually persist indefinitely. Most patients use masking cosmetics (ie, Covermark or Dermablend) to camouflage the lesions. The argon laser is being used on various angiomas with some success. Treatment of strawberry angiomas is more successful if undertaken as soon after birth as possible.

Pigmented Nevi: Moles

Moles are common skin tumors of various sizes and shades, ranging from yellowish brown to black. They may be flat, macular lesions or elevated papules or nodules that occasionally contain hair. Most pigmented nevi are harmless lesions. However, in rare cases, malignant changes occur, and a melanoma develops at the site of the nevus. Some authorities believe that all congenital moles should be removed because they may have a higher incidence of malignant change. However, depending on the quantity and location, this may be impractical. Nevi that show a change in color or size, become symptomatic (eg, itch), or develop irregular borders should be removed to determine if malignant changes have occurred. Moles that occur in unusual places should be examined carefully for any irregularity and for notching of the border and variation in color. Early melanomas may display some redness and irritation and

areas of bluish pigmentation where the pigment-containing cells have spread deeper into the skin. Late melanomas have areas of paler color, where pigment cells have stopped producing melanin. Nevi larger than 1 cm should be examined carefully. Excised nevi should be examined histologically.

Keloids

Keloids are benign overgrowths of fibrous tissue at the site of a scar or trauma. They appear to be more common among dark-skinned people. Keloids are asymptomatic but may cause disfigurement and cosmetic concern. The treatment, which is not always satisfactory, consists of surgical excision, intralesional corticosteroid therapy, and radiation.

Dermatofibroma

A dermatofibroma is a common, benign tumor of connective tissue that occurs predominantly on the extremities. It is a firm, dome-shaped papule or nodule that may be skin-colored or pinkish brown. Excisional biopsy is the recommended method of treatment.

Neurofibromatosis: Von Recklinghausen's Disease

Neurofibromatosis is a hereditary condition manifested by pigmented patches (*café-au-lait* macules), axillary freckling, and cutaneous neurofibromas that vary in size. Developmental changes may occur in the nervous system, muscles, and bone. Malignant degeneration of the neurofibromas occurs in some patients.

Malignant Skin Tumors

Skin cancer is the most common cancer in the United States. If the incidence continues at the present rate, an estimated one of eight fair-skinned Americans will eventually develop skin cancer, especially basal cell carcinoma (Chart 56-5). Because the skin is easily inspected, skin cancer is readily seen and detected and is the most successfully treated type of cancer (Neville, Welch & Leffell, 2007).

Exposure to the sun is the leading cause of skin cancer; incidence is related to the total amount of exposure to the sun. Sun damage is cumulative, and harmful effects may be severe by 20 years of age. The increase in skin cancer probably reflects changing lifestyles and the emphasis on sunbathing and related activities in light of changes in the environment, such as holes in the earth's ozone layer. Protective measures should be used throughout life, and nurses should inform patients about risk factors associated with skin cancer.

BASAL CELL AND SQUAMOUS CELL CARCINOMA

The most common types of skin cancer are basal cell carcinoma (BCC) and squamous cell (epidermoid) carcinoma (SCC). The third most common type, malignant melanoma, is discussed separately. Skin cancer is diagnosed by biopsy and histologic evaluation.

CHART
56-5

Risk Factors for Skin Cancer

Changes in the ozone layer from the effects of worldwide industrial air pollutants, such as chlorofluorocarbons, have prompted concern that the incidence of skin cancers, especially malignant melanoma, will increase. The ozone layer, a stratospheric blanket of bluish, explosive gas formed by the sun's ultraviolet radiation, varies in depth with the seasons and is thickest at the North and South Poles and thinnest at the equator. Scientists believe that it helps protect the earth from the effects of solar ultraviolet radiation. Proponents of this theory predict an increase in skin cancers as a consequence of changes in the ozone layer. Other skin cancer risk factors follow:

- Fair-skinned, fair-haired, blue-eyed people, particularly those of Celtic origin, with insufficient skin pigmentation to protect underlying tissues
- People who sustain sunburn and who do not tan
- Chronic sun exposure (certain occupations, such as farming, construction work)
- Exposure to chemical pollutants (industrial workers in arsenic, nitrates, coal, tar and pitch, oils and paraffins)
- Sun-damaged skin (elderly people)
- History of x-ray therapy for acne or benign lesions
- Scars from severe burns
- Chronic skin irritations
- Immunosuppression
- Genetic factors

Clinical Manifestations

BCC is the most common type of skin cancer. It generally appears on sun-exposed areas of the body and is more prevalent in regions where the population is subjected to intense and extensive exposure to the sun. The incidence is proportional to the age of the patient (average: 60 years) and the total amount of sun exposure, and it is inversely proportional to the amount of melanin in the skin.

BCC usually begins as a small, waxy nodule with rolled, translucent, pearly borders; telangiectatic vessels may be present. As it grows, it undergoes central ulceration and sometimes crusting (Fig. 56-5). The tumors appear most

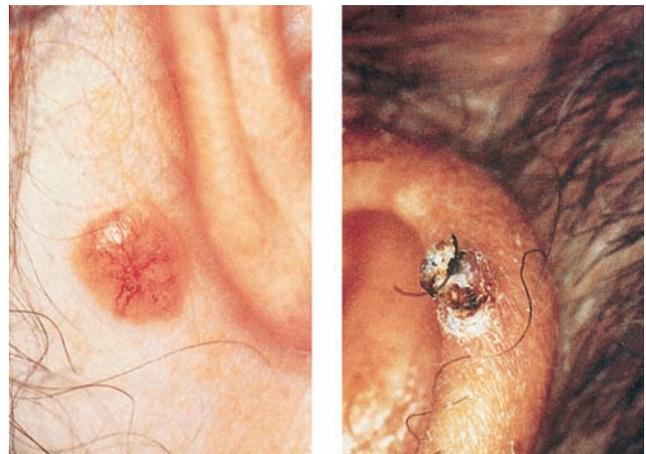

Figure 56-5 Basal cell carcinoma (*left*) and squamous cell carcinoma (*right*). Reprinted by permission from *New England Journal of Medicine*, 326, 169–170, 1992.

frequently on the face. BCC is characterized by invasion and erosion of contiguous (adjoining) tissues. It rarely metastasizes, but recurrence is common. However, a neglected lesion can result in the loss of a nose, an ear, or a lip. Other variants of BCC may appear as shiny, flat, gray or yellowish plaques.

SCC is a malignant proliferation arising from the epidermis. Although it usually appears on sun-damaged skin, it may arise from normal skin or from preexisting skin lesions. It is of greater concern than BCC because it is a truly invasive carcinoma, metastasizing by the blood or lymphatic system.

Metastases account for 75% of deaths from SCC. The lesions may be primary, arising on the skin and mucous membranes, or they may develop from a precancerous condition, such as actinic keratosis (lesions occurring in sun-exposed areas), leukoplakia (pre-malignant lesion of the mucous membrane), or scarred or ulcerated lesions. SCC appears as a rough, thickened, scaly tumor that may be asymptomatic or may involve bleeding (see Fig. 56-5). The border of an SCC lesion may be wider, more infiltrated, and more inflammatory than that of a BCC lesion. Secondary infection can occur. Exposed areas, especially of the upper extremities and of the face, lower lip, ears, nose, and forehead, are common sites.

The incidence of BCC and SCC is increased in all immunocompromised people, including those infected with HIV. Clinically, the tumors have the same appearance as in non-HIV-infected people; however, in HIV-positive people, the tumors may grow more rapidly and recur more frequently. These tumors are managed the same as those for the general population. Frequent follow-up (every 4 to 6 months) is recommended to monitor for recurrence.

Prognosis

The prognosis for BCC is usually good because tumors remain localized. Although some require wide excision with resultant disfigurement, the risk of death from BCC is low. The prognosis for SCC depends on the incidence of metastases, which is related to the histologic type and the level or depth of invasion. Usually, SCC arising in sun-damaged areas is less invasive and rarely causes death, whereas SCC that arises without a history of sun or arsenic exposure or scar formation appears to have a greater chance of spread. Regional lymph nodes should be evaluated for metastases.

Medical Management

The goal of treatment is to eradicate the tumor. The treatment method depends on the tumor location; the cell type, location, and depth; the cosmetic desires of the patient; the history of previous treatment; whether the tumor is invasive; and whether metastatic nodes are present. The management of BCC and SCC includes surgical excision, Mohs' micrographic surgery, electrosurgery, cryosurgery, and radiation therapy.

Surgical Management

The primary goal is to remove the tumor entirely. The best way to maintain cosmetic appearance is to place the incision properly along natural skin tension lines and natural anatomic body lines. In this way, scars are less noticeable.

The size of the incision depends on the tumor size and location but usually involves a length-to-width ratio of 3:1.

The adequacy of the surgical excision is verified by microscopic evaluation of sections of the specimen. When the tumor is large, reconstructive surgery with use of a skin flap or skin grafting may be required. The incision is closed in layers to enhance cosmetic effect. A pressure dressing applied over the wound provides support. Infection after a simple excision is uncommon if proper surgical asepsis is maintained.

Mohs' Micrographic Surgery

This technique is the most accurate surgical technique and best conserves normal tissue. The procedure removes the tumor layer by layer. The first layer excised includes all evident tumor and a small margin of normal-appearing tissue. The specimen is frozen and analyzed by section to determine if all the tumor has been removed. If not, additional layers of tissue are shaved and examined until all tissue margins are tumor free. In this manner, only the tumor and a safe, normal-tissue margin are removed. Mohs' surgery is the recommended tissue-sparing procedure, with extremely high cure rates for BCC and SCC. It is the treatment of choice and the most effective for tumors around the eyes, nose, upper lip, and auricular and periauricular areas (Bowen, White & Gerwels, 2005).

Electrosurgery

Electrosurgery is the destruction or removal of tissue by electrical energy. The current is converted to heat, which then passes to the tissue from a cold electrode. Electrosurgery may be preceded by curettage (excising the skin tumor by scraping its surface with a curette). Electrodesiccation is then implemented to achieve hemostasis and to destroy any viable malignant cells at the base of the wound or along its edges. Electrodesiccation is useful for lesions smaller than 1 to 2 cm (0.4 to 0.8 in) in diameter.

This method takes advantage of the fact that the tumor is softer than surrounding skin and therefore can be outlined by a curette, which "feels" the extent of the tumor. The tumor is removed and the base cauterized. The process is repeated twice. Usually, healing occurs within 1 month.

Cryosurgery

Cryosurgery destroys the tumor by deep freezing the tissue. A thermocouple needle apparatus is inserted into the skin, and liquid nitrogen is directed to the center of the tumor until the tumor base is -40°C to -60°C (-40°F to -76°F). Liquid nitrogen has the lowest boiling point of all cryogens, is inexpensive, and is easy to obtain. The tumor tissue is frozen, allowed to thaw, and then refrozen. The site thaws naturally and then becomes gelatinous and heals spontaneously. Swelling and edema follow the freezing. The appearance of the lesion varies. Normal healing, which may take 4 to 6 weeks, occurs faster in areas with a good blood supply.

Radiation Therapy

Radiation therapy is frequently performed for cancer of the eyelid, the tip of the nose, and areas in or near vital structures (eg, facial nerve). It is reserved for older patients, because x-ray changes may be seen after 5 to 10 years, and

malignant changes in scars may be induced by irradiation 15 to 30 years later.

The patient should be informed that the skin may become red and blistered. A bland skin ointment prescribed by the physician may be applied to relieve discomfort. The patient should also be cautioned to avoid exposure to the sun.

Nursing Management

Because many skin cancers are removed by excision, patients are usually treated in outpatient surgical units. The role of the nurse is to teach the patient about prevention of skin cancer and about self-care after treatment (Chart 56-6).

Promoting Home and Community-Based Care

Teaching Patients Self-Care

The wound is usually covered with a dressing to protect the site from physical trauma, external irritants, and contaminants. The patient is advised when to report for a dressing change or is given written and verbal information on how to change dressings, including the type of dressing to purchase, how to remove dressings and apply fresh ones, and the importance of hand hygiene before and after the procedure.

The patient is advised to watch for excessive bleeding and tight dressings that compromise circulation. If the lesion is in the perioral area, the patient is instructed to drink liquids through a straw and limit talking and facial movement. Dental work should be avoided until the area is completely healed.

After the sutures are removed, an emollient cream may be used to help reduce dryness. Applying a sunscreen over the wound is advised to prevent postoperative hyperpigmentation if the patient spends time outdoors.

Follow-up examinations should be at regular intervals, usually every 3 months for a year, and should include palpation of the adjacent lymph nodes. The patient should also

be instructed to seek treatment for any moles that are subject to repeated friction and irritation and to watch for indications of potential malignancy in moles as described previously. The importance of lifelong follow-up evaluations is emphasized.

Teaching About Prevention

Studies show that regular daily use of a sunscreen with a sun protection factor (SPF) of at least 15 can reduce the recurrence of skin cancer by as much as 40%. The sunscreen should be applied to head, neck, arms, and hands every morning at least 30 minutes before leaving the house and reapplied every 4 hours if the skin perspires. Intermittent application of sunscreen only when exposure is anticipated has been shown to be less effective than daily use. Research has shown that daily use of sunscreen on the hands and face reduces the total incidence of solar keratoses (Barclay, 2007), which are precursors of SCC, but has no effect on the overall incidence of BCC. These data are inconsistent, but one theory is that people have a false sense of security when wearing sunscreen and tend to stay out in the sun for longer periods. This longer exposure is believed to contribute to the increasing incidence of melanoma. Although the evidence is insufficient, nurses should discuss the issues with patients who are at high risk of skin cancer.

MALIGNANT MELANOMA

A malignant melanoma is a cancerous neoplasm in which atypical melanocytes are present in the epidermis and the dermis (and sometimes the subcutaneous cells). It is the most lethal of all the skin cancers and is responsible for about 3% of all cancer deaths (Porth & Maffin, 2009).

Malignant melanoma can occur in one of several forms: superficial spreading melanoma, lentigo-maligna melanoma, nodular melanoma, and acral-lentiginous melanoma. These types have specific clinical and histologic features as well as different biologic behaviors. Most melanomas arise from

CHART
56-6

HEALTH PROMOTION Preventing Skin Cancer

- Teach patients that sunscreens are rated in strength from 4 (weakest) to 50 (strongest). The solar protection factor, or SPF, indicates how much longer a person can stay in the sun before the skin begins to redden. For example, if the person can normally stay in the sun for 10 minutes before reddening begins, an SPF of 4 will protect the person from reddening for about 40 minutes.
- Remind patients that up to 50% of ultraviolet rays can penetrate loosely woven clothing.
- Remind patients that ultraviolet light can penetrate cloud cover, and a sunburn can still occur.
- Teach children to avoid all but modest sun exposure and to use a sunscreen regularly for lifelong protection.
- Advise patients to:
 - Avoid tanning if their skin burns easily, never tans, or tans poorly.
 - Avoid unnecessary exposure to the sun, especially during the time of day when ultraviolet radiation (sunlight) is most intense (10 AM to 3 PM).
- Avoid sunburns.
- Apply a sunscreen daily to block harmful sun rays.
- Use a sunscreen with an SPF of 15 or higher that protects against both ultraviolet-A (UVA) and ultraviolet-B (UVB) light.
- Reapply water-resistant sunscreens after swimming, if heavily sweating, and every 2 to 3 hours during prolonged periods of sun exposure.
- Avoid applying oils before or during sun exposure (oils do not protect against sunlight or sun damage).
- Use a lip balm that contains a sunscreen with an SPF of 15 or higher.
- Wear protective clothing, such as a broad-brimmed hat and long sleeves.
- Avoid using sun lamps for indoor tanning, and avoid commercial tanning booths.

cutaneous epidermal melanocytes, but some appear in pre-existing nevi (ie, moles) in the skin or develop in the uveal tract of the eye. Melanomas occasionally appear simultaneously with cancer of other organs.

The worldwide incidence of cutaneous melanoma continues to rise faster than any other malignancy in the Caucasian population. Despite better understanding of prevention and several new treatment options, mortality rates continue to climb. The highest incidence of the disease occurs in men, probably because of increased recreational sun exposure and decreasing ozone levels. In 2007, approximately 108,000 people in the United States were diagnosed with melanoma, and about 8,000 of these will die of the disease. Any short-term decrease in mortality will be related to improved detection and treatment. The impact of primary preventive measures will not be noticeable for several decades (American Melanoma Foundation, 2007).

Risk Factors

The cause of malignant melanoma is unknown, but ultraviolet rays are strongly suspected, based on indirect evidence such as the increased incidence of melanoma in countries near the equator and in people younger than 30 years of age who have used a tanning bed more than 10 times per year. One in 100 Caucasians develops melanoma each year. As many as 10% of patients with melanoma are members of melanoma-prone families who have multiple changing moles (dysplastic nevi) that are susceptible to malignant transformation. Patients with dysplastic nevus syndrome have been found to have unusual moles, larger and more numerous moles, lesions with irregular outlines, and pigmentation located all over the skin. Microscopic examination of dysplastic moles shows disordered, faulty growth (Sekulic, Haluska, Miller, et al., 2008). Chart 56-7 lists risk factors for malignant melanoma.

Research has identified a gene that resides on chromosome 9p, the absence of which increases the likelihood that potentially mutagenic DNA damage will escape repair before cell division. The absence of this gene can be identified in melanoma-prone families (Price, Herlyn, Dent, et al., 2005).

Patients who have the melanoma gene, those who have a larger number of pigmented lesions (more than 100), and those with a strong family history of melanoma can benefit from total body digital photography. This procedure is increasingly being offered at research facilities and

large teaching facilities as a way to document lesion status. It is intended to decrease the number of unnecessary skin biopsies; it targets only lesions that show change over time, usually 3 to 6 months. Although the use of this photographic method has not reduced the number of skin biopsies in the short term, most practitioners who specialize in the treatment of pigmented lesions believe that the diagnostic value of this procedure will be realized in the next several decades. Some patients with high risk of melanoma would also benefit from “mole mapping” to track changes in individual lesions (Risser, Pressley, Veledar, et al., 2007).

Clinical Manifestations

Superficial Spreading Melanoma

Superficial spreading melanoma occurs anywhere on the body and is the most common form of melanoma. It usually affects middle-age people and occurs most frequently on the trunk and lower extremities. The lesion tends to be circular, with irregular outer portions. The margins of the lesion may be flat or elevated and palpable (Fig. 56-6). This type of melanoma may appear in a combination of colors, with hues of tan, brown, and black mixed with gray, blue-black, or white. Sometimes a dull pink rose color can be seen in a small area within the lesion.

Lentigo-Maligna Melanoma

Lentigo-maligna melanoma is a slowly evolving, pigmented lesion that occurs on exposed skin areas, especially the dorsum of the hand, the head, and the neck in elderly people. Often, the lesion is present for many years before it is examined by a physician. It first appears as a tan, flat lesion, but in time it undergoes changes in size and color.

Nodular Melanomas

Nodular melanoma is a spherical, blueberry-like nodule with a relatively smooth surface and a relatively uniform, blue-black color (see Fig. 56-6). It may be dome shaped with a smooth surface. It may have other shadings of red, gray, or purple. Sometimes, nodular melanomas appear as irregularly shaped plaques. The patient may describe this as a blood blister that fails to resolve. A nodular melanoma directly invades the adjacent dermis (ie, vertical growth) and therefore has a poorer prognosis.

CHART
56-7

Risk Factors for Malignant Melanoma

- Fair-skinned or freckled, blue-eyed, light-haired people of Celtic or Scandinavian origin
- People who burn and do not tan or who have a significant history of severe sunburn
- Environmental exposure to intense sunlight (older Americans retiring to the southwestern United States appear to have a higher incidence)
- History of melanoma (personal or family)
- Skin with giant congenital nevi

Figure 56-6 Two forms of malignant melanoma: superficial spreading (left) and nodular (right). From Bickley, L. S. (2009). *Bates' guide to physical examination* (10th ed.). Philadelphia: Lippincott Williams & Wilkins.

Acral-Lentiginous Melanoma

Acral-lentiginous melanoma occurs in areas not excessively exposed to sunlight and where hair follicles are absent. It is found on the palms of the hands, on the soles, in the nail beds, and in the mucous membranes in dark-skinned people. These melanomas appear as irregular, pigmented macules that develop nodules. They may become invasive early.

Assessment and Diagnostic Findings

Biopsy results confirm the diagnosis of melanoma. An excisional biopsy specimen provides information on the type, level of invasion, and thickness of the lesion. An excisional biopsy specimen that includes a 1-cm margin of normal tissue and a portion of underlying subcutaneous fatty tissue is sufficient for staging a melanoma in situ or an early, noninvasive melanoma. Incisional biopsy should be performed when the suspicious lesion is too large to be removed safely without extensive scarring. Biopsy specimens obtained by shaving, curettage, or needle aspiration are not considered reliable histologic proof of disease.

A thorough history and physical examination should include a meticulous skin examination and palpation of regional lymph nodes that drain the lesion area. Because melanoma occurs in families, a positive family history of melanoma is investigated so that first-degree relatives, who may be at high risk for melanoma, can be evaluated for atypical lesions. After the diagnosis of melanoma has been confirmed, a chest x-ray, complete blood cell count, liver function tests, and radionuclide or computed tomography scans are usually performed to stage the extent of disease.

Prognosis

The prognosis for long-term (5-year) survival is considered poor when the lesion is more than 1.5 mm thick or there is regional lymph node involvement. A person with a thin lesion and no lymph node involvement has a 3% chance of developing metastases and a 95% chance of surviving 5 years. If regional lymph nodes are involved, there is a 20% to 50% chance of surviving 5 years. Patients with melanoma on the hand, foot, or scalp have a better prognosis; those with lesions on the torso have an increased chance of metastases to the bone, liver, lungs, spleen, and central nervous system. Men and elderly patients also have poor prognoses (Jade, Kashani-Sabet, Messina, et al., 2005).

Medical Management

Treatment depends on the level of invasion and the depth of the lesion. Surgical excision is the treatment of choice for small, superficial lesions. Deeper lesions require wide local excision, after which skin grafting may be necessary. Regional lymph node dissection is commonly performed to rule out metastasis, although new surgical approaches call for only sentinel node biopsy. This technique is used to sample the nodes nearest the tumor and to spare the patient the long-term sequelae of extensive removal of lymph nodes if the sample nodes are negative.

Despite many years of investigation, no dependable systemic treatment for melanoma has been identified. Recently, greater understanding of the stem cells of melanoma indicates that effective therapies will have to be individualized for each patient. Clinical observations suggest that very few single-agent therapies provide significant clinical benefits because of the complex molecular nature of melanoma and the need to further define individual cell variations (Sekulic, et al., 2008).

Current treatments for metastatic melanoma, rarely, if ever, produce a satisfactory outcome. Further surgical intervention may be performed to debulk the tumor or to remove part of the organ involved (eg, lung, liver, or colon). However, the rationale for more extensive surgery is for relief of symptoms, not for cure. Chemotherapy for metastatic melanoma may be used; however, only a few agents (eg, dacarbazine [DTIC-Dome], nitrosoureas, cisplatin [Platinol]) have been effective in controlling the disease. When the melanoma is located in an extremity, regional perfusion may be used; the chemotherapeutic agent is perfused directly into the area that contains the melanoma. This approach delivers a high concentration of cytotoxic agents while avoiding systemic, toxic side effects. The limb is perfused for 1 hour with high concentrations of the medication at temperatures of 39°C to 40°C (102.2°F to 104°F) with a perfusion pump. Inducing hyperthermia enhances the effect of the chemotherapy so that a smaller total dose can be used. The goal of regional perfusion is control of the metastasis, especially if it is used in combination with surgical excision of the primary lesion and with regional lymph node dissection.

Investigators are exploring the potential for the use of lipid-lowering medications to prevent melanoma. A 2008 review concluded that there was a reduction in the incidence of melanoma in patients taking statins and fibrates, but the results were not highly significant. More research is needed before conclusions can be drawn (Dellavalle, Drake, Graber, et al., 2005). Several other studies continue to explore the potential for vaccine therapy, but none has yet identified an effective agent (Russo, Maccalli, Pilla, et al., 2008).

NURSING PROCESS

CARE OF THE PATIENT WITH MALIGNANT MELANOMA

Assessment

Assessment of the patient with malignant melanoma is based on the patient's history and symptoms. The patient is asked specifically about pruritus, tenderness, and pain, which are not features of a benign nevus. The patient is also questioned about changes in preexisting moles or the development of new, pigmented lesions. People at risk are assessed carefully.

A magnifying lens and good lighting are needed for inspecting the skin for irregularity and changes in the mole. Signs that suggest malignant changes are referred to as the ABCDs of moles (Chart 56-8).

CHART
56-8

Assessing the ABCDs of Moles

A for Asymmetry

- The lesion does not appear balanced on both sides. If an imaginary line were drawn down the middle, the two halves would not look alike.
- The lesion has an irregular surface with uneven elevations (irregular topography) either palpable or visible. A change in the surface may be noted from smooth to scaly.
- Some nodular melanomas have a smooth surface.

B for Irregular Border

- Angular indentations or multiple notches appear in the border.
- The border is fuzzy or indistinct, as if rubbed with an eraser.

C for Variegated Color

- Normal moles are usually a uniform light to medium brown. Darker coloration indicates that the melanocytes have penetrated to a deeper layer of the dermis.
- Colors that may indicate malignancy if found together within a single lesion are shades of red, white, and blue; shades of blue are ominous.
- White areas within a pigmented lesion are suspicious.
- Some malignant melanomas, however, are not variegated but are uniformly colored (bluish-black, bluish-gray, bluish-red).

D for Diameter

- A diameter exceeding 6 mm (about the size of a pencil eraser) is considered more suspicious, although this finding without other signs is not significant. Many benign skin growths are larger than 6 mm, whereas some early melanomas may be smaller.

Common sites of melanomas are the skin of the back, the legs (especially in women), between the toes, and on the feet, face, scalp, fingernails, and backs of hands. In dark-skinned people, melanomas are most likely to occur in less pigmented sites: palms, soles, subungual areas, and mucous membranes. Satellite lesions (ie, those situated near the mole) are inspected.

Diagnosis

Nursing Diagnoses

Based on the nursing assessment data, the patient's major nursing diagnoses may include the following:

- Acute pain related to surgical excision and grafting
- Anxiety and depression related to possible life-threatening consequences of melanoma and disfigurement
- Deficient knowledge about early signs of melanoma

Collaborative Problems/Potential Complications

Based on the assessment data, potential complications include the following:

- Metastasis
- Infection of the surgical site

Planning and Goals

The major goals for the patient may include relief of pain and discomfort, reduced anxiety and depression, increased knowledge of early signs of melanoma, and absence of complications.

Nursing Interventions

Relieving Pain and Discomfort

Surgical removal of melanoma in different locations presents different challenges, taking into consideration the removal of the primary melanoma, the intervening lymphatic vessels, and the lymph nodes to which metastases may spread. Nursing management of the patient having surgery in these regions is discussed in the appropriate chapters.

Nursing interventions after surgery for a malignant melanoma center on promoting comfort, because wide excision surgery may be necessary. A split-thickness or full-thickness skin graft may be necessary when large defects are created by surgical removal of a melanoma. Anticipating the need for and administration of appropriate analgesic medications is important.

Reducing Anxiety and Depression

Psychological support is essential when disfiguring surgery is performed. Support includes allowing the patient to express feelings about the seriousness of the cutaneous neoplasm, understanding the patient's anxiety and depression, and conveying understanding of these feelings. During the diagnostic workup and staging of the depth, type, and extent of the tumor, the nurse answers questions, clarifies information, and helps clarify misconceptions. Learning that he or she has a melanoma can cause the patient considerable fear and anguish. Pointing out the patient's resources, past effective coping mechanisms, and social support systems helps the patient cope with the diagnosis and need for treatment and continuing follow-up. Family members should be included in all discussions to enable them to clarify information, ask questions that the patient might be reluctant to ask, and provide emotional support to the patient.

Monitoring and Managing Potential Complications

Metastasis of malignant melanoma is closely related to prognosis: the deeper and thicker (more than 4 mm) the melanoma, the greater is the likelihood of metastasis. If the melanoma is growing radially (ie, horizontally) and is characterized by peripheral growth with minimal or no dermal invasion, the prognosis is favorable. When the melanoma invades the dermal layer, the prognosis is poor. Lesions with ulceration have a poor prognosis. Melanomas of the trunk appear to have a poorer prognosis than those of other sites, perhaps because the network of lymphatics in the trunk permits metastasis to regional lymph nodes.

The role of the nurse in caring for the patient with metastatic disease is to provide holistic care. The nurse must be knowledgeable about the most effective current therapies and must deliver supportive care, provide and clarify information about the therapy and the rationale for

its use, identify potential side effects of therapy and ways to manage them, and instruct the patient and family about the expected outcomes of treatment. The nurse monitors and documents symptoms that may indicate metastasis: lung (eg, difficulty breathing, shortness of breath, increasing cough), bone (eg, pain, decreased mobility and function, pathologic fractures), and liver (eg, change in liver enzyme levels, pain, jaundice). Nursing care is based on the patient's symptoms and emotional needs.

Although the chance of a cure for malignant melanoma that has metastasized is poor, the nurse encourages hope while maintaining a realistic perspective about the disease and ultimate outcome. Furthermore, the nurse provides time for the patient to express fears and concerns regarding future activities and relationships, offers information about support groups and contact people, and arranges palliative and hospice care if appropriate (see Chapter 17).

Promoting Home and Community-Based Care

TEACHING PATIENTS SELF-CARE. The best hope of decreasing the incidence of skin cancer lies in educating patients about the early signs. Patients at risk are taught to examine their skin and scalp monthly in a systematic manner and to seek prompt medical attention if changes are detected (Chart 56-9). The nurse also points out that a key factor in the development of melanoma is exposure to sunlight. Because melanoma is thought to be genetically linked, the family as well as the patient should be taught sun-avoiding measures and the importance of annual assessment by a health care provider.

Evaluation

Expected Patient Outcomes

Expected patient outcomes may include the following:

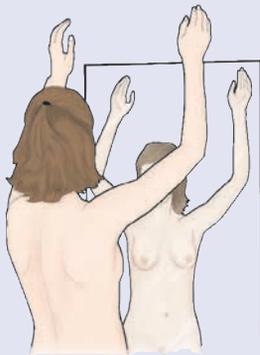

1. Experiences relief of pain and discomfort
 - a. States pain is diminishing
 - b. Exhibits healing of surgical scar without heat, redness, or swelling
2. Is less anxious
 - a. Expresses fears and fantasies
 - b. Asks questions about medical condition
 - c. Requests facts about melanoma
 - d. Identifies support and comfort provided by family member or significant other
3. Demonstrates understanding of the means for detecting and preventing melanoma
 - a. Demonstrates how to conduct self-examination of skin on a monthly basis
 - b. Verbalizes the following danger signals of melanoma: change in size, color, shape, or outline of mole, mole surface, or skin around mole
 - c. Identifies measures to protect self from exposure to sunlight
4. Experiences absence of complications
 - a. Recognizes abnormal signs and symptoms that should be reported to physician
 - b. Complies with recommended follow-up procedures and prevention strategies

CHART
56-9

PATIENT EDUCATION Periodic Self-Examination

Prevention of melanoma/skin cancer is the best weapon against these diseases, but if a melanoma should develop, it is almost always curable if caught in the early stages. Practice periodic self-examination to aid in early recognition of any new or developing lesion. The following is one way of self-examination that will ensure that no area of the body is neglected. To perform your self-examination, you will need a full-length mirror, a hand mirror, and a brightly lit room.

1. Examine the body front and back in the mirror, then the right and left sides, with the arms raised.

2. Bend the elbows, looking carefully at the forearms, back of the upper arms, and palms

3. Next, look at the back of the legs and feet, the spaces between the toes, and the soles of the feet.

4. Examine the back of the neck and the scalp with a hand-held mirror. Part the hair to lift.

5. Finally, check the back and buttocks with a hand mirror.

Metastatic Skin Tumors

The skin is an important, although not a common, site of metastatic cancer. All types of cancer may metastasize to the skin, but carcinoma of the breast is the primary source of cutaneous metastases in women. Other sources include cancer of the large intestine, ovaries, and lungs. In men, the most common primary sites are the lungs, large intestine, oral cavity, kidneys, or stomach. Skin metastases from melanomas are found in both genders. The clinical appearance of metastatic skin lesions is not distinctive, except perhaps in some cases of breast cancer in which diffuse, brawny hardening of the skin of the involved breast is seen. In most instances, metastatic lesions occur as multiple cutaneous or subcutaneous nodules of various sizes that may be skin colored or different shades of red.

Kaposi's Sarcoma

Kaposi's sarcoma (KS) is a malignancy of endothelial cells that line the small blood vessels. KS is manifested clinically by lesions of the skin, oral cavity, gastrointestinal tract, and lungs. The skin lesions consist of reddish-purple to dark-blue macules, plaques, or nodules. KS is subdivided into three categories:

- *Classic KS* occurs predominantly in men of Mediterranean or Jewish ancestry between 40 and 70 years of age. Most patients have nodules or plaques on the lower extremities that rarely metastasize beyond this area. Classic KS is chronic, relatively benign, and rarely fatal.
- *Endemic (African) KS* affects people predominantly in the eastern half of Africa near the equator. Men are affected more often than women, and children can be affected as well. The disease may resemble classic KS or it may infiltrate and progress to lymphadenopathic forms.
- *Immunosuppression-associated KS* occurs in transplant recipients and people with AIDS. This form of KS is characterized by local skin lesions and disseminated visceral and mucocutaneous diseases. The greater the degree of immunosuppression, the higher the incidence of KS. Immunosuppression-related KS that results from AIDS is an aggressive tumor that involves multiple body organs. Its presentation resembles that of KS associated with immunosuppressive therapy. Most patients are between 20 and 40 years of age. More information on AIDS-related KS can be found in Chapter 52.

DERMATOLOGIC AND PLASTIC RECONSTRUCTIVE PROCEDURES

The word *plastic* comes from a Greek word meaning to *form*. Plastic or reconstructive procedures are performed to reconstruct or alter congenital or acquired defects to restore or improve the body's form and function. Often the terms "plastic" and "reconstructive" are used interchangeably. This type of surgery includes closure of wounds, removal of

skin tumors, repair of soft tissue injuries or burns, correction of deformities, and repair of cosmetic defects. Plastic surgery can be used to repair many parts of the body and numerous structures, such as bone, cartilage, fat, fascia, mucous membrane, muscle, nerve, and cutaneous structures. Bone inlays and transplants for deformities and nonunion can be performed, muscle can be transferred, nerves can be reconstructed and spliced, and cartilage can be replaced. As important as any of these measures is the reconstruction of the cutaneous tissues around the neck and the face; this is usually referred to as aesthetic or cosmetic surgery.

Cosmetic procedures are generally considered to be ones that correct defects that are not life-threatening or caused by disease. An example would be removal of a benign mole or sebaceous cyst from the face. Most health insurance plans do not cover procedures deemed to be cosmetic, and these procedures can be expensive. Procedures that are performed to correct a surgical defect, such as removal of a skin cancer or correction of a significant congenital defect such as a cleft lip, are generally covered by insurance, but this should be confirmed before surgery is scheduled.

Wound Coverage: Grafts and Flaps

Various surgical techniques, including skin grafts and flaps, are used to cover skin wounds.

Skin Grafts

Skin grafting is a technique in which a section of skin is detached from its own blood supply and transferred as free tissue to a distant (recipient) site. Skin grafting can be used to repair almost any type of wound and is the most common form of reconstructive surgery.

Skin grafts are commonly used to repair surgical defects such as those that result from excision of skin tumors, to cover areas denuded of skin (eg, burns), and to cover wounds in which insufficient skin is available to permit wound closure. They are also used when primary closure of the wound increases the risk of complications or when primary wound closure would interfere with function.

Skin grafts may be classified as autografts, allografts, or xenografts. An autograft is tissue obtained from the patient's own skin. An allograft is tissue obtained from a donor of the same species. These grafts are also called allogeneic or homograft. A xenograft or heterograft is tissue obtained from another species. A common xenograft for human skin is the pig.

Grafts are also referred to by their thickness. A skin graft may be a split-thickness (ie, thin, intermediate, or thick) or a full-thickness graft, depending on the amount of dermis included in the specimen. A split-thickness graft can be cut at various thicknesses and is commonly used to cover large wounds or defects for which a full-thickness graft or flap is impractical (Fig. 56-7). A full-thickness graft consists of epidermis and the entire dermis without the underlying fat. It is used to cover wounds that are too large to be closed directly.

Site Selection

The site where the intact skin is harvested is called the donor site. Selection of the donor site is made to match the

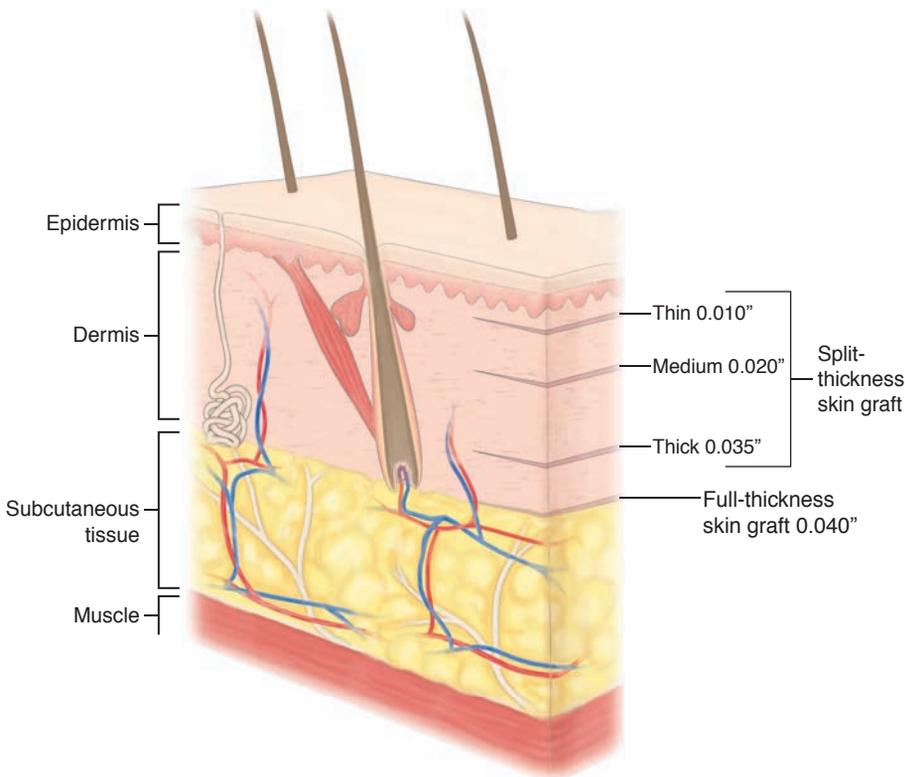

Figure 56-7 Layers of skin appropriate for split-thickness and full-thickness graft.

color and texture of skin at the surgical site and to leave as little scarring as possible.

Graft Application

The skin graft is taken from the donor or host site and applied to the desired site, called the recipient site or graft bed.

For a graft to survive and be effective, certain conditions must be met:

- The recipient site must have an adequate blood supply so that normal physiologic function can resume.
- The graft must be in close contact with its bed to avoid accumulation of blood or fluid between the graft and the recipient site.
- The graft must be fixed firmly (immobilized) so that it remains in place on the recipient site.
- The area must be free of infection.

The graft, when applied to the recipient site, may be sutured in place; alternatively, it may be slit and spread apart to cover a greater area. The process of revascularization (establishing the blood supply) and reattachment of a skin graft to a recipient bed is referred to as a “take.” After a skin graft is put in place, it may be left exposed (in areas that are impossible to immobilize) or covered with a light dressing or a pressure dressing, depending on the area of the body.

Nursing Interventions

The nurse must ensure that both the surgical and the donor sites receive proper postoperative care. The surgical site is covered by the harvested skin, and the donor site heals by re-epithelization of the raw, exposed dermis. Both sites are

protected by dressings as they heal. Prevention of infection is essential as with all surgical sites. Both sites can be kept soft and pliable with cream (eg, lanolin). Both the donor site and the grafted area must be protected from exposure to extremes in temperature, external trauma, and sunlight because these areas are sensitive, especially to thermal injuries.

Flaps

Another form of wound coverage is provided by flaps. A flap is a segment of tissue that remains attached at one end (ie, a base or pedicle) while the other end is moved to a recipient area. Its survival depends on functioning arterial and venous blood supplies and lymphatic drainage in its pedicle or base. A flap differs from a graft in that a portion of the tissue is attached to its original site and retains its blood supply. An exception is the free flap, which is described below.

Flaps may consist of skin, mucosa, muscle, adipose tissue, omentum, and bone. They are used for wound coverage and provide bulk, especially when bone, tendon, blood vessels, or nerve tissue is exposed. Flaps are used to repair defects caused by congenital deformity, trauma, or tumor ablation (removal, usually by excision) in an adjacent part of the body.

Flaps offer an aesthetic solution because a flap retains the color and texture of the donor area, is more likely to survive than a graft, and can be used to cover nerves, tendons, and blood vessels. However, several surgical procedures are usually required to advance a flap. The major complication is necrosis of the pedicle or base as a result of failure of the blood supply.

Free Flaps

A striking advance in reconstructive surgery is the use of free flaps or free-tissue transfer achieved by microvascular techniques. A free flap is completely severed from the body and transferred to another site. A free flap receives early vascular supply from microvascular anastomosis with vessels at the recipient site. The procedure usually is completed in one step, eliminating the need for a series of surgical procedures to move the flap. Microvascular surgery allows surgeons to use a variety of donor sites for tissue reconstruction.

Cosmetic Procedures

Chemical Face Peeling

Chemical face peeling involves application of a chemical mixture to the face for superficial destruction of the epidermis and the upper layers of the dermis to treat fine wrinkles, keratoses, and pigment problems. It is especially useful for wrinkles at the upper and lower lip, forehead, and periorbital areas. The type of chemical used depends on the planned depth of the peel. The conscious patient feels a burning sensation that continues for 12 to 24 hours. Frequent small doses of analgesics and tranquilizers are prescribed to keep the patient comfortable. The most common complications include discoloration of the skin, infection of the burned area, persistent sensory changes or itching, and occasionally permanent scarring of the skin.

Dermabrasion

Dermabrasion is a form of skin abrasion used to treat acne scarring, aging, and sun-damaged skin. A special instrument (ie, motor-driven wire brush, diamond-impregnated disk, or serrated wheel) is used. The epidermis and some superficial dermis are removed by a sanding-like action, and enough of the dermis is preserved to allow re-epithelization of the treated areas. Results are best in the face because it is rich in intradermal epithelial elements.

The primary reason for undergoing dermabrasion is to improve appearance.

Facial Reconstructive Surgery

Reconstructive procedures on the face are individualized to the patient's needs and desired outcomes. They are performed to repair deformities or restore normal function. They may vary from closure of small defects to complicated procedures involving implantation of prosthetic devices to conceal a large defect or reconstruct a lost part of the face (eg, nose, ear, jaw). Each surgical procedure is customized and involves a variety of incisions, flaps, and grafts. Multiple surgical procedures may be required.

The process of facial reconstruction is often slow and tedious. Because a person's facial appearance affects self-esteem so greatly, this type of reconstruction is often a very emotional experience for the patient.

Face Lift

Rhytidectomy (face lift) is a surgical procedure that removes soft tissue folds and minimizes cutaneous wrinkles on the face.

It is performed to create a more youthful appearance. Psychological preparation requires that the patient recognize the limitations of surgery and the fact that miraculous rejuvenation will not occur. The patient is informed that the face may appear bruised and swollen after the dressings are removed and that several weeks may pass before the edema subsides.

LASER TREATMENT OF CUTANEOUS LESIONS

Lasers are devices that amplify or generate highly specialized light energy. They can mobilize immense heat and power when focused at close range and are valuable tools in surgical procedures. The argon laser, carbon dioxide (CO₂) laser, and tunable pulse-dye laser are used in dermatologic surgery. Each type of laser emits its own wavelength within the color spectrum.

Argon Laser

The argon laser is useful in treating vascular lesions: port-wine stains, telangiectases, vascular tumors, and pigmented lesions. The argon beam can penetrate approximately 1 mm of skin and reach the pigmented layer, causing protein coagulation in this area. An immediate effect is that tiny blood vessels under the skin coagulate, causing the area to turn a much lighter color. A crust forms within a few days.

Carbon Dioxide Laser

The CO₂ laser is a precise surgical instrument that vaporizes and excises tissue with minimal damage. Because the beam can seal blood and lymphatic vessels, it creates a dry surgical field that makes many procedures easier and quicker. Therefore, it is safe to use on patients with bleeding disorders or those receiving anticoagulant therapy. It is useful for removing epidermal nevi, tattoos, certain warts, skin cancer, ingrown toenails, and keloids. Incisions made with the laser beam heal and scar much like those made by a scalpel.

Pulse-Dye Laser

The tunable pulse-dye laser is especially useful in treating cutaneous vascular lesions such as port-wine stains and telangiectasia. The procedure is generally painless. For procedures requiring anesthesia, lidocaine without epinephrine is sufficient because local vasoconstriction (which epinephrine induces) is unnecessary.

Nursing Management

The majority of dermatologic and reconstructive procedures are performed in the physician's office or in an outpatient surgical department; therefore, most care takes place in the home. Most procedures, except very extensive reconstruction, are performed under local anesthesia or moderate sedation, therefore requiring a very short recovery time. Unless there are complications, the patient does not need hospitalization. It is important for the nurse to prepare both the patient and family for what to expect during the postoperative recovery time. Table 56-7 lists a few of the nursing considerations that must be reviewed in educating the patient and family.

Table 56-7 NURSING CONSIDERATIONS IN COSMETIC PROCEDURES

Nursing Consideration	Interventions and Patient Education
Maintaining airway and pulmonary function	Cosmetic surgeries involving the face and neck can cause considerable swelling; bandages can restrict breathing or eating. Check dressings frequently and ensure that no constriction occurs as swelling develops.
Relieving pain and achieving comfort	Procedures that involve a large surface area will cause considerable pain. Cool compresses or ice packs will relieve the burning of dermabrasion or chemical peels. Oral analgesics should be administered regularly to control pain.
Maintaining adequate nutrition	When the face is involved, the patient may be unable to fully open the mouth, and chewing may be painful. Provide soft or liquid diet that is high in protein to assist with healing.
Enhancing communication	Depending on the type of cosmetic procedure, a nonverbal method of communication might be necessary until pain and swelling have subsided.
Improving self-concept	Recovery time from cosmetic procedures is slow. Expected results will take weeks to become apparent. Persons of color will experience increased pigmentation long after the initial wounds have healed. Helping patients to understand postoperative expectations will allow them to feel more comfortable with the healing process.
Promoting family coping	Most cosmetic procedures are performed in an outpatient facility; therefore, family members are integral to postoperative care. They should understand what to expect as the patient emerges from the procedure room: the type of dressings that will be in place, the skin care plan that is prescribed, and how to cope with the patient's pain.
Monitoring and managing potential complications	Infection is the most common complication, but excessive pain, nerve damage, and emotional distress about appearance are also common. If opioids are used, there may be gastrointestinal upset, mental status changes, or allergic reaction to the medication. Alert the caregiver to signs of these complications and how and when to report changes in status.

CRITICAL THINKING EXERCISES

EBP 1 You are caring for a middle-age woman who has diabetes and peripheral vascular disease. She has now developed a venous stasis ulcer on her lower leg just above the ankle. Her physician has prescribed a moisture-retentive dressing that is impregnated with hydrogel. The dressing is to be changed every 3 days, and the patient asks you why the dressing is not changed every day. How would you explain to the patient the purpose of the dressing? Identify the evidence that supports the use of moisture-retentive dressings for venous ulcers. Discuss the strength of the evidence regarding their effectiveness in the promotion of wound healing. What other teaching would you provide to this patient about care of her skin?

2 A 35-year-old woman, who has two small children at home and is in the middle of a divorce, is admitted to your nursing unit for treatment of an acute flare of psoriasis. Her skin is covered with bright red, dry scaling plaques, involving 60% of her body surface. Addition-

ally, she has distortions of her fingers and pitted nail plates, and she reports bilateral ankle pain on awakening each day. She has been admitted for twice-daily bath treatments and to initiate an injectable biologic for management of her condition. What should be included in the admission nursing assessment? What should be included in the teaching plan? List some of the possible psychosocial issues that may arise as you care for this patient.

3 A 50-year-old professional golfer is having a routine physical examination. He states that his mother had malignant melanoma and that he is concerned about several lesions on his arms and neck. He asks about the risk factors for melanoma and about total body digital photography that a colleague had recently had. How would you explain the purpose of this photographic method? Identify the evidence and the strength of the evidence that supports the diagnostic value of this procedure. What teaching would you provide to this patient about prevention of melanoma and self-examination of the skin?

Chapter 57

Management of Patients With Burn Injury

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

- 1 Discuss the incidence of burn injury in the United States today.
- 2 Describe the factors that affect the severity of burn injury.
- 3 Describe the local and systemic effects of a major burn injury.
- 4 Compare and contrast the potential fluid and electrolyte alterations of the emergent/resuscitative and acute phases of burn management.
- 5 Describe the goals of burn care and the nurse's role in wound assessment, wound cleansing, topical antibacterial therapy, wound dressing, débridement, excision, and skin grafting.
- 6 Describe the nurse's role in pain management, restoration of function, psychological support of the patient and family, nutritional support, pulmonary care, and patient and family education.
- 7 Describe patient care and the recovery process for burn patients

GLOSSARY

- AlloDerm:** processed dermis from human cadaver skin; can be used as dermal layer for skin grafts
- autograft:** a graft derived from one part of a patient's body and used on another part of that same patient's body
- Biobrane:** synthetic dressing composed of a nylon, Silastic membrane combined with a collagen derivative
- carboxyhemoglobin:** a compound of carbon monoxide and hemoglobin, formed in the blood with exposure to carbon monoxide
- collagen:** a protein present in skin, tendon, bone, cartilage, and connective tissue
- contracture:** shrinkage of burn scar through collagen maturation
- cultured epithelial autograft (CEA):** autologous epidermal cells that proliferate in culture and then are regrafted onto the patient
- débridement:** removal of foreign material and devitalized tissue until surrounding healthy tissue is exposed
- donor site:** the area from which skin is taken to provide a skin graft for another part of the body
- eschar:** devitalized tissue resulting from a burn
- escharotomy:** a linear excision made through eschar to release constriction of underlying tissue
- excision:** surgical removal of tissue
- fasciotomy:** an incision made through the fascia to release constriction of underlying muscle
- heterograft:** graft (ie, pigskin) obtained from an animal of a species other than that of the recipient; also called a xenograft
- homograft:** a graft transferred from one human (living or cadaveric) to another human; also called allograft
- hydrotherapy:** cleansing of wounds through use of bath, shower, shower cart table, or immersion
- hypertrophic scar:** excessive scar formation that rises above the level of the skin
- Integra:** synthetic dermal substitute
- rule of nines:** method for calculating body surface area burned by dividing the body into multiples of nine

The nurse who cares for a patient with a burn injury requires a high level of knowledge about the physiologic changes that occur after a burn, as well as astute assessment skills to detect subtle changes in the patient's condition. The patient's health history affects burn care. This makes each burn patient very unique and provides a variety of challenges to the patient's plan of care. In addition, the nurse provides sensitive, compassionate care to patients who are critically ill and initiates rehabilitation early in the course of care. The nurse must also be able to communicate effectively with patients who have burn injuries, family members in crisis, and members of the entire interdisciplinary burn management team. Care of the patient with a burn requires knowledge and skill throughout the care continuum from injury to recovery. This ensures quality care, improved patient outcomes, and optimal quality of life.

Overview of Burn Injury

Incidence

A burn injury can affect people of all age groups, in all socioeconomic groups. An estimated 500,000 people are treated for minor burn injury annually (Pitts, Niska, Xu, et al., 2008). The number of patients who are hospitalized each year with burn injuries is more than 40,000. This includes approximately 25,000 people who require hospitalization in specialized burn centers across the country. As emergency transportation and awareness of burn specialized hospitals has increased, the number of patients referred to these centers has risen. The remaining 5,000 hospitals see an average of three burns per year. Of those people admitted to burn centers, 47% of their injuries occurred at home, 27% on the road, 8% are occupational, 5% are recreational, and the remaining 13% from other sources. Forty percent of these injuries were flame related, 30% scald injuries, 4% electrical, 3% chemical, with the remaining unspecified (Miller, Bessey, Lentz, et al., 2008).

Males have greater than twice the chance of burn injury than women, and the most frequent age group for contact

burns is between 20 to 40 years of age (Miller, et al., 2008). The National Fire Protection Association reports 4,000 fire and burn deaths each year. Of these, 3,500 deaths occur from residential fires and the remaining 500 from other sources such as motor vehicle crashes, scalds, or electrical and chemical sources. The overall mortality rate, for all ages and for total body surface area (TBSA) burned is 4.9% (Miller, et al., 2008).

Gerontologic Considerations

Reduced mobility, coordination, strength, and sensation and changes in vision place elderly people at higher risk for burn injury. Difficulties cooking and bathing and other activities of daily living are associated with flame and scald injury in this age group. These changes also place older people at risk for severe burn because they have difficulty in extinguishing the fire and removing themselves from the burn source (Sheridan, 2007a).

Morbidity and mortality rates associated with burns are greater in elderly patients than in younger patients when comparing injuries with similar severity. In 2007 patients over the age of 60 who had a 60% TBSA or greater had an overall mortality rate of 96% (Sheridan, 2007a). Predisposing factors and the health history in the older adult influence the complexity of care for the patient. Pulmonary function is limited in the older adult, therefore, airway exchange, lung elasticity, and ventilation can be affected. This can be further affected by a history of smoking. Decreased cardiac function and coronary artery disease increase the risk of complications in elderly patients with burn injuries. Malnutrition and presence of diabetes mellitus or other endocrine disorders present nutritional challenges and require close monitoring. Varying degrees of orientation may present themselves on admission or through the course of care, making assessment of pain and anxiety a challenge for the burn team. The skin of the elderly is thinner and less elastic, which affects the depth of injury and its ability to heal (Sheridan, 2007a).

An important goal of nurses in community and home settings is to provide education on the prevention of burn injury, especially among the elderly (Chart 57-1). Nurses

CHART
57-1

HEALTH PROMOTION Burn Prevention

- Advise that matches and lighters be kept out of the reach of children.
- Emphasize the importance of never leaving children unattended around fire or in bathroom/bathtub.
- Advise the installation and maintenance of smoke detectors on every level of the home, changing batteries annually on birthday.
- Recommend the development and practice of a home exit fire drill with all members of the household.
- Advise setting the water heater temperature no higher than 120°F.
- Caution against smoking in bed, while using home oxygen, or against falling asleep while smoking.
- Caution against throwing flammable liquids onto an already burning fire.
- Caution against using flammable liquids to start fires.
- Caution against removing the radiator cap from a hot car engine.
- Recommend avoidance of overhead electrical wires and underground wires when working outside.
- Advise that hot irons and curling irons be kept out of the reach of children.
- Caution against running electric cords under carpets or rugs.
- Recommend storage of flammable liquids well away from a fire source, such as a pilot light.
- Advocate caution when cooking, being aware of loose clothing hanging over the stove top.
- Recommend having a working fire extinguisher in the home and knowing how to use it.

need to assess an elderly patient's ability to safely perform activities of daily living, assist elderly patients and families to modify their environment to ensure safety, and make referrals as needed.

Outlook for Survival and Recovery

The National Center for Injury Prevention and Control of the Centers for Disease Control and Prevention (CDC) identifies fire or burn injury as the fifth most common cause of death from unintentional injury in the United States and the third leading cause of death in the home from injury (CDC, 2008).

Great strides in research have helped to increase the survival rate of patients with burn injuries. Mortality has fallen to levels never thought possible. Long-term outcomes can now be explored because patients with very large burns are surviving their injuries. Research in areas such as fluid resuscitation, emergency burn treatment, inhalation injury and management, nutritional needs and changes in wound care practice with early excision, skin grafting, and use of skin substitutes have contributed greatly to the decrease in burn deaths. Continued research and advances in the areas of critical care, rehabilitation, psychosocial, and scar management are essential for continued progress in burn care.

Severity

The severity of each burn injury is determined by multiple factors that when assessed help the burn team estimate the likelihood that a patient will survive and plan for the care for each patient. These factors include age of the patient; depth of the burn; amount of surface area of the body that is burned; the presence of inhalation injury; presence of other injuries; location of the injury in special care areas such as the face, the perineum, hands, or feet; and the presence of a past medical history.

Age

Young children and the elderly continue to have increased morbidity and mortality when compared to other age groups with similar injuries and present a challenge for burn care. This is an important factor when determining the severity of injury and possible outcome for the patient.

Burn Depth

Burns are classified according to the depth of tissue destruction as superficial partial-thickness injuries, deep partial-thickness injuries, or full-thickness injuries (Table 57-1). These three categories are similar to, but not the same as, first-, second-, and third-degree burn classifications. Although the term fourth-degree burn is not used universally, it occurs with prolonged flame contact or high-voltage injury that destroys all layers of the skin and damages tendons and muscles.

In a superficial partial-thickness burn, the epidermis is destroyed or injured and a portion of the dermis may be injured. A deep partial-thickness burn involves destruction of the epidermis and upper layers of the dermis and injury to deeper portions of the dermis. Capillary refill follows tissue blanching. Hair follicles remain intact. A full-thickness burn involves total destruction of epidermis and dermis and, in some cases, destruction of underlying tissue, muscle, and bone. Wound color ranges widely from pale white to red, brown, or charred black. The burned area is painless and lacks sensation because nerve fibers are destroyed. The wound appears leathery; hair follicles and sweat glands are destroyed (Fig. 57-1). The severity of this burn is often deceiving to patients because they have no pain in the injury area. These wounds require skin grafting for healing.

Burn depth determines whether epithelialization will occur. Determining burn depth can be difficult even for the experienced burn care provider. The following factors are

Table 57-1 CHARACTERISTICS OF BURNS ACCORDING TO DEPTH

Depth of Burn and Causes	Skin Involvement	Symptoms	Wound Appearance	Recuperative Course
Superficial Partial-Thickness (Similar to First Degree)				
Sunburn Low-intensity flash	Epidermis; possibly a portion of dermis	Tingling Hyperesthesia (supersensitivity) Pain that is soothed by cooling	Reddened; blanches with pressure; dry Minimal or no edema Possible blisters	Complete recovery within a week; no scarring Peeling
Deep Partial-Thickness (Similar to Second Degree)				
Scalds Flash flame Contact	Epidermis, upper dermis, portion of deeper dermis	Pain Hyperesthesia Sensitive to cold air	Blistered, mottled red base; broken epidermis; weeping surface Edema	Recovery in 2 to 4 weeks Some scarring and depigmentation contractures Infection may convert it to full thickness
Full-Thickness (Similar to Third Degree)				
Flame Prolonged exposure to hot liquids Electric current Chemical Contact	Epidermis, entire dermis, and sometimes subcutaneous tissue; may involve connective tissue, muscle, and bone	Pain free Shock Hematuria (blood in the urine) and possibly hemolysis (blood cell destruction) Possible entrance and exit wounds (electrical burn)	Dry; pale white, leathery, or charred Broken skin with fat exposed Edema	Eschar sloughs Grafting necessary Scarring and loss of contour and function; contractures Loss of digits or extremity possible

Figure 57-1 Full-thickness injury to chest and upper extremity. Epidermis, varying levels of the dermis and subcutaneous tissue is injured. Used with permission. Lehigh Valley Health Network, Allentown, PA.

considered in determining the depth of a burn: how the injury occurred, causative agent (such as flame or scalding liquid), temperature of the burning agent, duration of contact with the agent, and thickness of the skin.

Extent of Body Surface Area Injured

Various methods are used to estimate the TBSA affected by burns; among them are the rule of nines, the Lund and Browder method, and the palmer method. These methods assist the burn team in making decisions about treatment and transfer of the patient to a burn center.

Rule of Nines

A common method, the **rule of nines** (Fig. 57-2), is a quick way to estimate the extent of burns in adults. The system divides the body into multiples of nine. The sum total of these parts equals the total body surface area and is an important measurement in the severity of injury (Shukla & Sheridan, 2008).

Lund and Browder Method

A more precise method of estimating the extent of a burn is the Lund and Browder method, which recognizes the percentage of surface area of various anatomic parts, especially the head and legs, as it relates to the age of the patient. By dividing the body into very small areas and providing an estimate of the proportion of TBSA accounted for by each body part, one can obtain a reliable estimate of TBSA burned. The initial evaluation is made on arrival of the patient at the hospital and is revised within the first 72 hours because demarcation of the wound and its depth presents itself more clearly by this time.

Palmer Method

In patients with scattered burns, or for a quick prehospital assessment, the palmer method may be used to estimate the extent of the burns. The size of the patient's palm, not including the surface area of the digits, is approximately 1% of the TBSA. The patient's palm without the fingers is equiv-

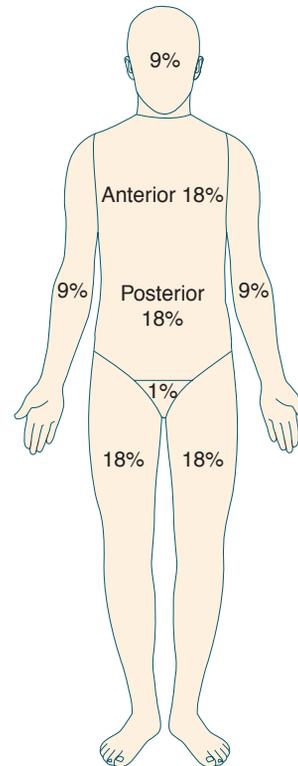

Figure 57-2 The rule of nines: Estimated percentage of total body surface area (TBSA) in the adult is arrived at by sectioning the body surface into areas with a numerical value related to nine. (Note: The anterior and posterior head total 9% of TBSA.)

alent to 0.5% TBSA and serves as a general measurement for all age groups (Shukla & Sheridan, 2008).

Pathophysiology

Burn injury is a result of heat transfer from one site to another. Tissue destruction results from coagulation, protein denaturation, or ionization of cellular contents (Fig. 57-3). The skin and the mucosa of the upper airways are sites of tissue destruction. Deep tissues, including the viscera, can be damaged by electrical burns (Chart 57-2) or by prolonged contact with a heat source. Disruption of the skin can lead to increased fluid loss, infection, hypothermia, scarring, compromised immunity, and changes in function, appearance, and body image.

The depth of the injury depends on the temperature of the burning agent and the duration of contact with the agent. For example, in the case of scald burns in adults, 1 second of contact with hot tap water at 68.9°C (156°F) may result in a burn that destroys both the epidermis and the dermis, causing a full-thickness (third-degree) injury. Fifteen seconds of exposure to hot water at 56.1°C (133°F) results in a similar full-thickness injury. Temperatures less than 44°C (111°F) can be tolerated for long periods without injury.

Burns that do not exceed 20% TBSA produce a primarily local response. Burns that exceed 20% TBSA may produce both a local and a systemic response and are considered major burn injuries. The systemic response is caused by

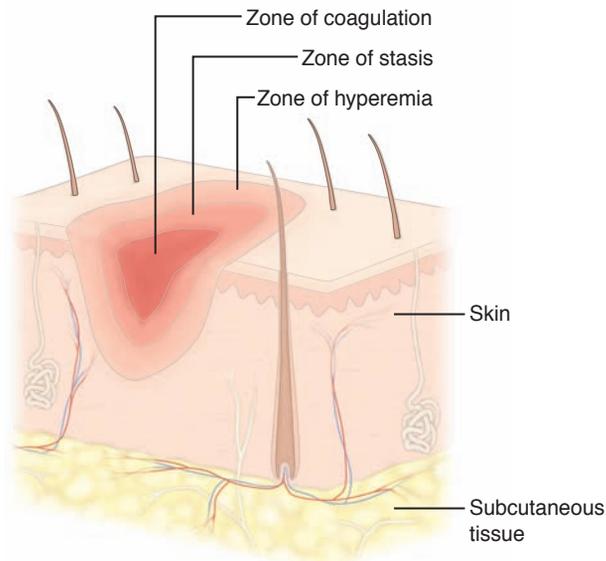

Figure 57-3 Zones of burn injury. Each burned area has three zones of injury. The inner zone (known as the area of coagulation, where cellular death occurs) sustains the most damage. The middle area, or zone of stasis, has a compromised blood supply, inflammation, and tissue injury. The outer zone—the zone of hyperemia—sustains the least damage.

the release of cytokines and other mediators into the systemic circulation. The release of local mediators and changes in blood flow, tissue edema, and infection can cause progression of the burn injury.

Pathophysiologic changes resulting from major burns during the initial burn-shock period include tissue hypoperfusion and organ hypofunction secondary to decreased cardiac output, followed by hyperdynamic and hypermetabolic phases. The incidence, magnitude, and duration of pathophysiologic changes in burns are proportional to the extent of burn injury, with a maximal response seen in burns covering 60% or more TBSA.

The initial systemic event after a major burn injury is hemodynamic instability, which results from loss of capillary integrity and a subsequent shift of fluid, sodium, and protein from the intravascular space into the interstitial spaces. Hemodynamic instability involves cardiovascular, fluid and electrolyte, blood volume, pulmonary, and other mechanisms.

Cardiovascular Alterations

Hypovolemia is the immediate consequence of fluid loss and results in decreased perfusion and oxygen delivery. Cardiac output decreases before any significant change in blood volume is evident. As fluid loss continues and vascular

Chart 57-2 • Electrical Burns

Electrical injury accounts for a small percentage of burn unit admissions each year, yet it is one of the most destructive types of burn injuries that can be sustained. The devastating effects of an electrical injury can cause lifelong neurovascular problems. Low-voltage injury (ie, less than 500 V exposure) generally does not cause significant damage or medical problems. Midrange exposure (ie, 200–1000 V) can cause local destruction to the tissue. High-voltage exposure (ie, greater than 1000 V) can cause loss of consciousness, fractures, compartment syndrome, arrhythmias, and is often associated with falls (Shukla & Sheridan, 2008).

Tissue and bone destruction often results in amputations and possible loss of life as the result of cardiac and respiratory abnormalities. A true electrical injury results when a current of electricity travels through the body and exits to the ground, causing internal damage to tissue and organs. Such an injury results in an entrance wound, which is the patient's point of contact with the source. The exit wound has a blow-out appearance, causing extensive damage to the surrounding tissue and structures. The amount of damage depends on the strength of the current and the length of the duration of contact with the source. An arc injury is the result of the electricity's traveling on the outside of the body or arcing around it. There is usually also a thermal injury due to clothing catching on fire. The surface injury from an electrical source is usually small compared with the damage under the surface of the skin. Electricity travels through areas of least resistance, nerves and blood vessels, to the most resistant, bone. The most severe damage occurs beneath the skin surface and is difficult to determine without surgical intervention (Shukla & Sheridan, 2008).

Once the patient is out of the path of the electricity, emergency care can safely be provided. The ABCs of emergency care are always followed. An electrical current immediately contracts muscles as it travels through the body, and cardiac dysrhythmias and spinal injuries often result from the

muscular contraction. Cardiac dysrhythmias can occur in both low-voltage and high-voltage injury and therefore require electrocardiogram evaluation and monitoring. Those patients with loss of consciousness, dysrhythmias, or ST changes on ECG must be admitted and cardiac monitoring should occur (Arnoldo, Klein & Gibran, 2006). Until it is known that the patient has no fractures, it is imperative that a neck collar remain in place and that the patient is log-rolled to eliminate the chance of further spinal cord injury. With high-voltage electrical injuries, cervical spine immobilization is a priority until cervical spine injury is ruled out.

Prompt administration of intravenous (IV) fluids and monitoring of urine output are critical components of care. Patients with electrical burns are prone to acute renal failure because of the release of myoglobin resulting from the destruction of muscle and tissue. Myoglobin can constrict renal arteries and block urine flow through the kidneys. Patients can have gross hematuria on admission to the hospital. Administration of large amounts of IV fluids helps maintain the flow of urine. It is difficult to assess the amount of fluid a patient will require because the electrical injury creates such extensive internal damage. The nurse should expect 75 to 100 mL/h of urine output for a patient who is receiving fluid resuscitation. Creatine kinase (CK) is released by damaged muscle cells and it is measured during the early phases of care to assist in determining the degree of muscle injury.

In patients with electrical injuries, neurovascular checks of affected extremities are very important. Assessment of color, temperature, and sensation in the extremity as well as the monitoring of palpable or Doppler pulses should be done to assess adequate blood flow to the extremity. If indicated by clinical assessment, the measurement of compartment syndrome to determine deep tissue injury can be performed. Compartment pressures greater than 30 mm Hg can indicate poor tissue perfusion and the need for surgical decompression (Arnoldo, et al., 2006).

volume decreases, cardiac output continues to decrease and the blood pressure drops. This is the onset of burn shock. In response, the sympathetic nervous system releases catecholamines, resulting in an increase in peripheral resistance (vasoconstriction) and an increase in pulse rate. Peripheral vasoconstriction further decreases cardiac output.

Prompt fluid resuscitation maintains the blood pressure in the low to normal range and improves cardiac output. Despite adequate fluid resuscitation, cardiac filling pressures (central venous pressure, pulmonary artery pressure, and pulmonary artery wedge pressure) remain low during the burn-shock period. If inadequate fluid resuscitation occurs, distributive shock occurs (see Chapter 15).

Generally the greatest volume of fluid leak occurs in the first 24 to 36 hours after the burn, peaking by 6 to 8 hours. As the capillaries begin to regain their integrity, burn shock resolves and fluid returns to the vascular compartment. As fluid is reabsorbed from the interstitial tissue into the vascular compartment, blood volume increases. If renal and cardiac function is adequate, urinary output increases. Diuresis continues for several days to 2 weeks.

At the time of burn injury, some red blood cells may be destroyed and others damaged, resulting in anemia. Despite this, the hematocrit may be elevated due to plasma loss. Blood losses sustained during surgical procedures, wound care, and diagnostic studies and ongoing hemolysis further contribute to anemia. Blood transfusions are required periodically to maintain adequate hemoglobin levels for oxygen delivery. Abnormalities in coagulation, including a decrease in platelets (thrombocytopenia) and prolonged clotting and prothrombin times, also occur with burn injury.

Fluid and Electrolyte Alterations

Edema forms rapidly after a burn injury. A superficial burn will cause edema to form within 4 hours after injury, while a deeper burn will continue to form over a longer period of time up to 18 hours postinjury. This is caused by increased perfusion to the injured area and is reflective of the amount of vascular and lymphatic damage to the tissue. There is loss of capillary integrity, and fluid is localized to the burn itself, resulting in blister formation and edema only in the area of injury. Patients with more severe burns develop massive systemic edema (Greenhalgh, 2007). Reabsorption begins at about 4 hours and is complete by 4 days postburn injury. However, the reabsorption is dependent on the depth of injury to the tissue. Partial-thickness injury resolves more quickly due to a more functioning lymphatic system and increased perfusion when compared to the full-thickness injury (Greenhalgh, 2007). Edema in burn wounds can be reduced by avoiding excessive fluid administration during the early postburn period. Excessive fluid administration increases edema formation in both burned and nonburned tissue.

As the taut, burned tissue becomes unyielding to the edema underneath its surface, it begins to act like a tourniquet, especially if the burn is circumferential. As edema increases, pressure on small blood vessels and nerves in the distal extremities causes an obstruction of blood flow and consequent ischemia. This complication is similar to a compartment syndrome. The physician may need to perform an **escharotomy**, a surgical incision into the **eschar** (devitalized

tissue resulting from a burn) to relieve the constricting effect of the burned tissue (Demling, 2005a).

Circulating blood volume decreases dramatically during burn shock. In addition, evaporative fluid loss through the burn wound may reach 3 to 5 L or more over a 24-hour period until the burn surfaces are covered.

During burn shock, serum sodium levels vary in response to fluid resuscitation. Usually, hyponatremia (sodium depletion) is present. Hyponatremia is also common during the first week of the acute phase, as water shifts from the interstitial space to the vascular space.

Immediately after burn injury, hyperkalemia (excessive potassium) results from massive cell destruction. Hypokalemia (potassium depletion) may occur later with fluid shifts and inadequate potassium replacement.

Pulmonary Alterations

Approximately 10% to 20% of patients admitted to burn centers have an inhalation injury. The presence of this injury increases the hospital length of stay, is a determinant of the severity of injury, and increases mortality and morbidity (Palmieri, 2007). An inhalation injury occurs when a person is trapped inside a burning structure or involved in an explosion that leads to the inhalation of superheated air and noxious gas (McCall & Cahill, 2005).

Deterioration in severely burned patients can occur without obvious evidence of a smoke inhalation injury. Bronchoconstriction (caused by release of histamine, serotonin, and thromboxane, a powerful vasoconstrictor) and chest constriction secondary to circumferential full-thickness chest burns cause this deterioration. Even without pulmonary injury, hypoxia (oxygen starvation) may be present. Early in the postburn period, catecholamine release in response to the stress of the burn injury alters peripheral blood flow, thereby reducing oxygen delivery to the periphery. Later, hypermetabolism and continued catecholamine release lead to increased tissue oxygen consumption, which can lead to hypoxia. To ensure that adequate oxygen is available to the tissues, supplemental oxygen may be needed.

Pulmonary injuries are categorized as upper airway injury or inhalation injury below the glottis. Upper airway injury results from inhalation of direct heat greater than 150°C (302°F) to the epithelium. This damage results in severe upper airway edema, which can cause obstruction of the upper airway, including the pharynx and larynx, in the early hours postburn (Palmieri, 2007). Because of the cooling effect of rapid vaporization in the pulmonary tract, direct heat injury does not normally occur below the level of the bronchus. Upper airway injury is treated by early nasotracheal or endotracheal intubation.

Inhalation injury below the glottis results from inhaling the products of incomplete combustion or noxious gases. Inhalation of noxious gases is often the source of death at the scene of a fire. These products include carbon monoxide, cyanide, ammonia, aldehydes, acrolein, sulfur dioxide, and isocyanates (Barillo, 2009; Kealey, 2009; Palmieri, 2007). Tissue hypoxia is the result of carbon monoxide inhalation. It combines with hemoglobin to form **carboxyhemoglobin**. The affinity of hemoglobin for carbon monoxide is 250 times greater than that for oxygen. This injury results

directly from chemical irritation of the pulmonary tissues at the alveolar level. Inhalation injuries below the glottis cause loss of ciliary action, hypersecretion, severe mucosal edema, and possibly bronchospasm. The pulmonary surfactant is reduced, resulting in atelectasis (collapse of alveoli). Expectoration of carbon particles in the sputum is the cardinal sign of this injury.

Treatment usually consists of early intubation and mechanical ventilation with 100% oxygen, which reduces the half-life of carboxyhemoglobin from 4 hours to 45 minutes (Kealey, 2009; Pham & Gibran, 2007). However, some patients require only oxygen therapy, depending on the extent of pulmonary injury and edema.

Restrictive pulmonary excursion may occur with full-thickness burns encircling the neck and thorax. Chest excursion may be greatly restricted, resulting in decreased tidal volume. In such situations, escharotomy is necessary.

Pulmonary abnormalities are not always immediately apparent. More than half of all patients with burn injuries with pulmonary involvement do not initially demonstrate pulmonary signs and symptoms. Any patient with possible inhalation injury must be observed for at least 24 hours for respiratory complications. Airway obstruction may occur very rapidly or develop in hours, even while fluid resuscitation is under way. Decreased lung compliance, decreased arterial oxygen levels, and respiratory acidosis may occur gradually over the first 5 days after a burn.

Indicators of possible upper airway injury include (1) injury occurring in an enclosed space; (2) burns of the face or neck; (3) singed nasal hair; (4) hoarseness, high-pitched voice change, dry cough, stridor; (5) sooty or bloody sputum; (6) labored breathing or tachypnea (rapid breathing) and other signs of reduced oxygen levels (hypoxemia); and (7) erythema and blistering of the oral or pharyngeal mucosa.

Diagnosis of lower airway inhalation injury includes monitoring of arterial blood gases and carboxyhemoglobin levels and direct observation of the airway by fiberoptic bronchoscopy to confirm the clinical diagnosis. Findings on bronchoscopy include airway edema, inflammation, necrosis, and soot in the airway (Edelman, White, Tyburski, et al., 2006). Less frequently, xenon scan and computed tomography scans can be used to aid diagnosis but are of questionable value (Pham & Gibran, 2007).

Pulmonary complications secondary to inhalation injuries include sloughing of the airway, increased secretions and inflammation, atelectasis, airway obstruction and ulceration, pulmonary edema, and tissue hypoxia. As a result, respiratory failure and acute respiratory distress syndrome (ARDS) and pneumonia can develop (Edelman, et al., 2006). Respiratory failure and ARDS are discussed in Chapter 23.

Renal Alterations

Renal function may be altered as a result of decreased blood volume. Destruction of red blood cells at the injury site results in free hemoglobin in the urine. If muscle damage occurs (eg, from electrical burns), myoglobin is released from the muscle cells and excreted by the kidneys. Adequate fluid volume replacement restores renal blood flow, increasing the glomerular filtration rate and urine volume. If there

is inadequate blood flow through the kidneys, the hemoglobin and myoglobin occlude the renal tubules, resulting in acute tubular necrosis and renal failure (see Chapter 44).

Immunologic Alterations

The immunologic defenses of the body are greatly altered by a burn injury. Patients with burn injury are at high risk for infection and sepsis. The skin is the largest barrier to infection, and when it is compromised, the patient is continually exposed to the environment. The loss of skin integrity is compounded by the release of abnormal inflammatory factors, altered levels of immunoglobulins and serum complement, impaired neutrophil function, and a reduction in lymphocytes (lymphocytopenia). These alterations result in immunosuppression and increase the risk for sepsis. As a result, the major cause of death in the burn patient who survives after 24 hours is multiple organ dysfunction syndrome (MODS) (Greenhalgh, 2007). Most burn centers are specifically designed to provide an infection-controlled environment to protect the patient and minimize exposure to potentially harmful organisms.

Thermoregulatory Alterations

Loss of skin also results in an inability to regulate body temperature. Patients with burn injuries may therefore exhibit low body temperatures in the early hours after injury. Then, as hypermetabolism resets core temperature, the patient becomes hypothermic for much of the postburn period, even in the absence of infection. Most burn centers have heat panels at the bedside and additional heating sources to help maintain the patient's body temperature.

Gastrointestinal Alterations

Two potential gastrointestinal (GI) complications may occur: paralytic ileus (absence of intestinal peristalsis) and Curling's ulcer. Decreased peristalsis and bowel sounds are manifestations of paralytic ileus resulting from burn trauma. Gastric distention and nausea may lead to vomiting unless gastric decompression is initiated. Gastric bleeding secondary to massive physiologic stress may be signaled by occult blood in the stool, regurgitation of "coffee ground" material from the stomach, or bloody vomitus. These signs suggest gastric or duodenal erosion (Curling's ulcer).

Other alterations affect the GI tract after burn injury: the mucosal barrier becomes permeable, the permeability allows for overgrowth of GI bacteria, and the bacteria translocate to other organs, causing infection. Patients are unable to defend against their own bacteria due to immunosuppression. In addition, alcohol ingestion, which is common in the burn population, affects GI integrity and immune response, further increasing the risk of infection and possible bleeding complications (Gosain & Gamelli, 2005a).

Patients with large TBSA burns are also at risk for abdominal compartment syndrome (ACS). During resuscitation, fluid shifts into the abdominal cavity, causing increased abdominal distention, decreased urine output, hypotension, and respiratory insufficiency. The development of ACS is related to the volume of fluids administered. Factors such as the presence of inhalation injury, deep thermal injury, glucosuria, delayed or inadequate

resuscitation, and hemoglobinuria may necessitate additional fluids that may not be calculated by formulas. Bladder pressure is measured to determine the need for invasive intervention to treat increasing abdominal pressure. Bladder pressures greater than 25 mm Hg over time indicate increasing abdominal pressure. Although the prevention of this complication is not always possible, cautious and continuous measurement of fluids administered and urine output is essential (Hershberger, Hunt, Arnoldo, et al., 2007).

Management of Burn Injury

Burn care is typically categorized into three phases of care: emergent/resuscitative phase, acute/intermediate phase, and rehabilitation phase. Although priorities exist for each of the phases, the phases overlap, assessment, and management of specific problems and complications are not limited to these phases but take place throughout burn care. The three phases and the priorities for care are summarized in Table 57-2.

EMERGENT/RESUSCITATIVE PHASE

On-the-Scene Care

Preventing injury to the rescuer is the first priority of on-the-scene care. If needed, fire and emergency medical services should be requested at the first opportunity. Usually, rescue workers cover the wound, establish an airway, supply oxygen, and insert at least one large-bore intravenous (IV) line. Chart 57-3 describes the procedures and care required at the burn scene.

The burned person's appearance can be frightening at first. Although the local effects of a burn are the most evident, the systemic effects pose greater threats to life. A primary survey of the patient is carried out to assess the airway (A), gas exchange or breathing (B), and circulatory status (C) as well as the need for cervical spine immobilization and cardiac monitoring for patients with high-voltage electrical injuries. The circulatory system must be assessed quickly. Apical pulse and blood pressure are monitored frequently. Tachycardia (abnormally rapid heart rate) and

slight hypotension are expected soon after the burn. In the patient with extensive burns, neurologic status is assessed quickly. Often the patient is awake and alert initially, and vital information can be obtained at that time.

NURSING ALERT

Breathing must be assessed and a patent airway established immediately during the initial minutes of emergency care. Immediate therapy is directed toward establishing an airway and administering humidified 100% oxygen. If such a high concentration of oxygen is not available under emergency conditions, oxygen by mask or nasal cannula is given initially. If qualified personnel and equipment are available and the victim has severe respiratory distress or airway edema, the rescuers can insert an endotracheal tube and initiate manual ventilation.

NURSING ALERT

No food or fluid is given by mouth, and the patient is placed in a position that will prevent aspiration of vomitus, because nausea and vomiting typically occur due to paralytic ileus resulting from the stress of injury.

The secondary survey focuses on the completion of the total body system assessment, including the mechanism of injury, inhalation injury, and presence of corneal injury. A secondary head-to-toe survey of the patient is carried out to identify other potentially life-threatening injuries (Shukla & Sheridan, 2008).

Medical Management

The patient is transported to the nearest emergency department (ED). The hospital and physician are alerted that the patient is en route so that life-saving measures can be initiated immediately by a trained team and plans for referral to a burn center can be made.

Initial priorities in the ED remain airway, breathing, and circulation. For mild pulmonary injury, 100% humidified

Table 57-2 PHASES OF BURN CARE

Phase	Duration	Priorities
Emergent/resuscitative	From onset of injury to completion of fluid resuscitation	<ul style="list-style-type: none"> • First aid • Prevention of shock • Prevention of respiratory distress • Detection and treatment of concomitant injuries
Acute/intermediate	From beginning of diuresis to near completion of wound closure	<ul style="list-style-type: none"> • Wound assessment and initial care • Wound care and closure • Prevention or treatment of complications, including infection
Rehabilitation	From major wound closure to return to individual's optimal level of physical and psychosocial adjustment	<ul style="list-style-type: none"> • Nutritional support • Prevention of scars and contractures • Physical, occupational, and vocational rehabilitation • Functional and cosmetic reconstruction • Psychosocial counseling

Chart 57-3 • Emergency Procedures at the Burn Scene

- **Extinguish the flames.** When clothes catch fire, the flames can be extinguished if the person falls to the floor or ground and rolls (“stop, drop, and roll”); anything available to smother the flames, such as a blanket, rug, or coat, may be used. Standing still forces the person to breathe flames and smoke, and running fans the flames. If the burn source is electrical, the electrical source must be disconnected safely.
- **Cool the burn.** After the flames are extinguished, the burned area and adherent clothing are soaked with *cool* water, briefly, to cool the wound and halt the burning process. Once a burn has been sustained, the application of cool water is the best first-aid measure. However, *never* apply ice directly to the burn, *never* wrap the person in ice, and *never* use cold soaks or dressings for longer than several minutes; such procedures may worsen the tissue damage and lead to hypothermia in people with large burns.
- **Remove restrictive objects.** If possible, remove clothing immediately. Adherent clothing may be left in place once cooled. Other clothing and all jewelry, including all piercings, should be removed to allow for assessment and to prevent constriction secondary to rapidly developing edema.
- **Cover the wound.** The burn should be covered as quickly as possible to minimize bacterial contamination, to maintain body temperature, and decrease pain by preventing air from coming in contact with the injured surface. Sterile dressings are best, but any clean, dry cloth can be used as an emergency dressing. Ointments and salves should *not* be used. Other than the dressing, no medication or material should be applied to the burn wound.
- **Irrigate chemical burns.** Chemical burns resulting from contact with a corrosive material are irrigated immediately. Most chemical laboratories have a high-pressure shower for such emergencies. If such an injury occurs at home, brush off the chemical agent, remove clothes immediately, and rinse all areas of the body that have come in contact with the chemical. Rinsing can occur in the shower or any other source of continuous running water. If a chemical gets in or near the eyes, the eyes should be flushed with cool, clean water immediately. Outcomes for the patient with chemical burns are significantly improved by rapid, sustained flushing of the injury at the scene.

oxygen is administered and the patient is encouraged to cough so that secretions can be removed by suctioning. For more severe situations, it is necessary to remove secretions by bronchial suctioning and to administer bronchodilators and mucolytic agents. If edema of the airway develops, endotracheal intubation may be necessary. Continuous positive airway pressure and mechanical ventilation may also be required to achieve adequate oxygenation.

After adequate respiratory function and circulatory status have been established, the patient is assessed for cervical spinal injuries or head injury if he or she was involved in an explosion, a fall, a jump, or an electrical injury. Once the patient's condition is stable, attention is directed to the burn wound itself. All clothing and jewelry are removed. For chemical burns, flushing of the exposed areas is continued. The patient is checked for contact lenses. These are removed immediately if chemicals have contacted the eyes or if facial burns have occurred.

It is important to validate an account of the burn scenario provided by the patient, witnesses at the scene, and paramedics. Information needs to include the time of the burn injury, the source of the burn, the place where the burn occurred, how long the patient was in the burning structure, how the burn was treated at the scene, and any history of falling or jumping at the scene. A history of pre-existing diseases, allergies, medications, and the use of drugs, alcohol, and tobacco is obtained at this point to aid in planning the patient's care. A large-bore (16- or 18-gauge) IV catheter should be inserted in a nonburned area (if not inserted earlier). Most patients will have a central venous catheter inserted so that large amounts of IV fluids can be administered quickly and central venous pressures can be monitored.

If the burn exceeds 20% to 25% TBSA, a nasogastric tube is inserted and connected to low intermittent suction.

Often, patients with large burns become nauseated as a result of the GI effects of the burn injury, such as paralytic ileus, and the effects of medication, such as opioids. All patients who are intubated should have a nasogastric tube inserted to decompress the stomach and prevent vomiting.

The physician evaluates the patient's general condition, assesses the burn, determines the priorities of care, and directs the individualized plan of treatment, which is divided into systemic management and local care of the burned area. Nonsterile gloves, caps, masks and cover gowns are worn by personnel while assessing the exposed burned areas. Clean technique is maintained while assessing and treating the burn wounds.

Assessment of both the TBSA burned and the depth of the burn are completed after soot and debris have been gently cleansed from the burn wound. Careful attention is paid to keeping the patient warm during wound assessment and cleansing. Assessment is repeated frequently throughout burn wound care. Photographs may be taken of the burn areas initially and periodically throughout treatment; in this way, the initial injury and burn wound can be documented. Such documentation is invaluable for insurance and legal claims.

Clean sheets are placed under and over the patient to protect the burn wound from contamination, maintain body temperature, and reduce pain caused by air currents passing over exposed nerve endings. An indwelling urinary catheter is inserted to permit more accurate monitoring of urine output and renal function for patients with moderate to severe burns. Baseline height, weight, arterial blood gases, hematocrit, electrolyte values, blood alcohol level, drug panel, urinalysis, and chest x-rays are obtained. If the patient is elderly or has an electrical burn, a baseline electrocardiogram (ECG) is obtained. Because burns are contaminated wounds, tetanus prophylaxis is administered if

the patient's immunization status is not current or is unknown.

NURSING ALERT

If necessary, a blood pressure cuff can be placed around a patient's burned extremity. The cuff must be of the correct size with accommodations made for bulky dressings.

Although the major focus of care during the emergent phase is physical stabilization, the nurse must also attend to the patient's and family's psychological needs. Burn injury is a crisis, one that causes varying emotional responses. The patient's and family's coping abilities and available supports are assessed. Circumstances surrounding the burn injury should be considered when providing care. Individualized psychosocial support must be given to the patient and family. Because the patient is usually anxious and in pain, nurses should provide reassurance and support, explanations of procedures, and adequate pain relief. Because poor tissue perfusion accompanies burn injuries, only IV analgesia (usually morphine) is administered, titrated for the individual patient. If the patient wishes to see a spiritual advisor or counselor, one is notified.

Transfer to a Burn Center

Patients with the following types of injuries are referred to a burn center for evaluation and care: burns with partial-thickness injury greater than 10% or full-thickness burns in any age group; a burn in an area of the body that requires special attention, such as the face, hands, feet, genitalia, perineum, and over joints; and chemical, electrical, or inhalation burns. Patients with preexisting medical problems or who may have additional trauma that could complicate care should be referred. Children with burns are transferred if they cannot be managed by the available pediatric team. Lastly, any burn injury that carries special social, emotional, or rehabilitative need should be referred to a burn center where these needs are addressed more readily (Guidelines for the Operation of Burn Centers, 2007).

If the patient is to be transported to a burn center, the following measures, listed in order of importance, are instituted before transfer:

- A patent airway is ensured.
- Adequate peripheral circulation is established in any burned extremity.
- A secure IV catheter is inserted with lactated Ringer's solution infusing at the rate required to maintain a urine output of at least 30 mL per hour.
- An indwelling urinary catheter is inserted.
- Adequate pain relief is attained.
- Wounds are covered with a clean, dry sheet, and the patient is kept comfortably warm.

All assessments and treatments are documented, and this information is provided to the burn center personnel. The transferring facility must relay accurate vital signs, temperature, and intake and output totals to burn center personnel so that adequate fluid resuscitation measures will continue.

Management of Fluid Loss and Shock

Next to managing respiratory difficulties, the most urgent need is preventing irreversible shock by replacing lost fluids and electrolytes. As stated previously, survival of the patient with burn injury depends on adequate fluid resuscitation. Table 57-3 describes the fluid changes that occur in the emergent/resuscitative phase of care. Baseline weight and laboratory test results are obtained, and these parameters must be monitored closely in the immediate postburn (resuscitation) period. Both underresuscitation and overresuscitation are associated with poor outcome, and the optimal formula has not been identified; however, regardless of rate and composition of the fluids and colloids administered, diligent monitoring through the first 72 hours is critical to ensure optimal management (Pham, Cancio & Gilbran, 2008).

Fluid Replacement Therapy

The total volume and rate of IV fluid replacement are gauged by the patient's response and guided by the resuscitation formula. The adequacy of fluid resuscitation is determined by monitoring urine output totals, an index of renal

Table 57-3 FLUID AND ELECTROLYTE CHANGES IN THE EMERGENT/RESUSCITATIVE PHASE

Fluid accumulation phase (shock phase)
Plasma → interstitial fluid (edema at burn site)

Observation

Generalized dehydration
Reduction of blood volume
Decreased urinary output

Potassium (K^+) excess

Sodium (Na^+) deficit

Metabolic acidosis (base-bicarbonate deficit)
Hemoconcentration (elevated hematocrit)

Explanation

Plasma leaks through damaged capillaries
Secondary to plasma loss, fall of blood pressure, and diminished cardiac output
Secondary to:

Fluid loss

Decreased renal blood flow

Sodium and water retention caused by increased adrenocortical activity

Hemolysis of red blood cells, causing hemoglobinuria and myonecrosis or myoglobinuria

Massive cellular trauma causes release of K^+ into extracellular fluid (ordinarily, most K^+ is intracellular)

Large amount of Na^+ is lost in trapped edema fluid and exudate and by shift into cells as K^+ is released from cells (ordinarily most Na^+ is extracellular)

Loss of bicarbonate ions accompanies sodium loss

Liquid blood component is lost into extravascular space

perfusion. Urine output totals of 0.5 to 1.0 mL/kg/h for adults have been used as resuscitation goals (Pham, et al., 2008).

NURSING ALERT

Clinical parameters are far more important in resuscitation than any formula. Indeed, the patient's individual response is the key to assessing the adequacy of fluid resuscitation.

Additional gauges of fluid requirements and response to fluid resuscitation include hematocrit and hemoglobin and serum sodium levels. Within the first 24 hours after injury, if the hematocrit and the hemoglobin levels decrease or if the urinary output exceeds 50 mL/h, the rate of IV fluid administration may be decreased. One goal is to maintain serum sodium levels in the normal range during fluid replacement.

Appropriate resuscitation endpoints for patients with burn injuries remain unresolved, although some studies have examined hemodynamic and oxygen transport as resuscitation endpoints. Successful resuscitation is associated with increased delivery of oxygen and consumption of oxygen with declining serum lactate levels (Demling, 2005a). Factors associated with increased fluid requirements include delayed resuscitation, full-thickness injury, and presence of inhalation injuries. A State-of-the-Science in Burn Care conference was held in 2006 to identify the focus of research in the next decade. Overresuscitation was identified as a high-priority topic along with a need to identify endpoints for resuscitation (Pham, et al., 2008).

Fluid Requirements

The projected fluid requirements for the first 24 hours are calculated by the clinician based on the extent of the burn injury. Some combination of fluid categories may be used, including colloids (whole blood, plasma, and plasma expanders) and crystalloids/electrolytes (physiologic sodium chloride or lactated Ringer's solution). Adequate fluid resuscitation results in slightly decreased blood volume levels during the first 24 postburn hours and restoration of plasma levels to normal by the end of 48 hours. Formulas have been developed for estimating fluid loss based on the estimated percentage of burned TBSA and the weight of the patient. TBSA greater than 20% to 25% is associated with increased capillary permeability and intravascular fluid shifts that are most profound in the first 24 hours postburn (Pham, et al., 2008).

Oral and enteral resuscitation can be successful in adults with less than 20% TBSA burned (Atiyeh, Gunn & Hayek, 2005). Intravenous resuscitation is recommended when burn TBSA is greater than 20% (Pham, et al., 2008).

Although there is no consensus on the formulas for resuscitation, currently the most popular formula provides for the volume of an isotonic solution to be administered during the first 24 hours in a range of 2 to 4 mL/kg per percentage of TBSA burned. As with the other formulas, half of the calculated total should be given over the first

8 postburn hours, and the other half should be given over the next 16 hours. The hourly rate and volume of the infusion are modified based on the patient's response (Pham, et al., 2008). Clinicians should take note that the resuscitation formulas serve only as guidelines, and the patient's response to fluid therapy is the best parameter to use (Atiyeh, et al., 2005).

With large burns, there is a failure of the sodium–potassium pump (a physiologic mechanism involved in fluid–electrolyte balance) at the cellular level. Therefore, patients with very large burns may need proportionately more milliliters of fluid per percentage of burn than those with smaller burns. Also, patients with electrical injury, inhalation injury, or delayed fluid resuscitation and those who were burned while intoxicated may need additional fluids.

The following example illustrates the use of the consensus formula in a 70-kg (154-lb) patient with a 50% TBSA burn:

1. Formula: 2 to 4 mL/kg/% TBSA
2. $2 \text{ mL} \times 70 \text{ kg} \times 50 \text{ TBSA} = 7000 \text{ mL}/24 \text{ h}$
3. Plan to administer: first 8 hours = 3500 mL, or 437 mL/h; next 16 hours = 3500 mL, or 219 mL/h

Most fluid replacement formulas use isotonic electrolyte solutions. Regardless of which standard replacement formula is used, the patient receives approximately the same fluid volume and sodium replacement during the first 48 hours.

Another fluid replacement method requires hypertonic electrolyte solutions. The goal is to deliver smaller amounts of fluid and maintain the same urine output. Hypertonic resuscitation increases the osmolarity of the blood and encourages a shift of fluid into the intravascular space from the interstitial space. Careful monitoring of serum sodium level is required to prevent hypernatremia and acute renal failure (Pham, et al., 2008).

The use of colloids during resuscitation has been the subject of much controversy. Administration of large volumes of crystalloid during resuscitation decreases the protein content in the blood. Proteins help to prevent the movement of fluid and decrease edema. The purpose of adding colloid to the formula is to decrease the amount of fluid needed and also prevent massive edema formation. In contrast, some clinicians believe that after 24 hours the integrity of the capillaries begins to be restored and the use of colloids during that time would not be advantageous. These theories require further study (Pham, et al., 2008).

NURSING ALERT

Formulas are only a guide. The patient's response, evidenced by heart rate, blood pressure, and urine output, is the primary determinant of actual fluid therapy and must be assessed at least hourly. Patient outcomes are improved by optimal fluid resuscitation.

Nursing Management

Nursing assessment in the emergent phase of burn injury focuses on the major priorities for any trauma patient; the burn wound is a secondary consideration. Aseptic management of the burn wounds and invasive lines continues.

The nurse monitors vital signs frequently. Respiratory status is monitored closely, and apical, carotid, and femoral pulses are evaluated particularly in areas of circumferential burn injury to an extremity. Cardiac monitoring is indicated initially or if the patient has a history of cardiac disease, electrical injury, or respiratory conditions.

If all extremities are burned, determining blood pressure may be difficult. A sterile dressing applied under the blood pressure cuff protects the wound from contamination. Because increasing edema makes blood pressure difficult to auscultate, a Doppler (ultrasound) device or a noninvasive electronic blood pressure device may be helpful. In patients with severe burns, an arterial catheter is used for blood pressure measurement and for collecting blood specimens. Peripheral pulses of burned extremities are checked hourly; the Doppler device is useful for this. Elevation of burned upper extremities above the level of the heart is crucial to decrease edema. Elevation of the lower extremities on pillows and of the upper extremities on pillows or by suspension using IV poles may be helpful.

Large-bore IV catheters and an indwelling urinary catheter are inserted, if not already in place, and the nurse's assessment includes monitoring of fluid intake and output. Urine output, an indicator of renal perfusion, is monitored carefully and measured hourly. The amount of urine first obtained when the urinary catheter was inserted is recorded. This may assist in determining the extent of preburn renal function and fluid status.

Burgundy-colored urine suggests the presence of hemochromogen and myoglobin resulting from muscle damage. This is associated with deep burns caused by electrical injury or prolonged contact with flames. Glycosuria, a common finding in the early postburn hours, results from the release of stored glucose from the liver in response to stress.

Although not responsible for prescribing the fluids the nurse should be able to calculate the patient's expected fluid requirements. Infusion pumps are used to deliver a complex regimen of IV fluids prescribed. Administering and monitoring IV therapy are major nursing responsibilities. Strict monitoring of fluid intake and output is essential during the resuscitative phase along with reporting laboratory values and reporting patient responses to the physician.

Body temperature, body weight, preburn weight, and history of allergies, tetanus immunization, past medical and surgical disorders, current illnesses, and a list of current medications are essential to help guide medication needs for the patient. A head-to-toe assessment is performed, focusing on signs and symptoms of concomitant illness, associated injury, or developing complications. If the patient has facial burns, his or her eyes should be examined for injury to the corneas. An ophthalmologist is consulted for complete assessment via fluorescent staining.

Assessing the extent of the burn wound continues and is facilitated with anatomic diagrams (described previously). In addition, the nurse works with the physician to assess the depth of the wound and areas of full-thickness and partial-thickness injury. Assessment of the circumstances surrounding the injury is important. Obtaining a history of the burn injury can help in planning the care for the patient. Assessment should include the time of injury, mechanism of burn, whether the burn occurred in a closed space, the possibility

of inhalation of noxious chemicals, and any related trauma. The neurologic assessment focuses on the patient's level of consciousness, psychological status, pain and anxiety levels, and behavior.

The patient's and family's understanding of the injury and treatment is assessed as well. A family meeting upon admission is helpful to explain the detail of the patient's injuries and the course of treatment. Ethical dilemmas, such as those discussed in Chart 57-4, may also occur during hospitalization.

Nursing care of the patient during the emergent/resuscitative phase of burn injury is detailed in the plan of nursing care in Chart 57-5.

Gerontologic Considerations

Comorbid conditions coupled with the burn injury contribute to the high mortality rates of patients 65 years and older. Demling (2005b) reported that more than 60% of elderly patients with burn injuries admitted to the hospital had moderate to severe protein-energy malnutrition, which contributed to an increase in infection compared with well-nourished elderly burn patients. Decreased function of the cardiovascular, renal, and pulmonary systems increases the need for close observation of elderly patients with even relatively minor burns during the emergent and acute phases. Acute renal failure is much more common in elderly patients than in those younger than 40 years of age. The margin of difference between hypovolemia and fluid overload is very small. Suppressed immunologic response, a high incidence of malnutrition, and an inability to withstand metabolic stressors (eg, a cold environment) further compromise the elderly person's ability to heal. As a result of these issues in elderly patients who sustain burn injury, close monitoring and prompt treatment of complications are mandatory.

ACUTE/INTERMEDIATE PHASE

The acute/intermediate phase of burn care follows the emergent/resuscitative phase and begins 48 to 72 hours after the burn injury. During this phase, attention is directed toward continued assessment and maintenance of respiratory and circulatory status, fluid and electrolyte balance, and GI function. Infection prevention, burn wound care (ie, wound cleaning, topical antibacterial therapy, wound dressing, dressing changes, wound débridement, and wound grafting), pain management, and nutritional support are priorities at this stage and are discussed in detail in the following sections.

Medical Management

Airway obstruction caused by upper airway edema can take as long as 48 hours to develop. Changes detected by x-ray and arterial blood gas analysis may occur as the effects of resuscitative fluid and the chemical reactions of smoke ingredients with lung tissues become apparent. Pulmonary complications are not unusual in burn injury. Those with ventilator-associated pneumonia (VAP) have a 40% mortality rate, increasing to 60% to 77% for VAP with an inhalation injury. Bronchial washing or bronchoalveolar lavage can assist in the diagnosis and treatment of pneumonia (Wahl, Ahrns, Brandt, et al., 2005). Ideally, the best practice

Ethics and Related Issues

How Much Is Enough and What Is Comfort Care?

Situation

A 71-year-old woman was flown to the nearest burn center. She lives alone and was cooking on top of a gas stove. She reached over the burner and caught her robe on fire. The flame consumed most of her upper body. She sustained a full-thickness burn to 42% of her body (face, neck, both arms, and chest). In addition, she turned to remove herself from the room quickly, slipped, and fell, fracturing two ribs and spraining her right ankle. Due to the nature of the fire she was enclosed in a burning area so she also sustained an upper airway inhalation injury. She was awake and alert at the scene and indicated a past medical history of diabetes, hypertension, and renal disease. She was in little pain at the time due to the depth of the burn injury; however, she was asking the team questions related to the survivability of her injury, "Am I going to die?"

Upon admission she was intubated to treat her upper airway edema and suspected inhalation injury. Family arrived and the burn surgeon explained the extent of injury. A decision was made to proceed with care and assess her progress postresuscitation. They were prepared for a future decision regarding withdrawal of care if survival becomes futile.

Dilemma

Initial resuscitation has occurred and approximately 4 days postburn the patient begins to show signs of renal failure. She has had one surgical procedure for débridement and grafting to her chest, and although grafts are intact, they do not look healthy. She is showing increased signs of discomfort and pain due to the operative procedure and the addition of another wound (the new donor site). The family decides in a team meeting that they do not want to initiate hemodialysis and therefore place the patient on comfort measures. Approximately 3 days later she remains on comfort care and

has increased signs of restlessness and pain. The nurse caring for the patient requests an order from the physician for an increase in pain medication from 5 mg morphine to 10 mg IV. Within 2 hours after administration the patient expired without discomfort. Six months later the facility is contacted by an attorney and informed that the family is taking legal action against the nurse and physician for performing euthanasia on their mother.

Discussion

The burn team is faced with these types of ethical dilemmas on a regular basis. Whenever possible the team should attempt to elicit the patient's wishes as early as possible, including any advanced directives. This should be considered again prior to intubation unless it is an emergency situation. The problem in this case is that due to absence of pain it is often difficult for a patient to understand the severity of his or her burn injury. The patient begins to experience increased pain as care progresses and increased medication is expected. Once the patient is unable to make decisions for herself, family members assume this responsibility. Clear and documented discussions with the family are essential for communication. Decision makers should always make decisions based on what the patient would want them to do, not their individual concerns. They often have difficulty making comfort care decisions; not all family members always agree. If death does not occur rapidly after a decision, they have feelings of remorse and guilt.

Discussion Questions

1. As a member of the team when the patient arrived at your facility, what would you have done differently?
2. Do you believe this was a survivable injury?
3. Given the failing renal status of the patient, do you believe additional medication should have been administered?
4. Do you believe there is reason for the family to seek legal action for their mother's death?

is to remove the endotracheal tube as soon as possible so that a route for pathogens is not accessible to the lungs. The arterial blood gas values and other parameters determine the need for intubation and mechanical ventilation.

As capillaries regain integrity, 48 or more hours after the burn, fluid moves from the interstitial to the intravascular compartment and diuresis begins (Table 57-4). If cardiac or renal function is inadequate, for example in an elderly patient or in a patient with preexisting cardiac disease, fluid overload occurs and symptoms of congestive heart failure may result (see Chapter 30).

Cautious administration of fluids and electrolytes continues during this phase of burn care because of the shifts in fluid from the interstitial to the intravascular compartment, losses of fluid from large burn wounds, and the patient's physiologic responses to the burn injury. Blood components are administered as needed to treat blood loss and anemia.

Fever is common in patients after burn shock resolves. A resetting of the core body temperature in severely burned patients results in a body temperature a few degrees higher than normal for several weeks after the burn. Bacteremia and septicemia also cause fever in many patients. Acetaminophen (Tylenol) and hypothermia blankets and

Table 57-4 FLUID AND ELECTROLYTE CHANGES IN THE ACUTE PHASE

Fluid remobilization phase (state of diuresis)
Interstitial fluid → plasma

Observation	Explanation
Hemodilution (decreased hematocrit)	Blood cell concentration is diluted as fluid enters the intravascular compartment; loss of red blood cells destroyed at burn site.
Increased urinary output	Fluid shift into intravascular compartment increases renal blood flow and causes increased urine formation.
Sodium (Na ⁺) deficit	With diuresis, sodium is lost with water; existing serum sodium is diluted by water influx.
Potassium (K ⁺) deficit (occurs occasionally in this phase)	Beginning on the fourth or fifth postburn day, K ⁺ shifts from extracellular fluid into cells.
Metabolic acidosis	Loss of sodium depletes fixed base; relative carbon dioxide content increases.

ancillary heating devices may be required to maintain body temperature in a range of 37.2°C to 38.3°C (99°F to 101°F) so as to reduce metabolic stress and tissue oxygen demand.

CHART
57-5

PLAN OF NURSING CARE

Care of the Patient During the Emergent/Resuscitative Phase of Burn Injury

NURSING DIAGNOSIS: Impaired gas exchange related to carbon monoxide poisoning, smoke inhalation, and upper airway obstruction

GOAL: Maintenance of adequate tissue oxygenation

Nursing Interventions

1. Provide humidified oxygen.
2. Assess breath sounds, and respiratory rate, rhythm, depth, and symmetry. Monitor patient for signs of hypoxia.
3. Observe for the following:
 - a. Erythema or blistering of lips or buccal mucosa
 - b. Singed nostrils
 - c. Burns of face, neck, or chest
 - d. Increasing hoarseness
 - e. Soot in sputum or tracheal tissue in respiratory secretions
4. Monitor arterial blood gas values, pulse oximetry readings, and carboxyhemoglobin levels.
5. Report labored respirations, decreased depth of respirations, or signs of hypoxia to physician immediately.
6. Prepare to assist with intubation and escharotomies.
7. Monitor mechanically ventilated patient closely.

Rationale

1. Humidified oxygen provides moisture to injured tissues; supplemental oxygen increases alveolar oxygenation.
2. These factors provide baseline data for further assessment and evidence of increasing respiratory compromise.
3. These signs indicate possible inhalation injury and risk of respiratory dysfunction.
4. Increasing PaCO₂ and decreasing PaO₂ and O₂ saturation may indicate need for mechanical ventilation.
5. Immediate intervention is indicated for respiratory difficulty.
6. Intubation allows mechanical ventilation. Escharotomy enables chest excursion in circumferential chest burns.
7. Monitoring allows early detection of decreasing respiratory status or complications of mechanical ventilation.

Expected Outcomes

- Absence of dyspnea
- Respiratory rate between 12 and 20 breaths/min
- Lungs clear on auscultation
- Arterial oxygen saturation greater than 96% by pulse oximetry
- Arterial blood gas levels within normal limits

NURSING DIAGNOSIS: Ineffective airway clearance related to edema and effects of smoke inhalation

GOAL: Maintain patent airway and adequate airway clearance

Nursing Interventions

1. Maintain patent airway through proper patient positioning, removal of secretions, and artificial airway if needed.
2. Provide humidified oxygen.
3. Encourage patient to turn, cough, and deep breathe. Encourage patient to use incentive spirometry. Suction as needed.

Rationale

1. A patent airway is crucial to respiration.
2. Humidity liquefies secretions and facilitates expectoration.
3. These activities promote mobilization and removal of secretions.

Expected Outcomes

- Patent airway
- Respiratory secretions are minimal, colorless, and thin
- Respiratory rate, pattern, and breath sounds normal

NURSING DIAGNOSIS: Fluid volume deficit related to increased capillary permeability and evaporative losses from the burn wound

GOAL: Restoration of optimal fluid and electrolyte balance and perfusion of vital organs

Nursing Interventions

1. Observe vital signs (including central venous pressure or pulmonary artery pressure, if indicated) and urine output, and be alert for signs of hypovolemia or fluid overload.
2. Monitor urine output at least hourly and weigh patient daily.

Rationale

1. Hypovolemia is a major risk immediately after the burn injury. Overresuscitation might cause fluid overload.
2. Output and weight provide information about renal perfusion, adequacy of fluid replacement, and fluid requirement and fluid status.

Expected Outcomes

- Serum electrolytes within normal limits
- Urine output between 0.5 and 1.0 mL/kg/h
- Blood pressure higher than 90/60 mm Hg
- Heart rate less than 120 beats/min
- Exhibits clear sensorium
- Voids clear yellow urine with specific gravity within normal limits

PLAN OF NURSING CARE
Care of the Patient During the Emergent/Resuscitative Phase of Burn Injury (Continued)

Nursing Interventions <ol style="list-style-type: none"> Maintain IV lines and regulate fluids at appropriate rates, as prescribed. Observe for symptoms of deficiency or excess of serum sodium, potassium, calcium, phosphorus, and bicarbonate. Elevate head of patient's bed and elevate burned extremities. Notify physician immediately of decreased urine output, blood pressure, central venous, pulmonary artery, or pulmonary artery wedge pressures, or increased pulse rate. 	Rationale <ol style="list-style-type: none"> Adequate fluids are necessary to maintain fluid and electrolyte balance and perfusion of vital organs. Rapid shifts in fluid and electrolyte status are possible in the postburn period. Elevation promotes venous return. Because of the rapid fluid shifts in burn shock, fluid deficit must be detected early so that distributive shock does not occur. 	Expected Outcomes
NURSING DIAGNOSIS: Hypothermia related to loss of skin microcirculation and open wounds GOAL: Maintenance of adequate body temperature		
Nursing Interventions <ol style="list-style-type: none"> Provide a warm environment through use of heat shield, space blanket, heat lights, or blankets. Work quickly when wounds must be exposed. Assess core body temperature frequently. 	Rationale <ol style="list-style-type: none"> A stable environment minimizes evaporative heat loss. Minimal exposure minimizes heat loss from wound. Frequent temperature assessments help detect developing hypothermia. 	Expected Outcomes <ul style="list-style-type: none"> Body temperature remains 36.1°C to 38.3°C (97°F to 101°F) Absence of chills or shivering
NURSING DIAGNOSIS: Pain related to tissue and nerve injury and emotional impact of injury GOAL: Control of pain		
Nursing Interventions <ol style="list-style-type: none"> Use pain intensity scale to assess pain level (ie, 1 to 10). Differentiate restlessness due to pain from restlessness due to hypoxia. Administer intravenous opioid analgesics as prescribed. Observe for respiratory depression in the patient who is not mechanically ventilated. Assess response to analgesic. Provide emotional support and reassurance. 	Rationale <ol style="list-style-type: none"> Pain level provides baseline for evaluating effectiveness of pain relief measures. Hypoxia can cause similar signs and must be ruled out before analgesic medication is administered. Intravenous administration is necessary because of altered tissue perfusion from burn injury. Emotional support is essential to reduce fear and anxiety resulting from burn injury. Fear and anxiety increase the perception of pain. 	Expected Outcomes <ul style="list-style-type: none"> States pain level is decreased Absence of nonverbal cues of pain
NURSING DIAGNOSIS: Anxiety related to fear and the emotional impact of burn injury GOAL: Minimization of patient's and family's anxiety		
Nursing Interventions <ol style="list-style-type: none"> Assess patient's and family's understanding of burn injury, coping skills, and family dynamics. Individualize responses to the patient's and family's coping level. 	Rationale <ol style="list-style-type: none"> Previous successful coping strategies can be fostered for use in the present crisis. Assessment allows planning of individualized interventions. Reactions to burn injury are extremely variable. Interventions must be appropriate to the patient's and family's present level of coping. 	Expected Outcomes <ul style="list-style-type: none"> Patient and family verbalize understanding of emergent burn care Able to answer simple questions

PLAN OF NURSING CARE

Care of the Patient During the Emergent/Resuscitative Phase of Burn Injury (Continued)

Nursing Interventions	Rationale	Expected Outcomes
<ol style="list-style-type: none"> 3. Explain all procedures to the patient and the family in clear, simple terms. 4. Maintain adequate pain relief. 5. Consider administering prescribed antianxiety medications if the patient remains extremely anxious despite nonpharmacologic interventions. 	<ol style="list-style-type: none"> 3. Increased understanding alleviates fear of the unknown. High levels of anxiety may interfere with understanding of complex explanations. 4. Pain increases anxiety. 5. Anxiety levels during the emergent phase may exceed the patient's coping abilities. Medication decreases physiologic and psychological anxiety responses. 	
<p>COLLABORATIVE PROBLEMS: Acute respiratory failure, distributive shock, acute renal failure, compartment syndrome, paralytic ileus, Curling's ulcer GOAL: Absence of complications</p>		
Nursing Interventions	Rationale	Expected Outcomes
<p>Acute Respiratory Failure</p> <ol style="list-style-type: none"> 1. Assess for increasing dyspnea, stridor, changes in respiratory patterns. 2. Monitor pulse oximetry, arterial blood gas values for decreasing PaO₂ and oxygen saturation, and increasing PaCO₂. 3. Monitor chest x-ray results. 4. Assess for restlessness, confusion, difficulty attending to questions, or decreasing level of consciousness. 5. Report deteriorating respiratory status immediately to physician. 6. Prepare to assist with intubation or escharotomies as indicated. <p>Distributive Shock</p> <ol style="list-style-type: none"> 1. Assess for decreasing urine output and blood pressure as well as increasing pulse rate. (If hemodynamic monitoring is used, assess for decreasing pulmonary artery and pulmonary artery wedge pressures and cardiac output.) 2. Assess for progressive edema as fluid shifts occur. 3. Adjust fluid resuscitation in collaboration with the physician in response to physiologic findings. <p>Acute Renal Failure</p> <ol style="list-style-type: none"> 1. Monitor urine output and blood urea nitrogen (BUN) and serum creatinine levels. 2. Report decreased urine output or increased BUN and creatinine values to physician. 3. Assess urine for hemoglobin or myoglobin. 	<ol style="list-style-type: none"> 1. Such signs reflect deteriorating respiratory status. 2. Such signs reflect decreased oxygenation status. 3. X-ray may disclose pulmonary injury. 4. Such manifestations may indicate cerebral hypoxia. 5. Acute respiratory failure is life-threatening, and immediate intervention is required. 6. Intubation allows mechanical ventilation. Escharotomies allow improved chest excursion with respirations. <ol style="list-style-type: none"> 1. Such signs and symptoms may indicate distributive shock and inadequate intravascular volume. 2. As fluid shifts into the interstitial spaces in burn shock, edema occurs and may compromise tissue perfusion. 3. Optimal fluid resuscitation prevents distributive shock and improves patient outcomes. <ol style="list-style-type: none"> 1. These values reflect renal function. 2. These laboratory values indicate possible renal failure. 3. Hemoglobin or myoglobin in the urine points to an increased risk of renal failure. 	<ul style="list-style-type: none"> • Arterial blood gas values within acceptable limits: PaO₂ greater than 80 mm Hg, PaCO₂ less than 50 mm Hg • Breathes spontaneously with adequate tidal volume • Chest x-ray findings normal • Absence of cerebral signs of hypoxia <ul style="list-style-type: none"> • Urine output between 0.5 and 1.0 mL/kg/h • Blood pressure within patient's normal range (usually greater than 90/60 mm Hg) • Heart rate within patient's normal range (usually less than 110/min) • Pressures and cardiac output remain within normal limits <ul style="list-style-type: none"> • Adequate urine output • BUN and serum creatinine values remain normal

 CHART
57-5

PLAN OF NURSING CARE
Care of the Patient During the Emergent/Resuscitative Phase of Burn Injury (Continued)

Nursing Interventions	Rationale	Expected Outcomes
4. Administer increased fluids as prescribed.	4. Fluids help to flush hemoglobin and myoglobin from renal tubules, decreasing the potential for renal failure.	<ul style="list-style-type: none"> • Absence of paresthesias or symptoms of ischemia of nerves and muscles • Peripheral pulses detectable by Doppler
Compartment Syndrome	1. Assessment with Doppler device substitutes for auscultation and indicates characteristics of arterial blood flow. 2. These assessments indicate characteristics of peripheral perfusion. 3. Cuff may act as a tourniquet as extremities swell. 4. Elevation reduces edema formation. 5. These signs and symptoms may indicate inadequate tissue perfusion. 6. Escharotomies relieve the constriction caused by swelling under circumferential burns and improve tissue perfusion.	
1. Assess peripheral pulses hourly with Doppler ultrasound device. 2. Assess warmth, capillary refill, sensation, and movement of extremity hourly. Compare affected with unaffected extremity. 3. Remove blood pressure cuff after each reading. 4. Elevate burned extremities. 5. Report loss of pulse or sensation or presence of pain to physician immediately. 6. Prepare to assist with escharotomies.		<ul style="list-style-type: none"> • Absence of abdominal distention • Normal bowel sounds within 48 hours
Paralytic Ileus	1. This measure relieves gastric and abdominal distention, also prevents vomiting. 2. As bowel sounds resume, feeding may be slowly initiated. Abdominal distention reflects inadequate decompression.	
1. Maintain nasogastric tube on low intermittent suction until bowel sounds resume. 2. Auscultate for bowel sounds, abdominal distention.		
Curling's Ulcer	1. Acidic pH indicates need for antacids or histamine blockers. Blood indicates possible gastric bleeding. 2. Blood in stools may indicate gastric or duodenal ulcer. 3. Such medications reduce gastric acidity and risk of ulceration.	<ul style="list-style-type: none"> • Absence of abdominal distention • Normal bowel sounds within 48 hours • Gastric aspirate and stools do not contain blood
1. Assess gastric aspirate for pH and blood. 2. Assess stools for occult blood. 3. Administer histamine blockers and antacids as prescribed.		

Central venous, peripheral arterial, or pulmonary artery thermodilution catheters may be required for monitoring venous and arterial pressures, pulmonary artery pressures, pulmonary capillary wedge pressures, or cardiac output. It is not uncommon for patients with major burns to have multiple invasive line sites due to the amount and frequency of fluid and medication that need to be administered. Whenever possible, burned areas of the body are avoided as sites for insertion of invasive lines.

Infection Prevention

Infection progressing to sepsis is the major cause of death in patients who have survived the first few days after a major burn. Burn patients are at risk for infection for a few reasons. The loss of skin removes their ability to protect

themselves from the environment. The longer length of stay in the hospital predisposes them to hospital-associated infections. The number and frequency of invasive procedures, both in the patient room and in the operating room, increase the risk of infection. Lastly, immunosuppression that accompanies extensive burn injury places patients at high risk. The nursing goal is to provide protection and safety in the patients' environment to ultimately prevent or control infection in the burn population (Hodler, Richter & Thompson, 2006).

The burn wound is an excellent medium for bacterial growth and proliferation. The burn eschar is nonviable tissue and has no blood supply; therefore, neither leukocytes or antibodies nor systemic antibiotics can reach the area. More than 1 billion bacteria per gram of tissue may

be present and subsequently spread to the bloodstream or release their toxins, which reach distant sites. *Pseudomonas* is the major challenge in 44% of burn centers. Other common organisms are methicillin-resistant *Staphylococcus aureus* (MRSA) and *Acinetobacter*. Important but somewhat less common are *Staphylococcus* and vancomycin-resistant enterococci (VRE) (Hodley, et al., 2006). *Staphylococcus* and *Enterococci* are responsible for more than 50% of nosocomial bloodstream infections in patients with burn injuries. Other bacteria that are important in burn care include *Proteus*, *Escherichia coli*, and *Klebsiella*. Bloodstream infections are confirmed if two positive blood cultures are obtained or if one positive culture is obtained in the presence of clinical signs of sepsis (Greenhalgh, 2007). Fungi such as *Candida albicans* also grow easily in burn wounds.

Infection impedes burn wound healing by promoting excessive inflammation and damaging tissue. When the burn wound is healing through spontaneous reepithelialization or is being prepared for skin grafting, it must be protected from sepsis. Characteristics of burn wound sepsis are 10^5 bacteria per gram of tissue, inflammation or destruction of unburned skin, and invasive infection with or without signs of sepsis (Greenhalgh, 2007).

A primary source of bacterial infection is the patient's intestinal tract, the source of most microbes. The intestinal mucosa normally serves as a barrier to keep the internal environment free from a variety of pathogens. After a severe burn injury, the intestinal mucosa becomes markedly permeable (Gosain & Gamelli, 2005b), allowing microbial flora and endotoxins to pass freely into the systemic circulation and causing infection. Early enteral feeding is one strategy to help avoid increased intestinal permeability and prevent early endotoxin translocation (De-Souza & Greene, 2005).

A major secondary source of pathogenic microbes is the environment. Compliance with infection-control policies has been identified as the single greatest challenge along with the abundance of resistant organisms (Hodley, et al., 2006). Burn centers are designed with specific measures to reduce the risk of infection: private rooms and bathrooms; increased airflow within patient rooms to create a more positive airflow; low humidification to prevent bacterial growth; limited use of cloth (eg, patient privacy curtains, window treatments); accessibility of proper protective equipment such as caps, masks, gowns and gloves; convenient and available hand washing/hand hygiene areas; and room design with antidust and dirt collection areas.

Use of cap, gown, mask, and gloves is essential while caring for the patient with open burn wounds. Aseptic technique is used when caring directly for burn wounds. Gowns and gloves are worn by all caregivers and visitors; hand hygiene is used before and after leaving the patient room. Special instruction is given to all visitors with the goal of preventing the spread of infection because of the immunosuppression experienced by patients with burns.

Bacteria are found on all skin surfaces; by itself, their presence does not determine burn infection. Constant monitoring and observation of the wound (eg, changes in the wound, presence of purulent drainage, pain, and increasing depth of burn wound) are needed to detect wound infection. Tissue

specimens may be obtained for culture to monitor colonization (Greenhalgh, 2007). Antibiotics are seldom prescribed prophylactically because of the risk of promoting resistant strains of bacteria. Systemic antibiotics are administered when there is documented burn wound sepsis or other positive cultures such as urine, sputum, or blood. Sensitivity of the organisms to the prescribed antibiotics should be determined before administration. Careful attention is paid to antibiotic use in the burn unit because inappropriate use of antibiotics significantly affects the microbial flora present in the burn unit and increases the risk of drug resistance.

Wound Cleaning

Various measures are used to clean the burn wound, such as **hydrotherapy**. If the patient is ambulatory, the wounds can be cleansed in a shower. The wounds of nonambulatory patients can be cleansed using shower carts—mobile stretchers made with removable sides, drainage holes, and positioning capabilities. Retractable shower hoses suspended from walls and ceilings provide the nurse with easy access to a water source for washing the wounds. Unstable patients may have their wounds washed at the bedside. Total immersion hydrotherapy is rarely performed. Because of the high risk for infection and sepsis, the use of plastic liners, water filters, and thorough decontamination of hydrotherapy equipment and wound care areas is required to prevent cross-contamination. The temperature of the water is maintained at 37.8°C (100°F), and the temperature of the room should be maintained between 26.6°C and 29.4°C (80°F to 85°F). The duration of wound cleansing and dressing change is determined by the patient's ability to tolerate the treatment and to maintain a satisfactory body temperature.

During the bath, the patient is encouraged to be as active as possible. Hydrotherapy provides an excellent opportunity for exercising the extremities and cleaning the entire body. When the patient is removed, any residue adhering to the body is washed away with a clear water spray or shower. Unburned areas, including the hair, must be washed regularly as well. At the time of wound cleaning, all skin is inspected for any hints of redness, breakdown, or local infection. Hair in and around the burn area, except the eyebrows, should be clipped short or shaved. Intact blisters should be left alone and debrided only if they rupture or break.

Conscientious management of the burn wound is essential. When nonviable loose skin is removed, aseptic conditions must be established. Wound cleansing is usually performed daily in wound areas that are not undergoing surgical intervention. Mechanical débridement can be performed to remove loose nonviable tissue. However, surgical removal as soon as possible is preferred.

After the burn wounds are cleaned, they are gently patted dry, and the prescribed method of wound care is performed. Whatever the method is used, the goal is to protect the wound from overwhelming proliferation of pathogenic organisms and invasion of deeper tissues until either spontaneous healing or skin grafting can be achieved.

Patient comfort and ability to participate in the prescribed treatment are also important considerations. During the treatment, the patient is assessed for signs of chilling, fatigue, changes in hemodynamic status, and pain unrelieved by analgesic medications or relaxation techniques.

Topical Antibacterial Therapy

Variations in topical wound care for nonsurgical burn wounds exist among burn centers across the country and choices are made based on the individualized needs of each patient. There is general agreement that some form of antimicrobial therapy applied to the burn wound is an acceptable method of local care in extensive burn injury. Silver sulfadiazine is considered the gold standard for protecting wounds from infection (Caruso, Foster, Blome-Eberwein, et al., 2006). Topical antibacterial therapy becomes more important in the deep dermal and full-thickness injury because they are more prone to infection. Silver has been introduced into a variety of topical treatments because of its broad spectrum effectiveness against *Staphylococcus aureus* and *Pseudomonas aeruginosa* (Pham & Gibran, 2007). The goal of topical therapy is to provide a dressing that

- Is effective against gram-positive and gram-negative organisms and fungi,
- Penetrates the eschar but is not systemically toxic,

- Does not lose effectiveness or allow another infection to develop,
- Is cost-effective, available, and acceptable to the patient,
- Is easy to apply and remove, and decreases the frequency of dressing changes, decreases pain, and minimizes nursing time.

Table 57-5 describes three commonly used topical agents, silver sulfadiazine (Silvadene), silver nitrate, and mafenide acetate (Sulfamylon), two of which contain silver. Many other topical agents are available, including povidone-iodine ointment 10% (Betadine), gentamicin sulfate, nitrofurazone (Furacin), Dakin's solution, acetic acid, and antifungal agents (miconazole, clotrimazole, and mupirocin [Bactroban]). Bacitracin or a triple antibiotic agent may be used for facial burns or on skin grafts initially.

No single topical medication is universally effective, and use of different agents at different times in the postburn period may be necessary. Prudent use and alternation of antimicrobial agents result in less-resistant strains of bacteria, greater effectiveness of the agents, and a decreased risk of sepsis.

Agent	Indication/Comment	Application	Nursing Implications
Silver sulfadiazine 1% (Silvadene) water-soluble cream	<ul style="list-style-type: none"> • Most bactericidal agent • Minimal penetration of eschar 	Apply 1/16-inch layer of cream with a sterile glove 1–3 times daily.	<ul style="list-style-type: none"> • Watch for leukopenia 2–3 days after initiation of therapy. (Leukopenia usually resolves within 2–3 days.) • Anticipate formation of pseudo-eschar (proteinaceous gel), which is removed easily after 72 hours.
Mafenide acetate 5% to 10% (Sulfamylon) hydrophilic-based cream	<ul style="list-style-type: none"> • Effective against gram-negative and gram-positive organisms • Diffuses rapidly through eschar • In 10% strength, it is the agent of choice for electrical burns because of its ability to penetrate thick eschar 	Apply thin layer with sterile glove twice a day and leave open as prescribed; if the wound is dressed, change the dressing every 6 hours as prescribed.	<ul style="list-style-type: none"> • Monitor arterial blood gas levels and discontinue as prescribed, if acidosis occurs. Mafenide acetate is a strong carbonic anhydrase inhibitor that may reduce renal buffering and cause metabolic acidosis. • Premedicate the patient with an analgesic before applying mafenide acetate because this agent causes severe burning pain for up to 20 minutes after application.
Silver nitrate 0.5% aqueous solution	<ul style="list-style-type: none"> • Bacteriostatic and fungicidal • Does not penetrate eschar 	Apply solution to gauze dressing and place over wound. Keep the dressing wet but covered with dry gauze and dry blankets to decrease vaporization. Remoisten every 2 hours, and redress wound twice a day.	<ul style="list-style-type: none"> • Monitor serum sodium (Na^+) and potassium (K^+) levels and replace as prescribed. Silver nitrate solution is hypotonic and acts as wick for sodium and potassium. • Protect bed linen and clothing from contact with silver nitrate, which stains everything it touches black.
Acticoat	<ul style="list-style-type: none"> • Effective against gram-negative and gram-positive organisms and some yeasts and molds • Delivers a uniform, antimicrobial concentration of silver to the burn wound 	Moisten with sterile water only (never use normal saline). Apply directly to wound. Cover with absorbent secondary dressing. Remoisten every 3–4 hours with sterile water.	<ul style="list-style-type: none"> • Do not use oil-based products or topical antimicrobials with Acticoat burn dressing. Keep Acticoat moist, not saturated. May produce a “pseudo-eschar” from silver after application. • Can be left in place for 3–5 days. Also available in Acticoat 7, which can be left in place for up to 7 days without the need to change the dressing.

Wound Dressing

After wound cleaning, the burned areas are patted dry and the prescribed topical agent is applied; the wound is then covered with several layers of dressings. A light dressing is used over joint areas to allow for motion (unless the particular area has a graft and motion is contraindicated). A light dressing is also applied over areas for which a splint has been designed to conform to the body contour for proper positioning. Circumferential dressings should be applied distally to proximally. If the hand or foot is burned, the fingers and toes should be wrapped individually to promote adequate healing.

Burns to the face may be left open to air once they have been cleaned and the topical agent has been applied. Careful attention must be given to ensure that the topical agent does not interfere with the eyes or mouth. A light dressing can be applied to the face to absorb excess exudates that might run into the eyes, causing irritation.

Occlusive dressings may be used over areas with new skin grafts to protect the graft and promote an optimal condition for its adherence to the recipient site. An occlusive dressing is a thin gauze that is impregnated with a topical antimicrobial agent or is applied after application of a topical antimicrobial agent. Ideally, these dressings remain in place for 3 to 5 days, at which time they are removed for examination of the graft. When occlusive dressings are applied, precautions are taken to prevent two body surfaces from touching, such as fingers or toes, ear and scalp, the areas under the breasts, any point of flexion, or between the genital folds. Functional body alignment positions are maintained by using splints or by regular repositioning of the patient.

NURSING ALERT

Dressings impede circulation if they are too tightly wrapped. The peripheral pulses must be checked frequently and burned extremities elevated on two pillows. Extremities are always wrapped from distal to proximal to the heart. If the patient's pulse is diminished, this is a critical situation and must be addressed immediately.

Dressings that adhere to the wound can be removed more comfortably and without damaging healing tissue by moistening the wound with tap water. The remaining dressings are carefully and gently removed. The patient may participate in removing the dressings, providing some degree of control over this painful procedure. The wounds are then cleaned and débrided to remove any remaining topical agent, exudate, and dead skin. Sterile scissors and forceps may be used to trim loose eschar and encourage separation of devitalized skin. During this procedure, the wound and surrounding skin are carefully inspected. The color, odor, size, exudate, signs of reepithelialization, and other characteristics of the wound and the eschar and any changes from the previous dressing change are noted.

Wound Débridement

The goals of **débridement**, the removal of devitalized tissue, are:

- Removal of tissue contaminated by bacteria and foreign bodies, thereby protecting the patient from invasion of bacteria

- Removal of devitalized tissue or burn eschar in preparation for grafting and wound healing

There are three types of débridement—natural, mechanical, and surgical.

Natural Débridement

With natural débridement, the dead tissue separates from the underlying viable tissue spontaneously. Bacteria that are present at the interface of the burned tissue and the viable tissue underneath gradually liquefy the fibrils of **collagen** that hold the eschar in place for the first or second postburn weeks. Proteolytic and other natural enzymes cause this phenomenon. However, use of antibacterial topical agents tends to slow this natural process of eschar separation and slows the healing process.

Mechanical Débridement

Mechanical débridement involves the use of surgical scissors, scalpels, and forceps to separate and remove the eschar. This technique can be performed by skilled physicians, nurses, or physical therapists and is usually done with daily dressing changes. If bleeding occurs, hemostatic agents or pressure can be used to stop the bleeding from small vessels. Wet-to-dry dressings are not advocated in burn care because of the chance of removing viable cells along with necrotic tissue. Dressing changes alone aid the removal of wound debris.

Chemical Débridement

Topical enzymatic débridement agents are available to promote débridement of the burn wounds. Because such agents usually do not have antimicrobial properties, they should be used together with topical antibacterial therapy to protect the patient from bacterial invasion. Heavy metals such as silver deactivate the débriding agent; therefore, caution is necessary to ensure that the débriding agent does not interfere with the topical antimicrobial agent. Separate dressings are used to prevent this from occurring.

Surgical Débridement

Early surgical excision to remove devitalized tissue along with early burn wound closure is now recognized as one of the most important factors contributing to survival in a patient with a major burn injury. Aggressive surgical wound closure has reduced the incidence of burn wound sepsis, thus improving survival rates (Burke, 2005). Early excision is carried out before the natural separation of eschar is allowed to occur.

Surgical débridement is an operative procedure involving either primary **excision** (surgical removal of tissue) of the full thickness of the skin down to the fascia (tangential excision) or shaving of the burned skin layers gradually down to freely bleeding, viable tissue. Surgical excision is initiated early in burn wound management. This may be performed within the first few days after the burn or as soon as the patient is hemodynamically stable and edema has decreased. Ideally, the wound is then covered immediately with a skin graft, if needed, and an occlusive dressing. If the wound bed is not ready for a skin graft at the time of excision, a temporary biologic dressing may be used until a skin graft can be applied during subsequent surgery.

The use of surgical excision carries with it risks and complications, especially with large burns. The procedure creates a high risk of extensive blood loss (as much as 100 to 125 mL of blood per percentage of body surface excised) and lengthy operating and anesthesia times. However, when conducted in a timely and efficient manner, surgical excision results in shorter hospital stays and possibly a decreased risk of complications from invasive burn wound sepsis.

Gerontologic Considerations

Eschar separation in full-thickness burns is typically delayed in elderly patients, and older patients are frequently poor risks for surgical excision. For these reasons, prolonged hospitalization, immobilization, and associated problems are common. If the elderly patient can tolerate surgery, early excision with skin grafting is the treatment of choice because it decreases the mortality rate in this population. If the patient is not a surgical candidate, chemical débridement is often chosen to enhance the removal of eschar over time. Prevention of complications of prolonged hospitalization, immobility, and surgery is essential in the care of the elderly burn patient.

Wound Grafting

The patient with deep partial-thickness or full-thickness burns may be a candidate for skin grafting. If so, temporary coverage of the burn wound is necessary until coverage with a graft of the patient's own skin (**autograft**) is possible. The purposes of wound coverage are to decrease the risk of infection; prevent further loss of protein, fluid, and electrolytes through the wound; and minimize heat loss through evaporation. Several methods of wound coverage are available; some are temporary until grafting with permanent coverage is possible. Wound coverage may consist of biologic, biosynthetic, synthetic, and autologous methods or a combination of these approaches.

The main areas for skin grafting include the face (for cosmetic and psychological reasons); functional areas, such as the hands and feet; and areas that involve joints. Grafting permits earlier functional ability and reduces wound **contractures**. When burns are very extensive, the order in which areas are grafted is chosen based on the ability to achieve wound closure as soon as possible, and, therefore, the chest and abdomen or back may be grafted first to reduce the burn surface.

Granulation tissue fills the space created by the wound, creates a barrier to bacteria, and serves as a bed for epithelial cell growth. Richly vascular granulation tissue is pink, firm, shiny, and free of exudate and debris. It should have a bacterial count of less than 100,000/g of tissue to optimize graft success. If the wound is not ready for skin grafting, the burn wound is excised and allowed to granulate. Once the wound is excised, a wound covering is applied to keep the wound bed moist and promote the granulation process.

Biologic Dressings (Homografts and Heterografts)

Biologic dressings have several uses. In extensive burns, they provide temporary wound coverage and protect the granulation tissue until autografting is possible. Biologic dressings are commonly used in patients with large areas of burn and little remaining normal skin for donor sites. They can be used as a test graft in preparation for the patient's own skin graft to determine if the bed will accept the graft.

Once the biologic dressing appears to be "taking," or adhering to the granulating surface with minimal underlying exudation, the patient is ready for an autologous skin graft.

Biologic dressings also provide temporary immediate coverage for clean, superficial burns and decrease the wound's evaporative water and protein loss. They decrease pain by protecting nerve endings and are an effective barrier against water loss and entry of bacteria. When applied to superficial partial-thickness wounds, they seem to speed healing. Biologic materials can be left open or covered. They stay in place for varying lengths of time but are removed in instances of infection or rejection. Another advantage for the patient is that these dressings often require fewer dressing changes, therefore, decreasing pain. They can also be used in the outpatient environment.

Biologic dressings consist of **homografts** (or allografts) and **heterografts** (or xenografts). Homografts are skin obtained from living or recently deceased humans. Heterografts consist of skin taken from animals (usually pigs). Most biologic dressings are used as temporary coverings of burn wounds and are eventually rejected because of the body's immune reaction to them as foreign.

Homografts tend to be the most expensive biologic dressings. They are available from skin banks in fresh and cryopreserved (frozen) forms. Homografts are thought to provide the best infection control of all the biologic or biosynthetic dressings available. Revascularization occurs within 48 hours, and the graft may be left in place for several weeks.

Pigskin is available from commercial suppliers. It is available fresh, frozen, or lyophilized (freeze dried) for longer shelf life. Pigskin is used for temporary covering of clean wounds such as superficial partial-thickness wounds and donor sites. Although pigskin does not vascularize, it does adhere to clean superficial wounds and provides excellent pain control while the underlying wound epithelializes (Atiyeh, et al., 2005).

Biosynthetic and Synthetic Dressings

Problems with availability, sterility, and cost have prompted the search for biosynthetic and synthetic skin substitutes, which may eventually replace biologic dressings as temporary wound coverings. A widely used synthetic dressing is **Biobrane**, which is composed of a nylon, silastic membrane combined with a collagen derivative. The material is semitransparent and sterile. It has an indefinite shelf life and is less costly than homograft or pigskin. Like biologic dressings, Biobrane protects the wound from fluid loss and bacterial invasion (Fig. 57-4).

Biobrane adheres to the wound fibrin, which binds to the nylon-collagen material. Within 5 days, cells migrate into the nylon mesh. In general, adherence to the wound surface correlates directly with low bacterial counts. When the Biobrane dressing adheres to the wound, the wound remains stable. Biobrane can remain in place until spontaneous epithelialization and wound healing occur. It can be laid on top of a wide-meshed autograft to protect the wound until the autograft epithelium grows out to close the interstices. As the Biobrane gradually separates, it is trimmed, leaving a healed wound.

Another temporary wound covering is BCG Matrix. This dressing combines beta-glucan, a complex carbohydrate, with collagen in a meshed reinforced wound dressing. Beta-glucan is known to stimulate macrophages, which are vital in the inflammatory process of healing. BCG Matrix is

Figure 57-4 Biobrane dressing for partial-thickness burn wound. Biobrane dressing applied to a clean wound bed on the hand. Used with permission. Lehigh Valley Health Network, Allentown, PA.

a temporary wound covering intended for use with partial-thickness burns and donor sites. It is applied immediately after cleaning and débridement. If the burn wound surface remains free of infection, BCG Matrix can be left in place until healing is complete (Atiyeh, et al., 2005).

Several other synthetic dressings are available for burn wound care. Op-Site, a thin, transparent, polyurethane elastic film, can be used to cover clean partial-thickness wounds and donor sites. This dressing is occlusive and waterproof but permeable to water vapor and air; this permeability not only provides protection from microbial contamination but also allows for the exchange of gases, which occurs much more quickly in

a moist environment. Other synthetic dressings used for burn wounds include Tegaderm, N-Terface, and DuoDerm.

Skin Substitutes

In an attempt to develop the ideal burn wound covering product, skin substitutes have been created that surgically replace the epidermis and the dermis. It is believed that skin substitutes enhance the healing process of an open wound when autologous skin is unavailable or limited for use. These products are often the choice when donor sites are inadequate or unavailable.

A **cultured epithelial autograft (CEA)** provides permanent coverage of large wounds when harvesting of skin for autografting is not an option. This involves a biopsy of the patient's skin in an unburned area. Keratinocytes are isolated, and epithelial cells are cultured in a laboratory. The original epithelial cell reproduces multiple plated sheets of CEA to cover an already surgically excised wound. These cells are then attached to the burn wound surface, and extreme care is taken until they have adhered to the wound surface. Varying degrees of success have been reported and results are encouraging. However, the disadvantages of the CEA are that the grafts are thin and fragile and can shear easily. Patients have longer hospital stays and higher hospital costs and require more surgical procedures than those treated by traditional methods. In addition, patients require more reconstructive procedures in the first 1 to 2 years after injury. Therefore, CEA use is very limited and is reserved for burn patients whose donor sites are limited (Pham & Gibran, 2007).

Two dermal substitutes are **Integra Artificial Skin** and **AlloDerm**. Artificial skin (Integra) is the newest type of dermal substitute (Fig. 57-5). A dermal analogue, Integra is

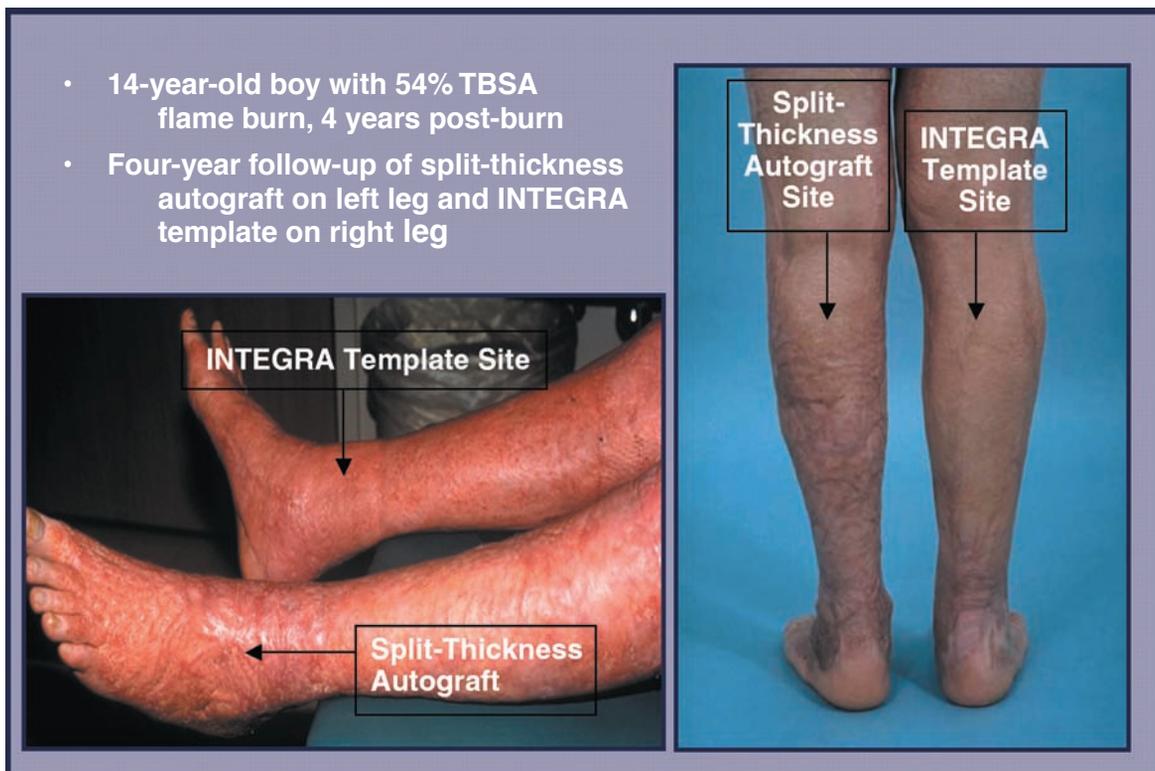

Figure 57-5 Comparison of Integra template site (*right leg*) to split-thickness autograft site (*left leg*). Used with permission from Glenn Warden, MD.

composed of two main layers. The epidermal layer, consisting of silicone, acts as a bacterial barrier and prevents water loss from the dermis. The dermal layer is composed of animal collagen. It interfaces with the open wound surface and allows migration of fibroblasts and capillaries into the material. This “neodermis” becomes a permanent structure. The artificial dermis is biodegraded and reabsorbed. The outer silicone membrane is removed 2 weeks after application and is replaced with the patient’s own skin in the form of a thin epidermal skin graft. When a thinner autologous donor graft is used, donor site healing is quicker. Long-term effects of Integra include minimal contracture formation. The graft site is very pliable, almost eliminating the need for repeated cosmetic surgery. Most important, Integra has resulted in less hypertrophic scarring, thus reducing the need for compression devices once the burn wound has healed. Because Integra allows for earlier excision and coverage of the burn wound, metabolic demands of the patient are reduced. Integra allows for the increased survivability of patients with large burn injuries and improves the functional and cosmetic qualities of the healed burns. The combination of Integra with cultured skin substitutes has demonstrated promise in burn management (Pham & Gibran, 2007).

Another promising dermal substitute is AlloDerm. It is processed dermis from human cadaver skin, which can be used as the dermal layer for skin grafts. When a **donor site** (the area from which skin is taken to provide a skin graft for another part of the body) is harvested for an autologous skin graft, both the epidermal and the dermal layers of skin are removed from the donor site. AlloDerm provides a permanent dermal layer replacement. Its use allows the burn surgeon to harvest a thinner skin graft, consisting of the epidermal layer only. The patient’s epidermal layer is placed directly over the dermal base (AlloDerm). The new graft is then treated according to the burn unit’s protocol. Use of AlloDerm has also resulted in less scarring and contractures with healed grafts; donor sites heal more quickly than conventional donor sites because only the epidermal layer has been harvested. This is important when donor sites are limited because of extensive burns (Boyce, Greenhalgh, Palmieri, et al., 2006; Pham & Gibran, 2007).

Autografts

Autografts remain the preferred material for definitive burn wound closure after excision. Autografts are the ideal means of covering burn wounds because the grafts are the patient’s own skin and therefore are not rejected by the patient’s immune system. They can be split-thickness (Fig. 57-6), full-thickness, pedicle flaps, or epithelial grafts. Full-thickness autografts and pedicle flaps are commonly used for reconstructive surgery, which may take place months or years after the initial injury.

Split-thickness autografts can be applied in sheets or they can be expanded by meshing so that they cover 1.5 to 9 times more than a given donor site area. Skin meshers enable the surgeon to cut tiny slits into a sheet of donor skin, making it possible to cover large areas with smaller amounts of donor skin. These expanded grafts adhere to the recipient site more easily than sheet grafts and prevent the accumulation of blood, serum, air, or purulent material under

Figure 57-6 Healed split-thickness skin graft to the chest and upper extremity. Used with permission. Lehigh Valley Health Network, Allentown, PA.

the graft. However, any kind of graft other than a sheet graft contributes to scar formation as it heals. Use of expanded grafts may be necessary in large wounds but should be viewed as a compromise in terms of cosmesis.

If blood, serum, air, fat, or necrotic tissue lies between the recipient site and the graft, there may be partial or total loss of the graft. Infection or mishandling of the graft and trauma during dressing changes account for most other instances of graft loss. Use of split-thickness grafts allows the remaining donor site to retain sweat glands and hair follicles and minimizes donor site healing time.

Care of the Graft Site. Protection is the key goal of caring for skin grafts postoperatively. Occlusive dressings are commonly used initially after grafting to immobilize the graft. Occupational therapists may be helpful in constructing splints to immobilize newly grafted areas to prevent dislodging of the graft. Homografts, heterografts, or synthetic dressings may also be used to protect grafts.

The first dressing change is usually performed 2 to 5 days after surgery, or earlier in the case of clinical signs of infection, purulent drainage, or a foul odor. Infection, bleeding beneath the graft, and shearing force are the most common reasons for graft loss in the early postoperative period.

The patient is positioned and turned carefully to avoid disturbing the graft or putting pressure on the graft site. If an extremity has been grafted, it is elevated to minimize edema. The patient begins exercising the grafted area 5 to 7 days after grafting.

Care of the Donor Site. Donor sites are clean new wounds that are usually very painful. Caregivers need to recognize this additional source of pain and possible site of infection. Since the donor site is a clean wound created in a surgical environment, it should heal easily unless other complications exist. A moist gauze dressing is applied at the time of surgery to maintain pressure and to stop any oozing. After the donor skin is excised, a thrombostatic agent such as thrombin or epinephrine may be applied directly to the site. The donor site may be covered in several ways, from single-

layer gauze impregnated with petrolatum, scarlet red, or bismuth to new biosynthetic dressings such as Biobrane or BCG Matrix. Acticoat can also be used as a dressing on donor sites. With all types of covering, donor sites must remain clean, dry, and free from pressure. Because a donor site is a partial-thickness wound, it is very painful and will heal spontaneously within 7 to 14 days with proper care.

Pain Management

The ability to quantify pain may be difficult in any patient; however, the patient who has experienced a burn has many additional challenges. A burn injury is considered one of the most painful types of trauma that a patient can endure. The nature of the injury requires multiple procedures, débridement, surgery and treatments. All of these experiences vary in length and intensity, therefore creating variations in sensation. Additional pain occurs with each skin graft because a new painful donor site is created. In addition, moving, changing position, and receiving occupational and physical therapy cause additional discomfort. This is a constantly changing source of pain throughout the entire healing process, and to the patient it appears to be never ending. Therefore, the pain management plan for any patient needs to be flexible, evaluated regularly using standardized scales, and individualized to meet the patient's needs (Faucher & Furukawa, 2006, Connor-Ballard, 2009a, 2009b).

The American Burn Association's guidelines for pain management are: there must be an organized approach to pain management that addresses background, procedural, and breakthrough pain; the goal should be for patients to be comfortable and alert; and pain needs to be differentiated from anxiety (Faucher & Furukawa, 2006).

Background pain is a continuous level of discomfort even when the patient is inactive or not undergoing any procedures. The goal of treatment is to provide a long-acting analgesic that will provide even coverage for this long-term discomfort. It is helpful to use escalating doses when initiating the medication to reach the level of pain control that is acceptable to the patient. The use of patient-controlled analgesia (PCA) gives control to the patient and achieves this goal. Breakthrough pain is described as acute, intense, and episodic pain. It is generally related to an activity or movement of the affected area. Short-acting agents are used to achieve pain control in addition to the baseline treatment the patient receives for background pain. Procedural pain is discomfort that occurs with procedures such as daily wound treatments, invasive line insertions, physical and occupational therapy. The goal is to plan proper sedation that will place the patient in a state of comfort throughout the procedure. Depending on the agent, an anesthesia provider can be helpful in achievement of pain relief (Faucher & Furukawa, 2006).

Most severe burns are a combination of partial-thickness and full-thickness burns and the depth influences the amount of pain the patient experiences. Superficial and deep partial-thickness burns are very painful because the nerve endings are exposed, resulting in excruciating pain with exposure to temperature, pressure, and movement. In a full-thickness burn the nerve endings are destroyed, and upon admission there is numbness and decreased sensation to the area. Thus, severe injuries are often underestimated

by the patient because the pain at that time is minimal. Educating patients and their families about burn pain and its relationship to the depth of injury as well as the pain management plan is an important priority for the nurse.

The pharmacologic treatment for the management of burn pain includes the use of opioids, nonsteroidal anti-inflammatory drugs (NASIDs), anxiolytics, and anesthetic agents. These and other pain management strategies are discussed in Chapter 13. Treatment of anxiety with benzodiazepines is used along with opioids to achieve both a pain-free and anxiety-free experience. The use of anesthetics in a nonoperative setting (ie, moderate sedation) requires administration by qualified personnel. Recent advances include the use of agents with rapid onset and short duration, which have been very effective in pain control during a planned procedure (Faucher & Furukawa, 2006).

Nonpharmacologic pain control can be achieved by using relaxation techniques, distraction, guided imagery, hypnosis, therapeutic touch, humor, music therapy, and more recently virtual reality techniques (see Chapter 13). These techniques can be used either alone or in conjunction with medications to achieve an acceptable level of comfort for the burn patient (Hansen, Gauld, Wathen, et al., 2008).

Nutritional Support

Burn injuries produce profound metabolic abnormalities fueled by the exaggerated stress response to the injury. The body's response has been classified as hyperdynamic, hypermetabolic, and hypercatabolic. Hypermetabolism can affect morbidity and mortality by increasing the risk for infection and slowing the healing rate. Patients' metabolic demands vary with the extent of the burn injury and age (Demling, 2005b). Hypermetabolism is evident immediately after a burn injury. The degree of the response depends on the size of the burn and the patient's age, body composition, size, and genetic response to insult (Jeschke, Chinkes, Finnerty, et al., 2008). Persistent hypermetabolism may last up to 1 year after burn injury.

Major metabolic abnormalities after a burn injury include increased catabolic hormones (cortisol and catechols); decreased anabolic hormones (human growth factor and testosterone); a marked increase in the metabolic rate; a sustained increase in body temperature; a marked increase in glucose demands; rapid skeletal muscle breakdown with amino acids serving as the energy source; lack of ketosis, indicating that fat is not a major source of calories; and catabolism that does not respond to nutrient intake (Pereira, Murphy & Herndon, 2005). Therefore, it is essential to control the stress response by increasing the anabolic process through adequate nutrition and increased muscle activity, decreasing heat loss from wounds, and maintaining a warm environment. Controlling secondary stressors, such as pain and anxiety, also helps control the stress response.

The most important nutritional intervention is to provide energy and nutrients for prevention of infection and promotion of wound healing (Wolfe, 2007). Healing of the burn wound consumes large quantities of energy. Patients with burns greater than 40% TBSA have resting metabolic rates twice that of normal (Pereira, et al., 2005). Effective nutrition management depends on how well the energy

expenditure due to the burn injury can be estimated and matched with appropriate amounts of micronutrients, carbohydrates, lipids, and protein. The nutritional support required is based on the patient's preburn status and the TBSA burned.

Several formulas exist for estimating the daily metabolic expenditure and caloric requirements of patients with burn injuries. The most commonly used formulas are the Harris-Benedict equation, which determines basal energy requirements based on activity and burn size, Ireton-Jones formula, and the Modified Schoefield (Masters & Wood, 2008). Protein requirements may range from 2.0 to 3.0 g of protein per kilogram of body weight every 24 hours, which is 15% to 25% of the caloric intake. Although variation exists, most burn centers use a low fat and high carbohydrate enteral feeding, approximately 55% to 85% carbohydrate and 3% to 20% fat. Carbohydrates are included to meet caloric requirements and to spare protein, which is essential for wound healing. The patient may also receive added vitamins and minerals in excess of the normal requirements (Masters & Wood, 2008).

Feeding usually begins immediately or at least within 24 to 72 hours postburn injury. Nutrition can be administered either by the enteral or parenteral route, or a combination of both. The goal is to reach the patient's nutritional needs, which are usually in proportion to the burn size. These feedings are continued until the patient can adequately consume the recommended daily requirements by mouth (Wolfe, 2007). When the oral route is used, high-protein, high-calorie meals and supplements are given. Dietary consultations are useful in helping patients meet their nutritional needs. Daily calorie counts aid in assessing the adequacy of nutritional intake.

Patients lose a great deal of weight during recovery from severe burns. Reserve fat deposits are catabolized, fluids are lost, and caloric intake may be limited. Because a burn injury decreases the patient's resistance to infection and disease, the nutritional status must be improved and maintained even though the patient has a poor appetite and is weak. One goal of nutrition management is to decrease or stop the catabolic process and promote protein anabolism.

In addition, research is focused on aggressive alteration of the hyperglycemic response and administration of insulin therapy to promote wound healing. Other treatment modalities include early excision and skin grafting of the burn wound, aggressive prevention or treatment of infections, and adequate exercise with physical therapy to lessen muscle wasting and increase strength. Additional pharmacologic modalities used to alter the hypermetabolic state of burn injury include the use of oxandrolone (Oxandrin), an anabolic steroid; an adrenergic antagonist (propranolol [Inderal]); and the anabolic protein, recombinant human growth hormone (Pereira, et al., 2005).

Indications for parenteral nutrition include weight loss greater than 10% of normal body weight, inadequate intake of enteral nutrition due to clinical status, prolonged wound exposure, and malnutrition or debilitated condition before injury. The risk of infection at the site of the central venous catheter required for parenteral nutrition must be considered.

Nursing Management

Continued assessment of the patient during the early weeks after the burn injury focuses on hemodynamic alterations, wound healing, pain and psychosocial responses, and early detection of complications. Assessment of respiratory and fluid status remains the highest priority for detection of potential complications.

The nurse assesses vital signs frequently. Continued assessment of peripheral pulses is essential for the first few postburn days while edema continues to increase, potentially damaging peripheral nerves and restricting blood flow. Close observation of the hourly fluid intake and urinary output as well as blood pressure and cardiac rhythm is essential during this phase and changes should be reported to the burn surgeon promptly.

The patient with an inhalation injury will require regular monitoring of level of consciousness, pulmonary function, and ability to ventilate. When inadequate ventilation and airway edema require the patient to be intubated and placed on a ventilator, frequent suctioning and assessment of the airway are priorities.

Restoring Normal Fluid Balance

To reduce the risk of fluid overload and consequent heart failure and pulmonary edema, the nurse closely monitors IV and oral fluid intake, using IV infusion pumps to minimize the risk of rapid fluid infusion. To monitor changes in fluid status, careful intake and output and daily weights are obtained. Changes, including those of blood pressure and pulse rate, are reported to the physician (invasive hemodynamic monitoring is avoided because of the high risk of infection).

Preventing Infection

A major part of the nurse's role during the acute phase of burn care is detection and prevention of infection. The nurse is responsible for providing a clean and safe environment and for closely scrutinizing the burn wound to detect early signs of infection. Culture results and white blood cell counts are monitored.

Aseptic technique is used for wound care procedures. Sterile technique is used for any invasive procedures, such as insertion of IV lines and urinary catheters or tracheal suctioning. Meticulous hand hygiene before and after each patient contact is also an essential component of preventing infection, even though gloves are worn to provide care.

The nurse protects the patient from sources of contamination, including other patients, staff members, visitors, and equipment. Invasive lines and tubing must be routinely changed according to recommendations of the CDC. Tube feeding reservoirs, ventilator circuits, and drainage containers are replaced regularly. Fresh flowers, plants, and fresh fruit baskets are not permitted in the patient's room because of the risk of microorganism growth. Visitors are screened to avoid exposure of the immunocompromised patient to pathogens.

Patients can inadvertently promote migration of microorganisms from one burned area to another by touching their wounds or dressings. Bed linens also can spread infection through either colonization with wound microorgan-

isms or fecal contamination. Regular bathing of unburned areas and changing of linens can help prevent infection.

Maintaining Adequate Nutrition

Oral fluids should be initiated slowly after bowel sounds resume. The patient's tolerance is recorded. If vomiting and distention do not occur, fluids may be increased gradually and the patient may be advanced to a normal diet or to tube feedings.

The nurse collaborates with the dietitian or nutrition support team to plan a protein- and calorie-rich diet that is acceptable to the patient. Family members may be encouraged to bring nutritious and favorite foods to the hospital. High-calorie nutritional supplements such as Ensure and Resource may be provided. Caloric intake must be documented. Vitamin and mineral supplements may be prescribed.

If caloric goals cannot be met by oral feeding, a feeding tube is inserted and used for continuous or bolus feedings of specific formulas. The volume of residual gastric secretions should be checked to ensure absorption.

The patient should be weighed each day and the results graphed. The patient can use this information to set goals for nutritional intake and to monitor weight loss and gain. Ideally, the patient will lose no more than 5% of preburn weight if aggressive nutritional management is implemented.

Promoting Skin Integrity

Wound care is usually the single most time-consuming element of burn care after the emergent phase. The physician prescribes the desired topical antibacterial agents and specific biologic, biosynthetic, or synthetic wound coverings and plans for surgical excision and grafting. The nurse needs to make astute assessments of wound status, use creative approaches to wound dressing, and support the patient during the emotionally distressing and very painful experience of wound care.

Assessment of the burn wound requires an experienced eye, hand, and sense of smell. Important wound assessment features include size, color, odor, eschar, exudate, epithelial buds (small pearl-like clusters of cells on the wound surface), bleeding, granulation tissue, the status of graft take, healing of the donor site, and the condition of the surrounding skin. Any significant changes in the wound are reported to the physician because they usually indicate burn infection and require immediate intervention.

A diagram, updated daily by the nurse responsible for the patient's care, helps inform all those concerned about the latest wound care procedures in use for the patient.

The nurse also assists the patient and family by providing instruction, support, and encouragement to take an active part in dressing changes and wound care when appropriate. Discharge planning needs for wound care are anticipated early in the course of burn management, and the strengths of the patient and family are assessed and used in preparing for the patient's eventual discharge and home care.

Relieving Pain and Discomfort

Pain measures are continued during the acute phase of burn recovery. Analgesic agents and anxiolytic medications are administered as prescribed. Frequent assessment of pain and discomfort is essential. To increase its effectiveness, analgesic medication is provided before the pain becomes severe.

Nursing interventions such as teaching the patient relaxation techniques, giving the patient some control over wound care and analgesia, and providing frequent reassurance are helpful. Guided imagery and distraction (eg, video programs or video games) can be used to alter the patient's perceptions of and responses to pain. Other pain-relieving approaches include hypnosis, music therapy, and virtual reality.

The nurse assesses the patient's sleep patterns daily. Lack of sleep and rest interferes with healing, comfort, and restoration of energy. If necessary, sedatives are prescribed on a regular basis in addition to analgesics and anxiolytics.

The nurse works quickly to complete treatments and dressing changes to reduce pain and discomfort. The patient is encouraged to take analgesic medications before painful procedures. The patient's response to the medication and other interventions is assessed and documented.

Healing burn wounds are typically described by patients as itchy and tight. Oral antipruritic agents, a cool environment, frequent lubrication of the skin with water or a silica-based lotion, exercise and splinting to prevent skin contracture, and diversional activities all help promote comfort in this phase.

Promoting Physical Mobility

An early priority is to prevent complications of immobility. Deep breathing, turning, and proper positioning are essential nursing practices that prevent atelectasis and pneumonia, control edema, and prevent pressure ulcers and contractures. These interventions are modified to meet the patient's needs. Low-air-loss and rotation beds may be useful, and early sitting and ambulation are encouraged. If the lower extremities are burned, elastic pressure bandages should be applied before the patient is placed in an upright position. These bandages promote venous return and minimize edema formation. Prevention of deep vein thrombosis (DVT) is an important factor in care. Patients with burn injuries are at high risk because of their hypercoagulability, loss of vascular integrity, immobility, multiple invasive lines and need for other operative procedures. In fact, there is a 1% to 23% incidence of DVT in burn patients documented. There is cautious use of heparin due to the bleeding potential; however, most burn centers use prophylactic therapy including sequential graduated compression devices in the high-risk groups (Faucher & Conlon, 2007).

The burn wound is in a dynamic state for at least 1 year after wound closure. During this time, aggressive efforts must be made to prevent contracture and hypertrophic scarring. Both passive and active range-of-motion exercises are initiated from the day of admission and are continued after grafting, within prescribed limitations. Splints or functional devices may be applied to the extremities for contracture control. The nurse monitors the splinted areas for signs of vascular insufficiency, nerve compression, and skin breakdown. Occupational and physical therapists are consulted to develop a patient-specific plan of care throughout hospitalization and recovery.

Strengthening Coping Strategies

In the acute phase of burn care, the patient is facing the reality of the burn injury and is grieving over obvious losses. Depression, anger, regression, and manipulative behavior

are common responses of patients who have burn injuries. Withdrawal from participation in required treatments and regression must be viewed with an understanding that such behavior may help the patient cope with an enormously stressful event. Although most patients recover emotionally from a burn injury, some have more difficult psychological reactions to the injury and its outcomes (Kildal, Willebrand, Andersson, et al., 2004). There is evidence that psychological distress and depression are common in people who have experienced burns; however, more studies are needed in this area (Fauerbach, Pruzinsky & Saxe, 2007).

Difficulty coping along with other psychological stressors often limits the patient's physical and psychological recovery (Fauerbach, Lezotte, Hills, et al., 2005). Patients who experience a burn injury tend to have high rates of involvement in risky behaviors (eg, alcohol and substance abuse, depression) before the injury (Appleby, 2005). Intrusive thoughts of the burn event and reliving it over and over may also occur and can indicate posttraumatic stress disorder (PTSD).

Much of the patient's energy goes into maintaining vital physical functions and wound healing in the early postburn weeks, leaving little emotional energy for coping in a more effective manner. The nurse can assist the patient to develop effective coping strategies by setting specific expectations for behavior, promoting truthful communication to build trust, helping the patient practice appropriate strategies, and giving positive reinforcement when appropriate.

The patient frequently vents feelings of anger. At times the anger may be directed inward because of a sense of guilt, perhaps for causing the fire or even for surviving when loved ones perished. The anger may be directed outward toward those who escaped unharmed or toward those who are now providing care. One way to help the patient handle these emotions is to enlist someone to whom the patient can vent feelings without fear of retaliation. A nurse, social worker, psychiatric liaison nurse, or spiritual advisor or counselor who is not involved in direct care activities may fill this role successfully.

Patients with burn injuries are very dependent on health care team members during the long period of treatment and recovery. However, even when physically unable to contribute much to self-care, they should be included in decisions regarding care and encouraged to assert their individuality in terms of preferences and recognition of their unique identities. As the patient improves in mobility and strength, the nurse works with the patient to set realistic expectations for self-care, including self-feeding, assistance with wound care procedures, exercise, and planning for the future. Many patients respond positively to the use of contractual agreements and other strategies that recognize their independence and their specific role as part of the health care team moving toward the goal of self-care. Consultation with psychiatric/mental health care providers may be helpful to assist the patient in developing effective coping strategies.

Supporting Patient and Family Processes

Family functioning is disrupted with burn injury. One of the nurse's responsibilities is to support the patient and family and to address their spoken and unspoken concerns. Family members need to be instructed about ways that they can support the patient as adaptation to burn trauma occurs.

The family also needs support from the health care team. The burn injury has tremendous psychological, economic, and practical impact on the patient and family. Referrals for social services or psychological counseling should be made as appropriate. This support continues into the rehabilitation phase. Some burn centers offer a peer support program that involves a burn survivor visiting the patient while hospitalized to provide support. Many survivors enjoy the opportunity to help others through this experience.

Patients who experience major burns are commonly sent to burn centers far from home. Because burn injuries are sudden and unexpected, family roles are disrupted. Therefore, both the patient and the family need thorough information about the patient's burn care and expected course of treatment. Patient and family education begins at the initiation of burn management. Barriers to learning are assessed and considered in teaching. The preferred learning styles of both the patient and family are assessed. This information is used to tailor teaching activities. The nurse assesses the ability of the patient and family to grasp and cope with the information. Verbal information is supplemented with videos, models, or printed materials if available. Patient and family education is a priority in the acute and rehabilitation phases.

Nurses must remain sensitive to the possibility of changing family dynamics. It is not unusual for the provider in the family to be the one who is injured. Roles begin to change, which adds more stress to the family. In addition, families are often relocated due to loss of property from the fire. Social services play an integral part in providing support at this time.

Monitoring and Managing Potential Complications

Heart Failure and Pulmonary Edema

The patient is assessed for fluid overload, which may occur as fluid is mobilized from the interstitial compartment back into the intravascular compartment. If the cardiac and renal systems cannot compensate for the excess vascular volume, heart failure and pulmonary edema may result. The patient is assessed for signs of heart failure, including decreased cardiac output, oliguria, jugular vein distention, edema, and the onset of an S_3 or S_4 heart sound. If invasive hemodynamic monitoring is used, increasing central venous, pulmonary artery, and wedge pressures indicate increased fluid volume.

Crackles in the lungs and increased difficulty with respiration may indicate a fluid buildup in the lungs, which is reported promptly to the physician. In the meantime, the patient is positioned comfortably, with the head of the bed raised (if not contraindicated because of other treatments or injuries) to promote lung expansion and gas exchange. Management of this complication includes providing supplemental oxygen, administering IV diuretic agents, carefully assessing the patient's response, and providing vasoactive medications, if indicated.

Sepsis

The signs of early systemic sepsis are subtle and require a high index of suspicion and very close monitoring of changes in the patient's status. Early signs of sepsis may include increased temperature, increased pulse rate,

widened pulse pressure, and flushed dry skin in unburned areas. As with many observations of the patient with a burn injury, one needs to look for patterns or trends in the data. (See Chapter 15 for a more detailed discussion of septic shock.)

Wound and blood cultures are performed as prescribed, and results are reported to the physician immediately. The nurse also observes for and reports early signs of sepsis and promptly intervenes, administering prescribed IV fluids and antibiotics to prevent septic shock, a complication with a high mortality rate. Antibiotics must be administered as scheduled to maintain proper blood concentrations. Serum antibiotic levels are monitored for evidence of maximal effectiveness, and the patient is monitored for toxic side effects.

Acute Respiratory Failure and Acute Respiratory Distress Syndrome

The patient's respiratory status is monitored closely for increased difficulty in breathing, change in respiratory pattern, or onset of adventitious (abnormal) sounds. Typically, at this stage, signs and symptoms of injury to the respiratory tract become apparent. Respiratory failure may follow. As described previously, signs of hypoxia (decreased oxygen to the tissues), decreased breath sounds, wheezing, tachypnea, stridor, and sputum tinged with soot (or in some cases containing sloughed tracheal tissue) are among the many possible findings. Patients receiving mechanical ventilation must be assessed for a decrease in tidal volume and lung compliance. The key sign of the onset of ARDS is hypoxemia while receiving 100% oxygen, with decreased lung compliance and significant shunting. The physician should be notified immediately of deteriorating respiratory status.

Medical management of the patient with acute respiratory failure requires intubation and mechanical ventilation (if not already in use). If ARDS has developed, higher oxygen levels, positive end-expiratory pressure, and pressure support are used with mechanical ventilation to promote gas exchange across the alveolar–capillary membrane (see Chapter 25).

Visceral Damage. The nurse must be alert to signs of necrosis of visceral organs due to electrical injury. Tissues affected are usually located between the entrance and exit wounds of the electrical burn. All patients with electrical burns should undergo cardiac monitoring, with dysrhythmias being reported to the physician. Careful attention must also be paid to signs or reports of pain related to deep muscle ischemia. To minimize the severity of complications, visceral ischemia must be detected as early as possible. In the operating room, the burn surgeon may perform **fasciotomies** to relieve the swelling and ischemia in the muscles and fascia and to promote oxygenation of the injured tissues. Because of the deep incisions involved with fasciotomies, the patient must be monitored carefully for signs of excessive blood loss and hypovolemia.

Gerontologic Considerations

In elderly patients, a careful history of preburn medications and preexisting illnesses is essential. Nursing assessment of the elderly patient with burns should include particular

attention to pulmonary function, response to fluid resuscitation, and signs of mental confusion or disorientation. Fever may be absent in the presence of complications such as sepsis. Therefore, surveillance for other signs of infection becomes even more important. Nursing care of the elderly patient with burn injuries promotes early mobilization, aggressive pulmonary care, and attention to preventing complications.

REHABILITATION PHASE

Rehabilitation begins immediately after the burn has occurred and often extends for years after injury. The emphasis on early rehabilitation cannot be overestimated. In this final phase of care, the focus becomes rehabilitation, reconstruction, and reintegration of the burn survivor (Sheridan, 2007b). In addition, the burn team focuses on late complications (Table 57-6).

Burn rehabilitation is time-consuming and challenging and is very specific to the severity and location of injury as well as the patient's needs and goals. These goals vary based on phase of care and need to be addressed frequently to ensure constant progress. During hospitalization the goals include maintaining range of motion (ROM), preventing contractures through splinting techniques, decreasing edema, and the preventing skin breakdown through proper positioning. As the acute phase comes to a close, patients become more aware of their injuries and the challenges they face. The goals are functional and aimed at activities of daily living such as ambulation and participation in self-care as well as scar management and returning to work or school (Chart 57-6). Occupational and physical therapists are essential to optimizing patient goals and outcomes (Sheridan, 2007b).

Psychological Support

A patient's outlook, motivation, and support system are important to his or her overall well-being and ability to progress through the rehabilitation phase. There are three basic phases of psychological recovery from a burn injury. During the critical phase, patients often are confused from medication they are taking, but they have an underlying sense of fear, anxiety, and pain. In the acute phase, patients recognize that survival is expected. They have periods of depression due to their awareness of the functional and body image challenges ahead and can recognize all they have lost. Thirty percent of burn patients develop some form of PTSD. The symptoms and psychological responses to traumatic events including PTSD are discussed further in Chapter 7.

The final stage of psychological recovery occurs within 1 to 2 years following discharge. This is an emotional time as the patient and family begin to live with new physical limitations and challenges in relationships. The role of various team members and the support from peer burn survivors during this time cannot be understated (Sheridan, 2007b).

Psychological treatment plans should include a full assessment of these issues and a targeted plan with the appropriate resources to promote the patient's social and vocational reintegration and improved quality of life (Wallis, Renneberg, Ripper, et al., 2006). Burn injuries can have a major impact

Table 57-6 COMPLICATIONS IN REHABILITATION PHASE OF BURN CARE

Complications	Contributing Factors	Interventions
Neuropathies, peripheral neuropathies, mononeuropathies, multimono-neuropathies, nerve entrapment	Electrical injury, large deep burns, improper positioning, edema, scar tissue	Assess peripheral pulses and sensation (neurovascular checks). Prevent edema and pressure by elevation, positioning, and prevention of constricting dressings. Assess splints for proper fit and application. Consult occupational therapy (OT) and physical therapy (PT) for positioning.
Heterotopic ossification (abnormal formation of bone in response to soft tissue trauma)	Prolonged immobility	Perform gentle range-of-motion exercises.
Hypertrophic scarring	Partial-thickness and full-thickness burns	Keep skin pliable and soft. Apply pressure garments as prescribed. Massage.
Contractures	Partial-thickness and full-thickness burns	Maintain position of joints in alignment. Perform gentle range of motion exercises. Consult OT and PT for exercises and positioning recommendations.
Wound breakdown	Shearing, pressure, inadequate nutrition	Teach patient about importance of good nutrition. Protect wound from pressure and shearing forces.
Gait deviations	Pain, burn wound, donor site, scarring of joints, electrical injury of the brain	Provide adequate pain management. Consult OT and PT. Promote ambulation and mobility training.
Complex regional pain syndrome (previous reflex sympathetic dystrophy [RSD])	Trauma and burns	Provide adequate pain management. Consult OT and PT for exercises. Promote gentle motion of affected extremities.
Joint instability	Burn wound, burn scar and contractures	Maintain joint through appropriate application of splints. Monitor joint pinning if indicated. Consult OT and PT.

on quality of life. Changes in physical activity as well as social and psychological adjustments, such as returning to school and employment status, may be challenging. It is important throughout this process to assess and address the family needs. When one member of a family sustains a major

burn injury, the entire family is affected. Separation, feelings of helplessness, loss, and psychological dysfunction may be experienced in varying degrees. Family and friends need support, education, and guidance in assisting the patient to return to their optimal health (Ceranoglu & Stern, 2006).

CHART 57-6 NURSING RESEARCH PROFILE Life After Burn Injury

Moi, A. L. & Gjengedal, E. (2008). Life after burn injury: Striving for regained freedom. *Qualitative Health Research*, 18(12), 1621–1630.

Purpose

Second only to the patient's survival, the priority of burn care today is optimal quality of life of survivors. The purpose of this study was to identify and describe the meaning of the experience of life after major burn injury.

Design

This qualitative study used a phenomenological perspective to describe and explore the meaning that 14 people who survived severe burn injury attributed to the experience. They were recruited from an outpatient clinic at a burn center in Norway. The researchers intentionally recruited participants of both genders (men = 11, women = 4), across a wide age range (19 to 74, with mean age of 46 years), who had experienced different types of burns (flames = 9, electrical injury = 3, scalding = 2), and received different treatments of their burns. In-depth unstructured interviews were conducted 10 to 35 months after the burn injury; the interviews were audiotaped, transcribed, and analyzed using Giorgi's phenomenological method.

Findings

The major finding was the effort on the part of participants to regain freedom that included reduced or absent bodily or social restrictions and a meaningful life that was the same as or better than before the injury occurred. The experiences described as supporting this goal included (1) facing the extreme and trying to restore order and minimize damage, (2) having a disrupted life history with the loss of memory that occurred during the immediate postburn period, (3) accepting the unchangeable, and (4) changing what could be changed. Some participants indicated that experiencing and surviving their injury gave them a new view of life and made their lives richer.

Nursing Implications

The experience of surviving a severe burn injury is life-altering. The researchers suggest that patients should be given the opportunity to tell their stories and to express their views. Positive feelings and growth on the part of patients should be recognized by burn-care staff, particularly during the later phases of burn care. Patients should be encouraged to share their experiences and views. The researchers also suggest that patients and families be provided with information about what to expect as they move through the phases of burn care.

Abnormal Wound Healing

Partial-thickness wounds involving the epidermis and superficial dermis tend to heal without scarring. However, deep partial-thickness and full-thickness wounds involving the dermis and subcutaneous tissue heal with varying degrees of scarring due to abnormal healing (Arnt, Dover & Alam, 2006).

Normal scarring occurs in a superficial tissue injury and begins forming within 7 to 10 days postinjury and progresses over the next 6 to 12 months. Abnormal scarring occurs after a longer period of wound healing and forms either hypertrophic or keloid scars.

Hypertrophic and Keloid Scars

Hypertrophic scars form within the boundaries of the initial wound and push outward on the perimeter of the wound. They are common in areas over joints and in the younger population. These scars may be hypopigmented or hyperpigmented (Arnt, et al., 2006).

The scar becomes red (because of its hypervascular nature), raised, and hard. A keloid is an irregularly formed scar that extends beyond the margins of the original wound. They are large, nodular, and ropelike, often causing itching and tenderness. They are more common in dark pigmented skin, uncommon in children and the elderly, and have familial tendencies. Scars occur in all forms and arise in different areas, making some more undesirable than others. Therefore, prevention and treatment is individualized to the patient's needs (Arnt, et al., 2006).

Prevention and Treatment of Scars

Treatment modalities that are theoretically based on wound healing and scar formation are used to prevent scar contractures and excess hypertrophic tissue. Compression is introduced early in burn wound treatment. Elastic bandage wraps are used initially to help promote adequate circulation, but they can also be used as the first form of compression followed by elasticized tubular bandage until the patient can be measured for a customized garment (Fig. 57-7). Tools of therapy include pressure, use of topical silicone, scar massage, and steroid injections (Sheridan, 2007b). Application of elastic pressure garments loosens collagen bundles and encourages parallel orientation of the collagen to the skin surface. As pressure continues over time, there is a restructuring of the collagen and a decrease in vascularity and cellularity. Although this therapy is somewhat controversial, pressure has shown to be beneficial in controlling scar formation over time. Garments are worn continuously (ie, 23 hours a day). Many areas of the body are difficult to compress due to the contours or location of the injury. Silicone sheets are helpful for these small troublesome areas and are placed beneath the garment to enhance scar compression. Gentle superficial scar massage can be performed with a moisturizer several times a day. This is helpful in smaller areas and is convenient for the patient. The use of steroid injections into the scar may be helpful in areas of scar development, but they are difficult and painful. Pruritus is a common discomfort in the healed burn wound and can last up to 6 months after healing has occurred. It is treated with moisturizers, massage, oral and topical antihis-

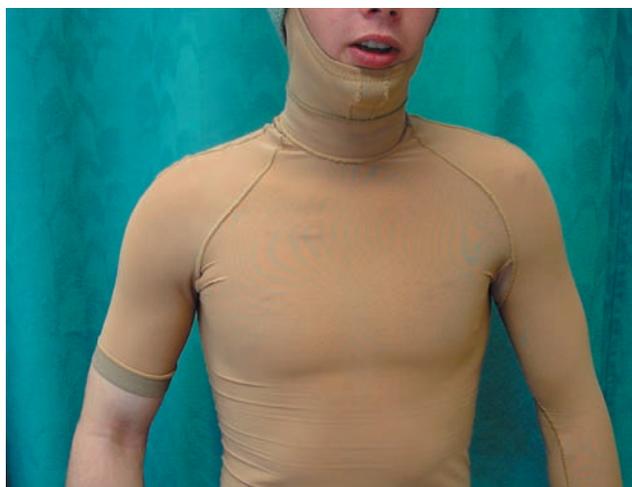

Figure 57-7 Pressure garments. Application of pressure garments helps prevent hypertrophic burn scarring. Used with permission of Jobst Institute, Inc., Toledo, OH.

tamines, and topical compresses or baths. This is a troublesome part of recovery and requires further research (Sheridan, 2007b).

Burn reconstruction is a treatment option after all scars have matured and is discussed within the first few years after injury. This decision requires individualized planning, realistic expectations, and patience. The procedures utilized by the surgeon include contracture release and skin grafting, use of tissue expansion, and skin flaps to cover or reconstruct the defect area (Sheridan, 2007b).

NURSING PROCESS

CARE OF THE PATIENT DURING THE REHABILITATION PHASE

Assessment

The nurse obtains information about the patient's education level, occupation, leisure activities, cultural background, religion, and family interactions early. The patient's self-concept, mental status, emotional response to the injury and hospitalization, level of intellectual functioning, previous hospitalizations, response to pain and pain relief measures, and sleep pattern are also essential components of a comprehensive assessment. Information about the patient's general self-concept, self-esteem, and coping strategies in the past are valuable in addressing emotional needs.

Ongoing physical assessments related to rehabilitation goals include range of motion of affected joints, functional abilities in activities of daily living, early signs of skin breakdown from splints or positioning devices, evidence of neuropathies (neurologic damage), activity tolerance, and quality or condition of healing skin. The patient's participation in care and ability to demonstrate self-care in such areas as ambulation, eating, wound cleaning, and applying pressure wraps are documented on a regular basis. In addition to these assessment parameters, specific complications and treatments require additional specific assessments; for

example, the patient undergoing primary excision requires postoperative assessment.

Diagnosis

Nursing Diagnoses

Based on the assessment data, priority nursing diagnoses in the long-term rehabilitation phase of burn care may include the following:

- Activity intolerance related to pain on exercise, limited joint mobility, muscle wasting, and limited endurance
- Disturbed body image related to altered physical appearance and self-concept
- Deficient knowledge about postdischarge home care and recovery needs

Collaborative Problems/Potential Complications

Based on the assessment data, potential complications that may develop in the rehabilitation phase include:

- Contractures
- Inadequate psychological adaptation to burn injury

Planning and Goals

The major goals for the patient include increased participation in activities of daily living; increased understanding of the injury, treatment, and planned follow-up care; adaptation and adjustment to alterations in body image, self-concept, and lifestyle; and absence of complications.

Nursing Interventions

Promoting Activity Tolerance

Nursing interventions that must be carried out according to a strict regimen and the pain that accompanies movement take their toll on the patient. The patient may become confused and disoriented and lack the energy or motivation to participate optimally in care. The nurse must schedule care in such a way that the patient has periods of uninterrupted sleep. A good time for planned patient rest is after the stress of dressing changes and exercise, while pain interventions and sedatives are still effective. This plan must be communicated to family members and other care providers.

The patient may have insomnia related to frequent nightmares about the burn injury or to other fears and anxieties about the outcome of the injury. The nurse listens to and reassures the patient and administers hypnotic agents, as prescribed, to promote sleep.

Reducing metabolic stress by relieving pain, preventing chilling or fever, and promoting the physical integrity of all body systems help the patient conserve energy for therapeutic activities and wound healing.

The nurse incorporates physical therapy exercises in the patient's care to prevent muscle atrophy and to maintain the mobility required for daily activities. The patient's activity tolerance, strength, and endurance gradually increase if activity occurs over increasingly longer periods. Fatigue, fever, and pain tolerance are monitored and used to determine the amount of activity to be encouraged on a daily basis. Activities such as family visits and recreational or play therapy (eg, video games, radio, television) can provide diversion, improve the patient's outlook, and increase

tolerance for physical activity. In elderly patients and those with chronic illnesses and disabilities, rehabilitation must take into account preexisting functional abilities and limitations.

Improving Body Image and Self-Concept

Patients who have survived burn injuries frequently suffer profound losses. These include not only a loss of body image due to disfigurement but also losses of personal property, homes, loved ones, and ability to work. They lack the benefit of anticipatory grief often seen in a patient who is approaching surgery or dealing with the terminal illness of a loved one.

As care progresses, the patient who is recovering from burns becomes aware of daily improvement and begins to exhibit basic concerns: Will I be disfigured or be disabled? How long will I be in the hospital? What about my job and family? Will I ever be independent again? How can I pay for my care? Was my burn the result of my carelessness?

As the patient expresses such concerns, the nurse must take time to listen and to provide realistic support. The nurse can refer the patient to a support group, such as those usually available at regional burn centers or through organizations such as the Phoenix Society (see Resources at the end of the chapter). Through participation in such groups, the patient will meet others with similar experiences and learn coping strategies to help him or her deal with losses. Interaction with other burn survivors allows the patient to see that adaptation to the burn injury is possible. If a support group is not available, visits from other survivors of burn injuries can be helpful to the patient coping with such a traumatic injury.

A major responsibility of the nurse is to constantly assess the patient's psychosocial reactions. Questions to consider include the following: What are the patient's fears and concerns? Does the patient fear loss of control of care, independence, or sanity itself? Is the patient afraid of rejection by family and loved ones? Does he or she fear being unable to cope with pain or physical appearance? Does the patient have concerns about sexuality, including sexual function? Being aware of these anxieties and understanding the basis of the patient's fears enable the nurse to provide support and to cooperate with other members of the health care team in developing a plan to help the patient deal with these feelings. Journaling can be helpful for patients to express themselves and track their progress with psychological healing.

When caring for a patient with a burn injury, the nurse needs to be aware that there are prejudices and misunderstandings in society about those who are viewed as different. Opportunities and accommodations available to others are often denied those who are disfigured. These include social participation, employment, prestige, various roles, and status. The health care team must actively promote a healthy body image and self-concept in patients with burn injuries so that they can accept or challenge others' perceptions of those who are disfigured or disabled. Survivors themselves must show others who they are, how they function, and how they want to be treated.

The nurse can help patients practice their responses to people who may stare or inquire about their injury once

they are discharged from the hospital. The nurse can help patients build self-esteem by recognizing their uniqueness—for example, with small gestures such as providing a birthday cake, combing the patient's hair before visiting hours, giving information about the availability of a cosmetician to enhance appearance, and teaching the patient ways to direct attention away from a disfigured body to the self within. Consultants such as psychologists, social workers, vocational counselors, and teachers are valuable participants in assisting burn patients to regain their self-esteem.

Monitoring and Managing Potential Complications

CONTRACTURES. With early and aggressive physical and occupational therapy, contractures are rarely a long-term complication. However, surgical intervention is indicated if a full range of motion in the burn patient is not achieved. (See Chapter 11 for a discussion of prevention of contractures.)

IMPAIRED PSYCHOLOGICAL ADAPTATION TO THE BURN INJURY. Some patients, particularly those with limited coping skills or psychological function or a history of psychiatric problems before the burn injury, may not achieve adequate psychological adaptation to the burn injury. Psychological counseling or psychiatric referral may be made to assess the patient's emotional status, to help the patient develop coping skills, and to intervene if major psychological issues or ineffective coping is identified.

Promoting Home and Community-Based Care

TEACHING PATIENTS SELF-CARE. As the inpatient phase of recovery becomes shorter, the focus of rehabilitative interventions is directed toward outpatient care, home care, or care in a rehabilitation center. Throughout the phases of burn care, efforts are made to prepare the patient and family for the care that will continue at home. They are instructed about the measures and procedures that they will need to perform. For example, patients commonly have small areas of clean, open wounds that are healing slowly. They are instructed to wash these areas daily with mild soap and water and to apply the prescribed topical agent or dressing.

In addition to instructions about wound care, patients and families require careful written and verbal instructions about pain management, nutrition, and prevention of complications. Information about specific exercises and use of pressure garments and splints is reviewed with both the patient and the family, and written instructions are provided for their use at home. The patient and family are taught to recognize abnormal signs and report them to the physician. The patient and family are assisted in planning for the patient's continued care by identifying and acquiring supplies and equipment that are needed at home (Chart 57-7).

CONTINUING CARE. Follow-up care after discharge by the multidisciplinary team is necessary. Patients who receive care in a burn center usually return to the burn clinic or center periodically for evaluation by the burn team, modification of home care instructions, and planning for reconstructive surgery. Other patients receive ongoing care from the burn surgeon who cared for them during the acute phase of their management. Still other patients require the

services of a rehabilitation center and may be transferred to such a center for aggressive rehabilitation before going home. Many patients require outpatient physical or occupational therapy, often several times weekly. It is often the nurse who is responsible for coordinating all aspects of care and ensuring that the patient's needs are met. Such coordination is an important aspect of assisting the patient to achieve independence.

Patients who return home after a severe burn injury, those who cannot manage their own burn care, and those with inadequate support systems need referral for home care. During visits to the patient at home, the home care nurse assesses the patient's physical and psychological status as well as the adequacy of the home setting for safe and adequate care. The nurse monitors the patient's progress and adherence to the plan of care and notes any problems that interfere with the patient's ability to carry out the care. During the visit, the nurse assists the patient and family with wound care and exercises. Patients with severe or persistent depression or difficulty adjusting to changes in their social or occupational roles are identified and referred to the burn team for possible referral to a psychologist, psychiatrist, or vocational counselor.

The burn team or home care nurse identifies community resources that may be helpful for the patient and family. Several burn patient support groups and other organizations throughout the United States offer services for burn survivors. They provide contact with caring people (often people who have themselves recovered from burn injuries) who can visit the patient in the hospital or home or telephone the patient and family periodically to provide support and counseling about skin care, cosmetics, and problems related to psychosocial adjustment. Such organizations, and many regional burn centers, sponsor group meetings and social functions at which outpatients are welcome. Some also provide reentry programs or burn retreats and are active in burn prevention activities.

Evaluation

Expected Patient Outcomes

Expected patient outcomes may include the following:

1. Demonstrates activity tolerance required for desired daily activities
 - a. Obtains adequate sleep daily
 - b. Reports absence of nightmares or sleep disturbances
 - c. Shows gradually increasing tolerance and endurance in physical activities
 - d. Can concentrate during conversations
 - e. Has energy available to sustain desired daily activities
2. Adapts to altered body image
 - a. Verbalizes accurate description of alterations in body image and accepts physical appearance
 - b. Demonstrates interest in resources that may improve body appearance and function
 - c. Uses cosmetics, wigs, and prostheses as desired to achieve acceptable appearance
 - d. Socializes with significant others, peers, and usual social group

CHART
57-7

HOME CARE CHECKLIST

The Patient With a Burn Injury

At the completion of the home care instruction, the patient or caregiver will be able to:	PATIENT	CAREGIVER
Mental Health		
Identify strategies to promote own mental health; for example:		
• Remember that changes in lifestyle take time.	✓	✓
• Resume previous interests and activities gradually.	✓	
• Take one day at a time to regain physical and mental strength.	✓	
• Be aware of own feelings and fears and discuss them with selected others.	✓	✓
• Expect concerns, frustrations, and depression about changes in appearance.	✓	✓
• Be honest with self, family, and friends about needs, hopes, and fears.	✓	✓
• Realize that emotional adjustment to the burn injury will occur with time.	✓	✓
Burn Skin Precautions and Wound Care		
Identify the following skin precautions and wound care:		
• Wear sun block with the highest SPF possible to protect burned skin from the sun.	✓	
• Avoid further trauma to burned skin; leave unbroken blisters that may form.	✓	✓
• Lubricate healed burned skin with mild lotion (as prescribed); avoid scratching.	✓	
• Wear wide-brimmed hats if face has been burned to protect the area from the sun.	✓	
• Use only mild soap and lotion (ie, products without perfume) on burned areas.	✓	✓
Exercise		
Describe the following guidelines for exercise:		
• Do as much for self as possible.	✓	
• Adhere to the exercise regimen given by the therapist.	✓	
• Participate in exercise every day, several times a day, even when "not feeling like it."	✓	
Nutrition		
Identify the following guidelines for nutrition:		
• Eat a diet high in calories and protein.	✓	
• Drink adequate volume of fluids to prevent constipation associated with use of analgesic medications.	✓	
Pain Management		
Describe the following steps for managing pain:		
• Avoid situations that require alertness (analgesic agents may produce drowsiness).	✓	
• Take analgesic medication as prescribed (30 minutes before painful procedures such as dressing changes).	✓	
• Use relaxation and distraction to relieve pain and discomfort.	✓	
Thermoregulation		
Identify strategies to compensate for inability to regulate body temperature:		
• Dress to accommodate cold and hot weather or environment.	✓	
• Avoid extremes of temperature.	✓	

CHART
57-7

HOME CARE CHECKLIST

The Patient With a Burn Injury (Continued)

	PATIENT	CAREGIVER
Clothing Considerations		
State the following strategies in selection of clothing to wear:		
• Avoid tight clothing over burned areas.	✓	
• Select white cotton, loose-fitting clothing so that dyes in colored clothes do not irritate healing skin.	✓	
• Wear clothing and gloves to protect healing skin from unnecessary bruises, bumps, and scratches.	✓	
Management of Burn Scar		
Describe the following strategies to manage burn scar:		
• Massage and stretch skin to maintain/increase its elasticity.	✓	✓
• Use lotion for massage as recommended by therapist.	✓	✓
• Wear compression garments 23 hours a day.	✓	
Resumption of Sexual Relations		
Identify the following guidelines regarding resumption of sexual relationships:		
• Realize that resumption of sexual relationships is the rule rather than the exception.	✓	✓
• Expect sensitivity of and around the genital area for several months if these areas were burned.	✓	
• Resume sexual activity slowly; endurance will increase with time.	✓	

Adapted with permission from Orlando Regional Medical Center Burn Unit's Personal Guide to Burn Care.

- e. Seeks and achieves return to role in family, school, and community as a contributing member
- 3. Demonstrates knowledge of required self-care and follow-up care
 - a. Describes surgical procedures and treatments accurately
 - b. Verbalizes detailed plan for follow-up care
 - c. Demonstrates ability to perform wound care and prescribed exercises
 - d. Returns for follow-up appointments as scheduled
 - e. Identifies resource people and agencies to contact for specific problems
- 4. Exhibits no complications
 - a. Demonstrates full range of motion
 - b. Shows no signs of withdrawal or depression
 - c. Displays no psychotic behaviors

The goals for treatment in an outpatient setting may include burn wound management, pain management, scar and reconstructive care, and rehabilitation. However, a number of factors must be considered in determining if outpatient care is appropriate for the patient: age, past medical history, the extent and depth of the burn, location of the burn wounds, the availability of family support systems and community resources, the patient's compliance and the distance from home, and availability of transportation from home to the outpatient setting.

The frequency of follow-up visits is individualized and based on these factors. The initial outpatient visit for a discharged burn patient is usually scheduled within 2 or 3 days after hospital discharge and then biweekly until there is evidence of a successful outcome. After healing has occurred, appointments are monthly and eventually every 4 to 6 weeks for continued assessment of pain, physical limitations, and scar maturation. Patient and family education is very important and should include verbal and written instructions as well as return demonstration of the burn or scar care required. These include the wound treatment, pain management, treatment for itching, provision of adequate nutrition, and promotion of exercise and rest. Instruction is also provided about the signs and symptoms of infection that should be reported to the burn team. The importance of notifying the outpatient setting about early complications and of keeping follow-up appointments is emphasized to the patient and family. Physical therapy and occupational therapy are often provided in the outpatient

Outpatient Burn Care

Increasing numbers of patients receive treatment of burns in outpatient settings in an effort to coordinate specific burn care needs and to decrease healthcare costs and length of hospitalization. The increased availability of outpatient surgery and access to expert burn care in outpatient settings make this option possible for the treatment of minor burn care as well as a destination for the discharged burn patient.

burn setting. The rehabilitation goals are to increase range of motion and to strengthen and build the patient's endurance. This is accomplished with a specific plan of care and includes routine visits for up to 2 years following the injury. Adaptation to lifestyle changes and emotional status should be assessed during the outpatient visits and proper referrals made for counseling services. These assessments are difficult to recognize due to the infrequent nature of the visits, and, therefore, it is helpful to incorporate family response and interactions into the assessment. The health care team must also be alert to issues of substance abuse, safety concerns, suicidal thoughts, depression, and PTSD.

CRITICAL THINKING EXERCISES

1 A 35-year-old woman was scalded in the bathtub, where she sustained 40% full-thickness burns to her lower legs, right arm, and back. It is not known how long the woman was in the tub. She apparently had a seizure while showering and fell onto the hot water faucet. On admission to the emergency department, the woman's temperature is 35.5°C (94°F) and her weight is 111 lb (50 kg). She has diabetes as well as a history of uncontrolled seizure activity. What are the priorities in her medical and nursing care during the emergent phase of burn care? What assessment parameters would you monitor closely?

2 An 82-year-old man who is wheelchair dependent and has a history of chronic obstructive pulmonary disease was smoking while using oxygen at home. He sustained superficial partial-thickness burns to his face, including his nose, lips, and chin. This is his second admission for the same type of injury in less than 1 year. His pulse oximetry is 91% and his vital signs are stable. Before he is intubated in the emergency room, he asks for a cigarette and states he wants to go home. What are this patient's immediate care needs? What referrals for inpatient services should be arranged before his discharge? What important factors need to be addressed as part of his discharge plan?

3 A 19-year-old, 233 lb (105 kg) man sustained partial-thickness and full-thickness burn injuries to his face, neck, and both hands and forearms circumferentially that occurred while he was working on his car while smoking a cigarette. Using the rule of nines, estimate the percentage of TBSA burned and estimate his fluid resuscitation needs. What immediate concerns would you have for his airway? How would you handle the care of the circumferential injury of his forearms?

EBP 4 A 52-year-old man suffered an electrical burn when he touched a high-voltage wire inside a closet while on the job. There was an explosion and he was thrown backward. The current entered his right hand and exited his left knee, leaving a large deficit in his knee. He also sustained a 45% TBSA flame burn when his clothing ignited. When asked to rate the intensity of his pain, he reports a "10" on a 10-point pain scale. What immediate concerns would

you have related to his cardiopulmonary and neurological status? What strategies would you use to relieve his pain? What is the evidence that supports the pain relief strategies that you identified and the strength of that evidence?

5 A 28-year-old woman involved in a house fire is brought to the emergency department by her boyfriend. There is no information from the scene. She is complaining of severe pain in her neck and back. She sustained a full-thickness burn of her lower extremities and her lower back. She is asking about the status of her two children who perished in the fire. What would you be concerned about related to her complaints that requires action from the burn team? What are the psychological and emotional issues that need to be addressed? Who might you consult to assist in the psychological management of this patient?

Sensorineural Function

Case Study • Applying Concepts From NANDA, NIC, and NOC

A Patient With Impaired Vision and Decreased Attention to One Side of the Body

Mr. Martin is a 60-year-old man who has had several strokes. Ophthalmologic testing reveals that he has homonymous hemianopsia of the left visual field and visual spatial neglect; as a result, he has limited vision in the left visual fields of both eyes. He has difficulty in many areas, such as bumping into objects and ignoring the left side of his body.

Visit thePoint to view a concept map that illustrates the relationships that exist between the nursing diagnoses, interventions, and outcomes for the patient's clinical problems.

Nursing Classifications and Languages

NANDA NURSING DIAGNOSES	NIC NURSING INTERVENTIONS	NOC NURSING OUTCOMES
		Return to functional baseline status, stabilization of, or improvement in:
DISTURBED SENSORY PERCEPTION: VISUAL —Change in the amount or patterning of incoming stimuli accompanied by a diminished, exaggerated, distorted, or impaired response to such stimuli	COMMUNICATION ENHANCEMENT: VISUAL DEFICIT —Assistance in accepting and learning alternative methods for living with diminished vision	VISION COMPENSATION BEHAVIOR —Personal actions to compensate for visual impairment
UNILATERAL NEGLECT —Lack of awareness and attention to one side of the body	UNILATERAL NEGLECT MANAGEMENT —Protecting and safely reintegrating the affected part of the body while helping the patient adapt to disturbed perceptual abilities	SAFE HOME ENVIRONMENT —Physical arrangements to minimize environmental factors that might cause physical harm or injury in the home
RISK FOR INJURY —At risk for injury as a result of environmental conditions interacting with the individual's adaptive and defensive resources	POSITIONING —Deliberative placement of the patient or a body part to promote physiological and/or psychological well-being	PHYSICAL INJURY SEVERITY —Severity of injuries from trauma

Assessment and Management of Patients With Eye and Vision Disorders

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

- 1 Identify significant eye structures and describe their functions.
- 2 Identify diagnostic tests for assessment of vision and evaluation of visual disabilities.
- 3 Discuss clinical features, diagnostic assessment and examinations, medical or surgical management, and nursing management of ocular disorders.
- 4 Describe therapeutic effects of ophthalmic medications.
- 5 Define low vision and blindness and differentiate between functional and visual impairment.
- 6 List and describe assessment and management strategies for low vision.
- 7 Demonstrate orientation and mobility techniques for patients with low vision in a hospital setting.
- 8 Demonstrate instillation of eye drops and ointment.
- 9 Discuss general discharge instructions for patients after ocular surgery.
- 10 Discuss strategies for patient safety in ophthalmology.

GLOSSARY

accommodation: process by which the eye adjusts for near distance (eg, reading) by changing the curvature of the lens to focus a clear image on the retina

anterior chamber: space in the eye bordered anteriorly by the cornea and posteriorly by the iris and pupil

aphakia: absence of the natural lens

aqueous humor: watery fluid that fills the anterior and posterior chambers of the eye

astigmatism: refractive error in which light rays are spread over a diffuse area rather than sharply focused on the retina, a condition caused by differences in the curvature of the cornea and lens

binocular vision: normal ability of both eyes to focus on one object and fuse the two images into one

blindness: inability to see, usually defined as corrected visual acuity of 20/400 or less, or a visual field of no more than 20 degrees in the better eye

bullous keratopathy: corneal edema with painful blisters in the epithelium due to excessive corneal hydration

chemosis: edema of the conjunctiva

cones: retinal photoreceptor cells essential for visual acuity and color discrimination

GLOSSARY (Continued)

diplopia: seeing one object as two; double vision

emmetropia: absence of refractive error

enucleation: complete removal of the eyeball and part of the optic nerve

evisceration: removal of the intraocular contents through a corneal or scleral incision; the optic nerve, sclera, extraocular muscles, and sometimes, the cornea are left intact

exenteration: surgical removal of the entire contents of the orbit, including the eyeball and lids

hyperemia: "red eye" resulting from dilation of the vasculature of the conjunctiva

hyperopia: farsightedness; a refractive error in which the focus of light rays from a distant object is behind the retina

hyphema: blood in the anterior chamber

hypopyon: collection of inflammatory cells that has the appearance of a pale layer in the inferior anterior chamber of the eye

injection: congestion of blood vessels

keratoconus: cone-shaped deformity of the cornea

limbus: junction of the cornea and sclera

miotics: medications that cause pupillary constriction

mydriatics: medications that cause pupillary dilation

myopia: nearsightedness; a refractive error in which the focus of light rays from a distant object is anterior to the retina

neovascularization: growth of abnormal new blood vessels

nystagmus: involuntary oscillation of the eyeball

papilledema: swelling of the optic disc due to increased intracranial pressure

photophobia: ocular pain on exposure to light

posterior chamber: space between the iris and vitreous

proptosis: downward displacement of the eyeball resulting from an inflammatory condition of the orbit or a mass within the orbital cavity

ptosis: drooping eyelid

refraction: determination of the refractive errors of the eye and correction by lenses

rods: retinal photoreceptor cells essential for bright and dim light

scotomas: blind or partially blind areas in the visual field

strabismus: a condition in which there is deviation from perfect ocular alignment

sympathetic ophthalmia: an inflammatory condition created in the fellow eye by the affected eye (without useful vision); the condition may become chronic and result in blindness (of the fellow eye)

trachoma: a bilateral chronic follicular conjunctivitis of childhood that leads to blindness during adulthood, if left untreated

vitreous humor: gelatinous material (transparent and colorless) that fills the eyeball behind the lens

Note: Common abbreviations related to vision and eye health are OD (oculus dexter, right eye), OS (oculus sinister, left eye), and OU (oculus uterque, both eyes).

The ability to see the world clearly can easily be taken for granted. The eye is a sensitive, highly specialized sense organ subject to various disorders, many of which lead to impaired vision. Impaired vision may affect a person's independence in self-care, work and lifestyle choices, sense of self-esteem, safety, ability to interact with society and the environment, and overall quality of life. Many of the leading causes of visual impairment are associated with aging (eg, cataracts, glaucoma, macular degeneration). Careful fitting with corrective lenses could help more than 80% of the 14 million Americans who are visually impaired (Bressler, Quigley & Schein, 2008). Two thirds of the population with impaired vision is older than 65 years of age. Younger people are also at risk for eye disorders, particularly traumatic injuries. The rapidly changing technological advances of ophthalmic surgery affect all age groups. These include refractive procedures as well as implantation of intraocular lenses and telescopic devices.

Although most people with eye disorders are treated in an ambulatory care setting, many patients receiving health care have an eye disorder as a comorbid condition. In addition to understanding the prevention, treatment, and consequences of eye disorders, nurses in all settings assess visual acuity in patients at risk (eg, those who are elderly, those with diabetes or acquired immunodeficiency syndrome [AIDS]), refer patients to eye care specialists as appropriate, implement measures to prevent further visual loss, and help patients adapt to impaired vision.

ASSESSMENT OF THE EYE

Anatomic and Physiologic Overview

Unlike most organs of the body, the eye is available for external examination, and its anatomy is more easily assessed than many other body parts (Fig. 58-1). The eyeball, or globe, sits in a protective bony structure known as the orbit.

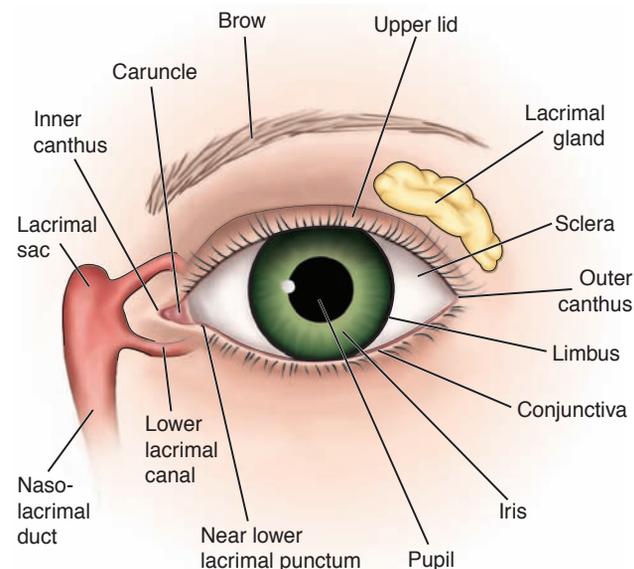

Figure 58-1 External structures of the eye and position of the lacrimal structures.

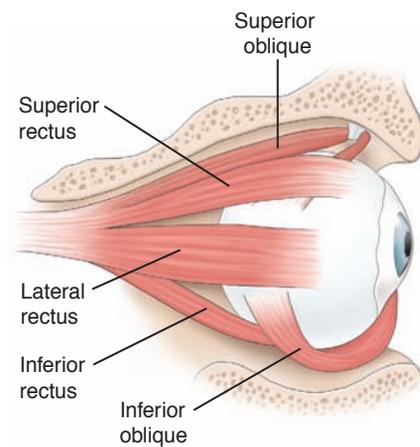

Figure 58-2 The extraocular muscles responsible for eye movement. The medial rectus muscle (not shown) is responsible for opposing the movement of the lateral rectus muscle.

Lined with muscle and connective and adipose tissues, the orbit is about 4-cm high, wide, and deep, and it is shaped roughly like a four-sided pyramid, surrounded on three sides by the sinuses: ethmoid (medially), frontal (superiorly), and maxillary (inferiorly). The optic nerve and the ophthalmic artery enter the orbit at its apex through the optic foramen. The eyeball is moved through all fields of gaze by the extraocular muscles. The four rectus muscles and two oblique muscles (Fig. 58-2) are innervated by cranial nerves (CN) III, IV, and VI. Normally, the movements of the two eyes are coordinated, and the brain perceives a single image.

The eyelids, composed of thin elastic skin that covers striated and smooth muscles, protect the anterior portion of the eye. The eyelids contain multiple glands, including sebaceous, sweat, and accessory lacrimal glands, and they are lined with conjunctival material. The upper lid normally covers the uppermost portion of the iris and is innervated by the oculomotor nerve (CN III). The lid margins contain meibomian glands, the inferior and superior puncta, and the eyelashes. The triangular spaces formed by the junction of the eyelids are known as the inner or medial canthus and the outer or lateral canthus. With every blink of the eyes, the lids wash the cornea and conjunctiva with tears.

Tears are vital to eye health. They are formed by the lacrimal gland and the accessory lacrimal glands. A healthy tear is composed of three layers: lipoid, aqueous, and mucoid. If there is a defect in the composition of any of these layers, the integrity of the cornea may be compromised. Tears are secreted in response to reflex or emotional stimuli.

The conjunctiva, a mucous membrane, provides a barrier to the external environment and nourishes the eye. The goblet cells of the conjunctiva secrete lubricating mucus. The bulbar conjunctiva covers the sclera, whereas the palpebral conjunctiva lines the inner surface of the upper and lower eyelids. The junction of the two portions is known as the fornix.

The sclera, commonly known as the white of the eye, is a dense, fibrous structure that makes up the posterior five sixths of the eye (Fig. 58-3). The sclera helps maintain the shape of the eyeball and protects the intraocular contents from trauma. The sclera may have a slightly bluish tinge in young children, a dull white color in adults, and a slightly

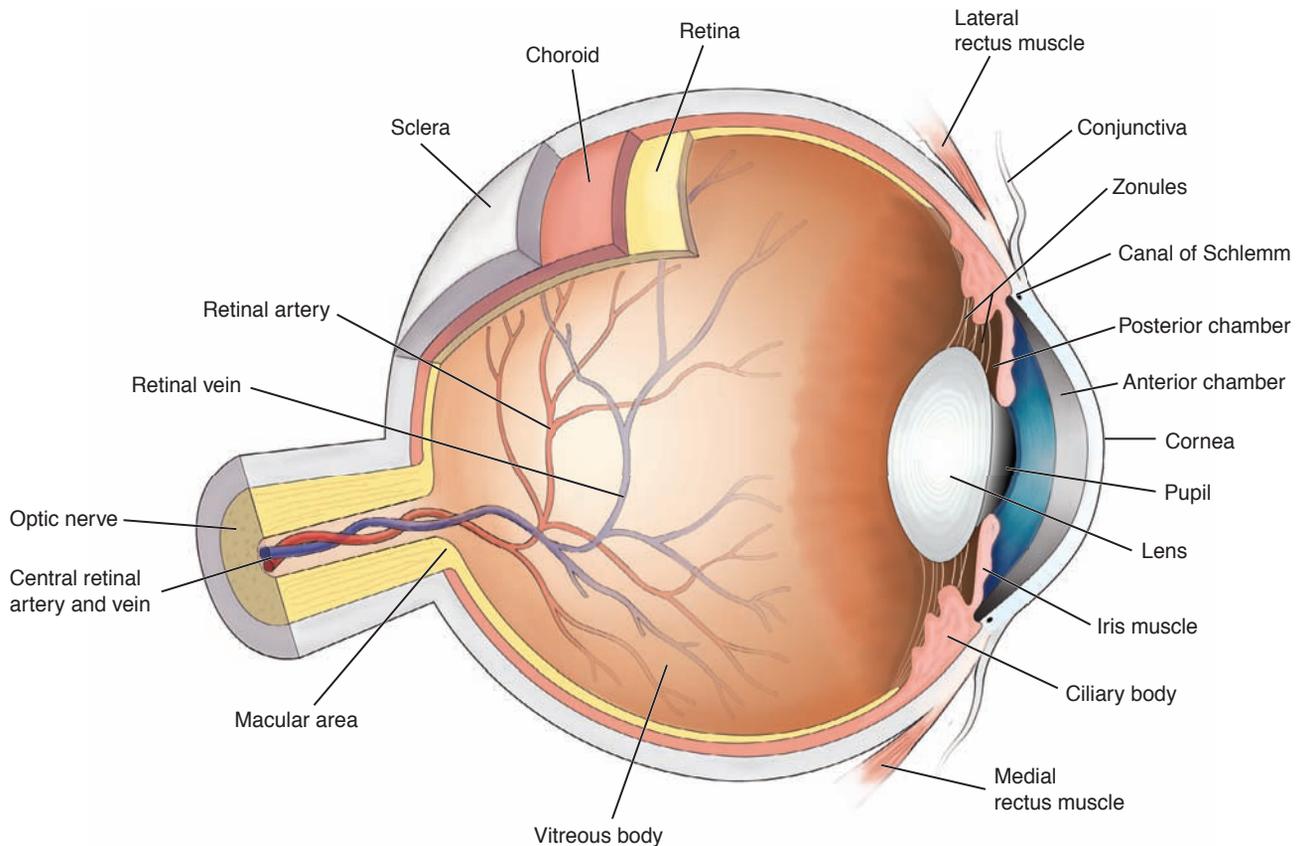

Figure 58-3 Three-dimensional cross-section of the eye.

yellowish color in the elderly. Externally, it is overlaid with conjunctiva, which is a thin, transparent, mucous membrane that contains fine blood vessels. The conjunctiva meets the cornea at the **limbus** on the outermost edge of the iris.

The cornea (Fig. 58-4), a transparent, avascular, domelike structure, forms the most anterior portion of the eyeball and is the main refracting surface of the eye. It is composed of five layers: epithelium, Bowman's membrane, stroma, Descemet's membrane, and endothelium. The epithelial cells are capable of rapid replication and are completely replaced every 7 days.

Behind the cornea lies the **anterior chamber**, filled with a continually replenished supply of clear aqueous humor, which nourishes the cornea. The **aqueous humor** is produced by the ciliary body, and its production is related to the intraocular pressure (IOP). Normal IOP is 10 to 21 mm Hg.

The uvea consists of the iris, the ciliary body, and the choroid. The iris, or colored part of the eye, is a highly vascularized, pigmented collection of fibers surrounding the pupil. The pupil is a space that dilates and constricts in response to light. Normal pupils are round and constrict symmetrically when a bright light shines on them. About 20% of the population have pupils that are slightly unequal in size but that respond equally to light. Dilation and constriction are controlled by the sphincter and dilator pupillae muscles. The dilator muscles are controlled by the sympathetic nervous system, whereas the sphincter muscles are controlled by the parasympathetic nervous system.

Directly behind the pupil and iris lies the lens, a colorless and almost completely transparent, biconvex structure held in position by zonular fibers. It is avascular and has no nerve or pain fibers. The lens enables focusing for near vision and refocusing for distance vision. The ability to focus and refocus is called **accommodation**. The lens is suspended behind the iris by the zonules and is connected to the ciliary body. The ciliary body controls accommodation through the zonular fibers and the ciliary muscles. The aqueous humor is anterior to the lens; posterior to the lens is the vitreous humor. All cells formed throughout life are retained by the lens, which makes the cell structure of the lens susceptible to the degenerative effects of aging. The lens continues to grow throughout life, laying down fibers in concentric rings. This gradual thickening becomes evident in the fifth decade of life and eventually results in an increasingly dense core or nucleus, which can limit accommodative powers.

The **posterior chamber** is a small space between the vitreous and the iris. Aqueous fluid is manufactured in the posterior chamber by the ciliary body. This aqueous fluid flows from the posterior chamber into the anterior chamber, from which it drains through the trabecular meshwork into the canal of Schlemm.

The choroid lies between the retina and the sclera. It is avascular tissue, supplying blood to the portion of the sensory retina closest to it.

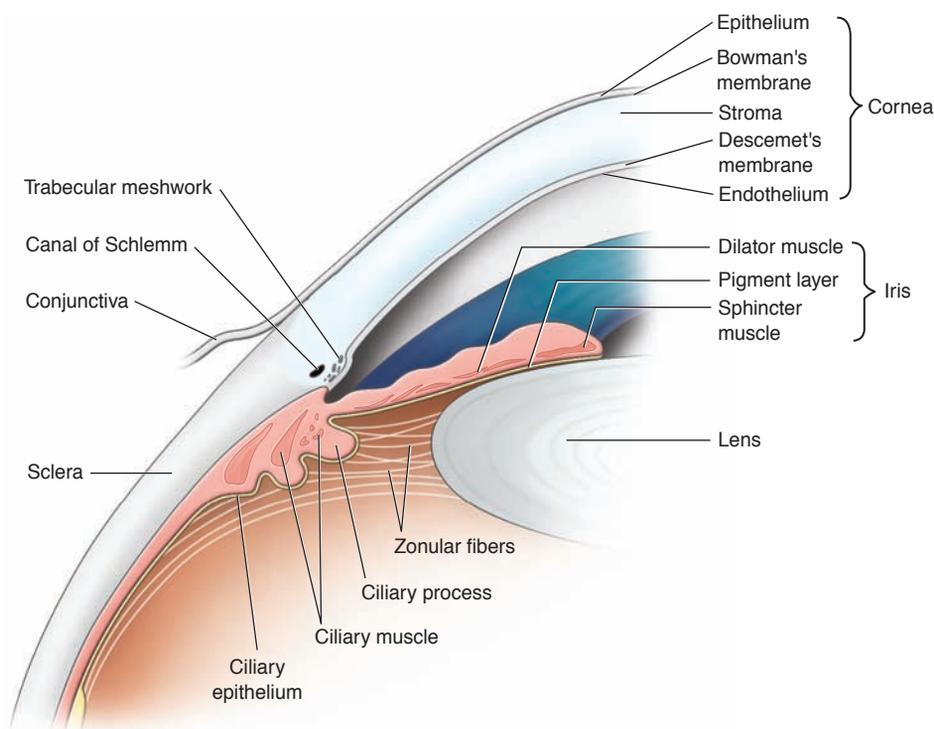

Figure 58-4 Internal structures of the eye. From American Society of Ophthalmic Registered Nurses. (2008). *Core curriculum for ophthalmic nursing* (3rd ed.) Dubuque, IA: Kendall/Hunt Publishing.

The ocular fundus is the largest chamber of the eye and contains the **vitreous humor**, a clear, gelatinous substance, composed mostly of water and encapsulated by a hyaloid membrane. The vitreous humor occupies about two thirds of the eye's volume and helps maintain the shape of the eye. As the body ages, the gel-like characteristics are gradually lost, and various cells and fibers cast shadows that the patient perceives as "floaters." The vitreous is in continuous contact with the retina and is attached to the retina by scattered collagenous filaments. The vitreous shrinks and shifts with age.

The innermost surface of the fundus is the retina. The retina is composed of 10 microscopic layers and has the consistency of wet tissue paper. It is neural tissue, an extension of the optic nerve. Viewed through the pupil, the landmarks of the retina are the optic disc, the retinal vessels, and the macula. The point of entrance of the optic nerve into the retina is the optic disc. The optic disc is pink; it is oval or circular and has sharp margins. In the disc, a physiologic depression or cup is present centrally, with the retinal blood vessels emerging from it. The retinal tissues arise from the optic disc and line the inner surface of the vitreous chamber. The retinal vessels also enter the eye through the optic disc, branching out through the retina and forming superior and inferior branches. The macula is the area of the retina responsible for central vision. The rest of the retina is responsible for peripheral vision. In the center of the macula is the most sensitive area, the fovea, which is avascular and surrounded by the superior and inferior vascular arcades. Two important layers of the retina are the retinal pigment epithelium (RPE) and the sensory retina. A single layer of

cells constitutes the RPE, and these cells have numerous functions, including the absorption of light. The sensory retina contains the photoreceptor cells: **rods** and **cones**. The rods are mainly responsible for night vision or vision in low light, whereas the cones provide the best vision for bright light, color vision, and fine detail. Cones are distributed throughout the retina, with their greatest concentration in the fovea. Rods are absent in the fovea.

Visual acuity depends on a healthy, functioning eyeball and an intact visual pathway (Fig. 58-5). This pathway is made up of the retina, optic nerve, optic chiasm, optic tracks, lateral geniculate bodies, and optic radiations, and the visual cortex area of the brain. The pathway is an extension of the central nervous system.

The optic nerve is also known as the second cranial nerve (CN II). Its purpose is to transmit impulses from the retina to the occipital lobe of the brain. The optic nerve head, or optic disc, is the physiologic blind spot in each eye. The optic nerve leaves the eye and then meets the optic nerve from the other eye at the optic chiasm. The chiasm is the anatomic point at which the nasal fibers from the nasal retina of each eye cross to the opposite side of the brain. The nerve fibers from the temporal retina of each eye remain uncrossed. Fibers from the right half of each eye, which would be the left visual field, carry impulses to the right occipital lobe. Fibers from the left half of each eye, or the right visual field, carry impulses to the left occipital lobe. Beyond the chiasm, these fibers are known as the optic tract. The optic tract continues on to the lateral geniculate body. The lateral geniculate body leads to the optic radiations and then to the cortex of the occipital lobe of the brain.

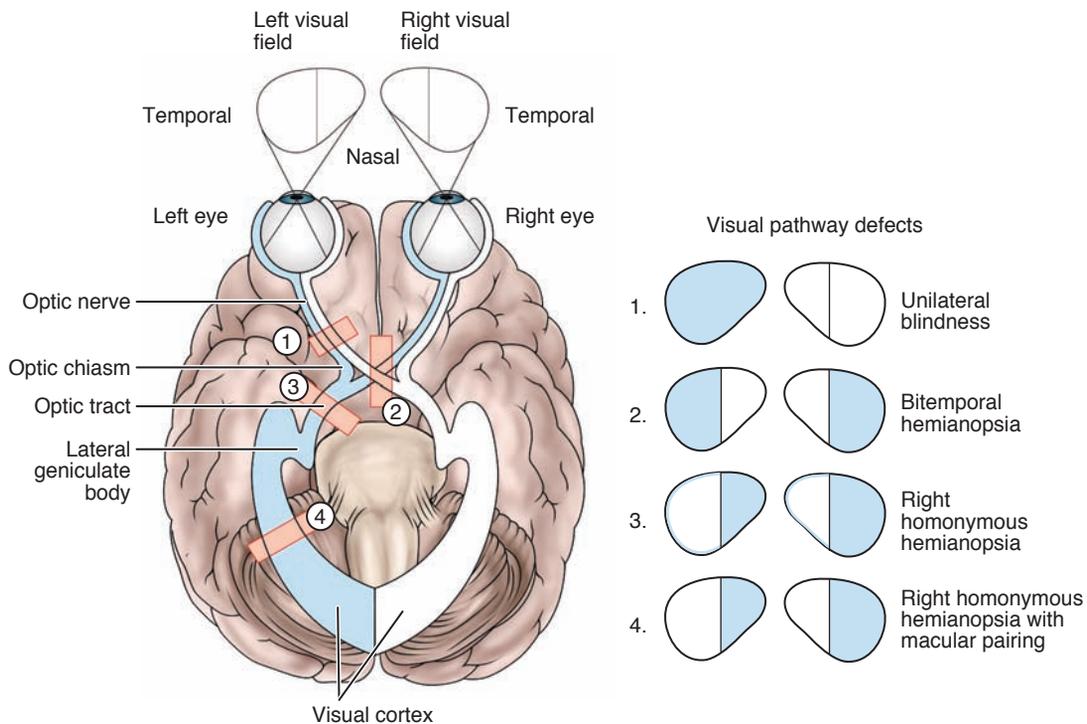

Figure 58-5 The visual pathway. From Fuller, J. & Schaller-Ayers, J. (2000). *Health assessment: A nursing approach* (3rd ed.). Philadelphia: Lippincott Williams & Wilkins.

Assessment

Ocular History

The nurse, through careful questioning, elicits the necessary information that can assist in diagnosis of an ophthalmic condition. Pertinent questions to ask during the interview are presented in Chart 58-1. Genetics plays a role in many eye and vision problems; for more information, see Chart 58-2.

Visual Acuity

Following the health history, the patient's visual acuity is assessed. This is an essential part of the eye examination and a measure against which all therapeutic outcomes are based.

The Snellen chart, which is composed of a series of progressively smaller rows of letters, is used to test distance vision. The fraction 20/20 is considered the standard of normal vision. Most people can see the letters on the line designated as 20/20 from a distance of 20 feet. A person whose vision is 20/200 can see an object from 20 feet away that a person with 20/20 vision can see from 200 feet away. The patient is positioned at the prescribed distance, usually 20 feet, from the chart and is asked to read the smallest line that he or she can see. The patient should wear distance correction (eyeglasses or contact lenses) if required, and each eye should be tested separately. If the patient cannot read the 20/20 line, he or she is given a pinhole occluder and asked to read again using the eye in question. A makeshift occluder may be created by making a pinhole in an index card and asking the patient to look through the pinhole. Squinting produces the same effect. Patients should be encouraged to read more letters and to guess, if

necessary. Often, patients avoid guessing and prefer not to try at all rather than to make a mistake. The patient should be encouraged to read every letter possible.

CHART 58-1

Taking an Ocular History

- What does the patient perceive to be the problem?
- Is visual acuity diminished?
- Does the patient experience blurred, double, or distorted vision?
- Is there pain; is it sharp or dull; is it worse when blinking?
- Is the discomfort an itching sensation or more of a foreign body sensation?
- Are both eyes affected?
- Is there a history of discharge? If so, inquire about color, consistency, odor.
- Describe the onset of the problem (sudden, gradual). Is it worsening?
- What is the duration of the problem?
- Is this a recurrence of a previous condition?
- How has the patient self-treated?
- What makes the symptoms improve or worsen?
- Has the condition affected performance of activities of daily living (ADLs)?
- Are there any systemic diseases? What medications are used in their treatment?
- What concurrent ophthalmic conditions does the patient have?
- Is there a history of ophthalmic surgery?
- Have other family members had the same symptoms or condition?

CHART
58-2GENETICS IN NURSING PRACTICE
Eye and Vision Disorders

Several eye and vision disorders are associated with genetic abnormalities. Some examples are:

- Albinism
- Aniridia
- Color blindness
- Glaucoma
- Homocystinuria
- Isolated familial congenital cataracts
- Leber hereditary optic neuropathy
- Leber congenital amaurosis
- Marfan syndrome
- Retinitis pigmentosa

Nursing Assessments**Family History Assessment**

- Assess history of family members with glaucoma, cataracts, night blindness (retinitis pigmentosa), color blindness, or other vision impairment.
- Inquire about the age of onset of symptoms (the onset of Leber congenital amaurosis is in childhood, while the onset of Leber hereditary optic neuropathy is in young adulthood).
- Inquire about family members with other disorders that may include visual impairment, such as cutaneous, metabolic, or connective tissue disorders and hearing loss.

Patient Assessment

- Assess for other systemic and/or clinical features such as cutaneous or skeletal conditions, or hearing loss.

Management Issues Specific to Genetics

- Inquire whether DNA gene mutation or other genetics testing has been performed on any affected family members.
- If indicated, refer for further genetics counseling and evaluation so that family members can discuss inheritance, risk to other family members, availability of genetics testing, and gene-based interventions.
- Offer appropriate genetics information and resources.
- Assess patient's understanding of genetics information.
- Provide support to families with newly diagnosed genetic-related sensorineural disorders.
- Participate in management and coordination of care of patients with genetic conditions and individuals pre-disposed to develop or pass on a genetic condition

Genetics Resources

Genetic Alliance—a directory of support groups for patients and families with genetic conditions, www.geneticalliance.org

Gene Clinics—a listing of common genetic disorders with up-to-date clinical summaries, genetic counseling and testing information, www.geneclinics.org

National Organization of Rare Disorders—a directory of support groups and information for patients and families with rare genetic disorders, www.rarediseases.org

OMIM: Online Mendelian Inheritance in Man—a complete listing of inherited genetic conditions, www.ncbi.nlm.nih.gov/omim/stats/html

Visual acuity is then recorded. If the patient reads all five letters from the 20/20 line with the right eye (OD) and three of the five letters on the 20/15 line with the left eye (OS), the examiner writes OD 20/20, OS 20/15-2.

If the patient cannot read the largest letter on the chart (the 20/200 line), the patient should be moved toward the chart or the chart moved toward the patient until the patient can identify the largest letter on the chart. If the patient can recognize only the letter E on the top line at a distance of 10 feet, the visual acuity would be recorded as 10'/200. If the patient cannot see the letter E at any distance, the examiner should determine if the patient can count fingers (CF). The examiner holds up a random number of fingers and asks the patient to count the number he or she sees. If the patient correctly identifies the number of fingers at 3 feet, the examiner would record CF/3'.

If the patient cannot count fingers, the examiner raises one hand up and down or moves it side to side and asks in which direction the hand is moving. This level of vision is known as hand motion (HM). A patient who can perceive only light is described as having light perception (LP). The vision of a patient who cannot perceive light is described as no light perception (NLP).

External Eye Examination

After the visual acuity has been recorded, an external eye examination is performed. The position of the eyelids is

noted. Commonly, the upper 2 mm of the iris are covered by the upper lid. The patient is examined for **ptosis** (drooping eyelid) and for lid retraction (too much of the eye exposed). Sometimes, the upper or lower lid turns out, affecting closure. The lid margins and lashes should have no edema, erythema, or lesions. The examiner looks for scaling or crusting, and the sclera is inspected. A normal sclera is opaque and white. Lesions on the conjunctiva, discharge, and tearing or blinking are noted.

The room should be darkened so that the pupils can be examined. The pupillary response is checked with a penlight to determine if the pupils are equally reactive and regular. A normal pupil is black. An irregular pupil may result from trauma, previous surgery, or a disease process.

The patient's eyes are observed in primary or direct gaze, and any head tilt is noted. A tilt may indicate cranial nerve palsy. The patient is asked to stare at a target; each eye is covered and uncovered quickly while the examiner looks for any shift in gaze. The examiner observes for **nystagmus** (ie, oscillating movement of the eyeball). The extraocular movements of the eyes are tested by having the patient follow the examiner's finger, pencil, or a hand light through the six cardinal directions of gaze (ie, up, down, right, left, and both diagonals). This is especially important when screening patients for ocular trauma or for neurologic disorders.

Diagnostic Evaluation

Direct Ophthalmoscopy

A direct ophthalmoscope is a hand-held instrument with various plus and minus lenses. The lenses can be rotated into place, enabling the examiner to bring the cornea, lens, and retina into focus sequentially. The examiner holds the ophthalmoscope in the right hand and uses the right eye to examine the patient's right eye. The examiner switches to the left hand and left eye when examining the patient's left eye. During this examination, the room should be darkened, and the patient's eye should be on the same level as the examiner's eye. The patient and the examiner should be comfortable, and both should breathe normally. The patient is given a target to gaze at and is encouraged to keep both eyes open and steady.

When the fundus is examined, the vasculature comes into focus first. The veins are larger in diameter than the arteries. The examiner focuses on a large vessel and then follows it toward the midline of the body, which leads to the optic nerve. The central depression in the disc is known as the cup. The normal cup is about one-third the size of the diameter of the disc. The size of the physiologic optic cup should be estimated and the disc margins described as sharp or blurred. A silvery or coppery appearance, which indicates arteriosclerosis, should be noted. The periphery of the retina is examined by having the patient shift his or her gaze. The last area of the fundus to be examined is the macula, because this area is the most sensitive to light. The retina of a young person often has a glistening effect, sometimes referred to as a cellophane reflex.

The healthy fundus should be free of any lesions. The examiner looks for intraretinal hemorrhages, which may appear as red smudges, and, if the patient has hypertension, they may be somewhat flame shaped. Lipid may be present in the retina of patients with hypercholesterolemia or diabetes. This lipid has a yellowish appearance. Soft exudates that have a fuzzy, white appearance (cotton-wool spots) should be noted. The examiner looks for microaneurysms, which look like little red dots, and nevi. Drusen (small, hyaline, globular deposits), commonly found in macular degeneration, appear as yellowish areas with indistinct edges. Small drusen have a more distinct edge. The examiner should sketch the fundus and document any abnormalities.

Indirect Ophthalmoscopy

The indirect ophthalmoscope is an instrument commonly used by the ophthalmologist to see larger areas of the retina, although in an unmagnified state. It produces a bright and intense light. The light source is affixed with a pair of binocular lenses mounted on the examiner's head. The ophthalmoscope is used with a hand-held, 20-diopter lens.

Slit-Lamp Examination

The slit lamp is a binocular microscope mounted on a table. This instrument enables the user to examine the eye with magnification of 10 to 40 times the real image. The illumination can be varied from a broad to a narrow beam of light for different parts of the eye. For example, by varying the

width and intensity of the light, the anterior chamber can be examined for signs of inflammation. Cataracts may be evaluated by changing the angle of the light. When a hand-held contact lens, such as a three-mirror lens, is used with the slit lamp, the angle of the anterior chamber may be examined, as may the ocular fundus.

Color Vision Testing

The ability to differentiate colors has a dramatic effect on the activities of daily living (ADLs). For example, the inability to differentiate between red and green can compromise traffic safety. Some careers (eg, commercial artist, [color] photographer, airline pilot, electrician) may be closed to people with significant color deficiencies. The photoreceptor cells responsible for color vision are the cones, and the greatest area of color sensitivity is in the macula, the area of densest cone concentration.

A screening test, such as the polychromatic plates discussed in the next paragraph, can be used to establish whether a person's color vision is within normal range. Color vision deficits can be inherited. For example, red-green color deficiencies are inherited in an X-linked manner, affecting approximately 8% of men and 0.4% of women. Acquired color vision losses may be caused by medications (eg, digitalis) or pathology (eg, cataracts). A simple test, such as asking a patient if the red top on a bottle of eye drops appears redder to one eye than the other, can be an effective tool. A difference in the perception of the intensity of the color red between the two eyes can be a symptom of a neurologic problem and may provide information about the location of the lesion.

Because alteration in color vision sometimes indicates conditions of the optic nerve, color vision testing is often performed in a neuro-ophthalmologic workup. The most common color vision test is performed using Ishihara polychromatic plates. These plates are bound together in a booklet. On each plate of this booklet are dots of primary colors that are integrated into a background of secondary colors. The dots are arranged in simple patterns, such as numbers or geometric shapes. Patients with diminished color vision may be unable to identify the hidden shapes. Patients with central vision conditions (eg, macular degeneration) have more difficulty identifying colors than those with peripheral vision conditions (eg, glaucoma) because central vision identifies color.

Amsler Grid

The Amsler grid is a test often used for patients with macular problems, such as macular degeneration. It consists of a geometric grid of identical squares with a central fixation point. The grid should be viewed by the patient wearing normal reading glasses. Each eye is tested separately. The patient is instructed to stare at the central fixation spot on the grid and report any distortion in the squares of the grid itself. For patients with macular problems, some of the squares may look faded, or the lines may be wavy. Patients with age-related macular degeneration are commonly given these Amsler grids to take home. The patient is encouraged to check them frequently, as often as daily, to detect any early signs of distortion that may indicate the development of a neovascular choroidal membrane, an advanced stage of

macular degeneration characterized by the growth of abnormal choroidal vessels.

Ultrasonography

Lesions in the globe or the orbit may not be directly visible and are evaluated by ultrasonography. Ultrasonography is a valuable diagnostic technique, especially when the view of the retina is obscured by opaque media such as cataract or hemorrhage. Ultrasonography can be used to identify orbital tumors, retinal detachment, vitreous hemorrhage, and changes in tissue composition with minimal discomfort for the patient.

Optical Coherence Tomography

Optical coherence tomography is a technology that involves low-coherence interferometry. Light is used to evaluate retinal and macular diseases as well as anterior segment conditions. This method is noninvasive and involves no physical contact with the eye.

Color Fundus Photography

Fundus photography is used to detect and document retinal lesions. The patient's pupils are widely dilated before the procedure. The resulting fundus photographs can be viewed stereoscopically so that elevations such as macular edema can be identified. Visual acuity is diminished for about 30 minutes as a result of retinal "bleaching" by the intense flashing lights.

Fluorescein Angiography

Fluorescein angiography evaluates clinically significant macular edema, documents macular capillary nonperfusion, and identifies retinal and choroidal **neovascularization** (growth of abnormal new blood vessels) in age-related macular degeneration. It is an invasive procedure in which fluorescein dye is injected, usually into an antecubital vein. Within 10 to 15 seconds, this dye can be seen coursing through the retinal vessels. Over a 10-minute period, serial black-and-white photographs are taken of the retinal vasculature. The dye may impart a gold tone to the skin of some patients, and urine may turn deep yellow or orange. This discoloration usually disappears in 24 hours.

Indocyanine Green Angiography

Indocyanine green angiography is used to evaluate abnormalities in the choroidal vasculature, conditions often seen in macular degeneration. Indocyanine green dye is injected intravenously, and multiple images are captured using digital videoangiography over a period of 30 seconds to 20 minutes. The dye is generally well tolerated, but some patients experience nausea and vomiting. Allergic reactions are rare; however, indocyanine green angiography is contraindicated in patients with a history of iodide reactions.

Tonometry

Tonometry measures IOP by determining the pressure necessary to indent or flatten (applanate) a small anterior area of the globe of the eye. Pressure is measured in millimeters of mercury (mm Hg). High readings indicate high pressure; low readings indicate low pressure. The procedure is noninvasive and usually painless. A topical anesthetic eye drop is

instilled in the lower conjunctival sac, and the tonometer is then used to measure the IOP.

Perimetry Testing

Perimetry testing evaluates the field of vision. A visual field is the area or extent of physical space visible to an eye in a given position. Its average extent is 65 degrees upward, 75 degrees downward, 60 degrees inward, and 95 degrees outward when the eye is in the primary gaze (ie, looking directly forward). Visual field testing (ie, perimetry) helps identify which parts of the patient's central and peripheral visual fields have useful vision. It is most helpful in detecting central **scotomas** (blind areas in the visual field) in macular degeneration and the peripheral field defects in glaucoma and retinitis pigmentosa.

IMPAIRED VISION

Refractive Errors

In refractive errors, vision is impaired because a shortened or elongated eyeball prevents light rays from focusing sharply on the retina. Blurred vision from refractive error can be corrected with eyeglasses or contact lenses. The appropriate eyeglass or contact lens is determined by **refraction**. Ophthalmic refraction consists of placing various types of lenses in front of the patient's eyes to determine which lens best improves the patient's vision.

The depth of the eyeball is important in determining refractive error (Fig. 58-6). Patients for whom the visual image focuses precisely on the macula and who do not need

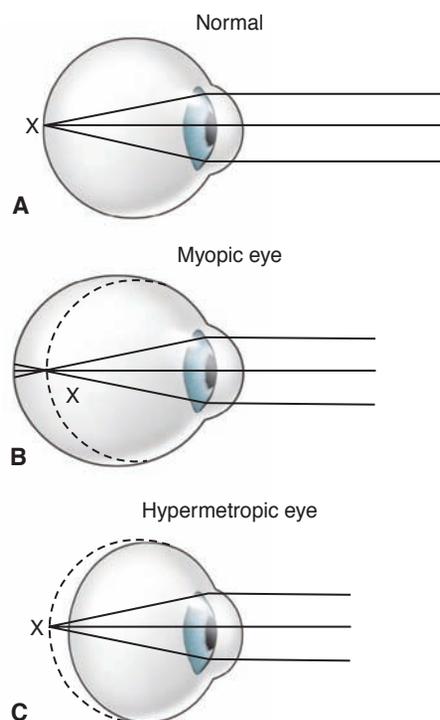

Figure 58-6 Eyeball shape determines visual acuity in refractive errors. **A**, Normal eye. **B**, Myopic eye. **C**, Hypermetropic eye.

eyeglasses or contact lenses are said to have **emmetropia** (normal vision). Some people have deeper eyeballs; thus, the distant visual image focuses in front of, or short of, the retina. They have **myopia**, are said to be nearsighted, and have blurred distance vision. Other people have shallower eyeballs; thus, the visual image focuses beyond the retina. They have **hyperopia**, are said to be farsighted, and have excellent distance vision but blurry near vision.

Another important cause of refractive error is **astigmatism**, an irregularity in the curve of the cornea. Because astigmatism causes a distortion of the visual image, acuity of distance and near vision can be decreased. Hard contact lenses, which by means of their tear film correct astigmatic errors, or soft toric contact lenses with a cylinder correction may be used in place of eyeglasses for patients with astigmatism.

Ophthalmology has entered the era of customized vision correction in its desire to achieve “super-normal vision.” Wavefront technology to measure unique refractive imperfections of the cornea or higher aberrations (ie, myopia, hyperopia, astigmatism) is currently used to customize laser-assisted in situ keratomileusis (LASIK) procedures. To customize the corneal flaps during LASIK, a newer procedure uses a femtosecond (ultrashort-pulse) laser (Slade, 2007).

Low Vision and Blindness

Low vision is a general term describing visual impairment that requires patients to use devices and strategies in addition to corrective lenses to perform visual tasks. Low vision is defined as a best corrected visual acuity (BCVA) of 20/70 to 20/200.

Blindness is defined as a BCVA that can range from 20/400 to no light perception. The clinical definition of absolute blindness is the absence of light perception. Legal blindness is a condition of impaired vision in which a person has a BCVA that does not exceed 20/200 in the better

eye or whose widest visual field diameter is 20 degrees or less. This definition neither equates with functional ability nor classifies the degrees of visual impairment. Legal blindness ranges from an inability to perceive light to having some vision remaining. A person who meets the criteria for legal blindness may be eligible for government financial assistance.

Impaired vision is often accompanied by difficulty in performing functional activities. People with visual acuity of 20/80 to 20/100 with a visual field restriction of 60 degrees to greater than 20 degrees can read at a nearly normal level with optical aids. Their visual orientation is near normal but requires increased scanning of the environment (ie, systematic use of head and eye movements). In a visual acuity range of 20/200 to 20/400 with a 20-degree to greater than 10-degree visual field restriction, the person can read slowly with optical aids. His or her visual orientation is slow, with constant scanning of the environment. People in this category may have the ability to negotiate their environment without auxiliary aids. This ability is termed “travel vision.” People with HM vision or no vision may benefit from the use of mobility devices (eg, cane, guide dog) and should be encouraged to learn Braille and to use computer aids.

The most common causes of blindness and visual impairment among adults 40 years of age or older are diabetic retinopathy, macular degeneration, glaucoma, and cataracts (Prevent Blindness America, 2008). Macular degeneration is more prevalent among Caucasians, whereas glaucoma is more prevalent among African Americans. Age-related changes in the eye are summarized in Table 58-1.

Assessment and Diagnostic Testing

The assessment of low vision includes a thorough history and the examination of distance and near visual acuity, visual field, contrast sensitivity, glare, color perception, and refraction. Specially designed, low-vision visual acuity charts are used to evaluate patients.

Table 58-1 AGE-RELATED CHANGES IN THE EYE

The External Eye	Structural Change	Functional Change	History & Physical Findings
Eyelids and lacrimal structures	Loss of skin elasticity and orbital fat, decreased muscle tone; wrinkles develop	Lid margins turn in, causing lashes to irritate cornea and conjunctiva (entropion); or lid margins may turn out, resulting in increased corneal exposure (ectropion).	Reports of burning, foreign body sensation, increased tearing (epiphoria); injection, inflammation, and ulceration may occur
Refractive changes; presbyopia	Loss of accommodative power in the lens with age	Reading materials must be held at increasing distance in order to focus.	Patient reports, “Arms are too short!”; need for increased light; reading glasses or bifocals needed
Cataract	Opacities in the normally crystalline lens	Interference with the focus of a sharp image on the retina	Patients report increased glare, decreased vision, changes in color values (blue and yellow especially affected)
Posterior vitreous detachment	Liquefaction and shrinkage of vitreous body	May lead to retinal tears and detachment	Reports light flashes, cobwebs, floaters
Age-related macular degeneration (AMD)	Drusen (yellowish aging spots in the retina) appear and coalesce in the macula. Abnormal choroidal blood vessels may lead to formation of fibrotic disciform scars in the macula.	Central vision is affected; onset is more gradual in dry AMD, more rapid in wet AMD; distortion and loss of central vision may occur.	Reading vision is affected; words may be missing letters, faded areas appear on the page, straight lines may appear wavy; drusen, pigmentary changes in retina; abnormal submacular choroidal vessels

Table 58-2 ACTIVITIES AFFECTED BY VISUAL IMPAIRMENT AND SUGGESTIONS FOR LOW-VISION AIDS

Activity	Optical Aids	Nonoptical Aids
Shopping	Hand magnifier	Lighting, color cues
Fixing a snack	Bifocals	Color cues; consistent food storage plan
Eating out	Hand magnifier	Flashlight, portable lamp
Identifying money	Bifocals, hand magnifier	Arrange paper money in wallet compartments
Reading print	High-power spectacle, bifocals, hand magnifier, stand magnifier, closed-circuit television	Lighting, high-contrast print, large print, reading slit
Writing	Hand magnifier,	Lighting, bold-tip pen, black ink
Using a telephone	Hand magnifier	Large print dial or touch tone buttons, hand-printed directory
Crossing streets	Lightweight hand held monoscopes/telescopes	Cane, ask directions
Finding taxis and bus signs	Lightweight hand held monoscopes/telescopes	Ask for assistance
Reading medication labels	Hand magnifier	Color codes, large print
Reading stove dials	Hand magnifier	Color codes, raised dots
Adjusting the thermostat	Hand magnifier	Enlarged print model
Using a computer	Spectacles	High-contrast color, large-print program
Reading signs	Spectacles	Move closer
Watching sporting event	Lightweight hand held monoscopes/telescopes	Sit in front rows

Adapted from Riordan-Eva, P. & Whitcher, J. P. (2008). *Vaughn and Asbury's general ophthalmology*. New York: McGraw-Hill.

Patient Interview

During history taking, the cause and duration of the patient's visual impairment are identified. Patients with retinitis pigmentosa, for example, have a genetic abnormality. Patients with diabetic macular edema typically have fluctuating visual acuity. Patients with macular degeneration have central acuity problems, which cause difficulty in performing activities that require finer vision, such as reading. People with peripheral field defects have more difficulties with mobility. The patient's customary ADLs, medication regimen, habits (eg, smoking), acceptance of the physical limitations brought about by the visual impairment, and realistic expectations of low-vision aids are identified and included in the plan of care, including provision of guidelines for safety and referrals to social services.

Contrast-Sensitivity Testing and Glare Testing

Contrast-sensitivity testing measures visual acuity in different degrees of contrast. The initial test may take the form of simply turning on the lights while testing the distance acuity. If the patient can read better with the lights on, the patient can benefit from magnification. Glare testing enables the examiner to obtain a more realistic evaluation of the patient's ability to function in his or her environment. Glare can reduce a person's ability to see, especially in patients with cataracts. Devices that test glare, such as the Brightness Acuity Tester, produce three degrees of bright light to create a dazzle effect while the patient is viewing a target, such as Snellen letters on the wall. The lights have been calibrated to imitate certain objects that create glare, such as a car's headlights at night.

Medical Management

Managing low vision involves magnification and image enhancement through the use of low-vision aids and strategies and referrals to social services and community agencies serving those with visual impairment. The goals are to optimize the patient's remaining vision, whether central or

peripheral, and assist the patient to perform customary activities. Low-vision aids include optical and nonoptical devices (Table 58-2). The optical devices include convex lens aids, such as magnifiers and spectacles; telescopic devices; antireflective lenses that diminish glare; and electronic reading systems, such as closed-circuit television and computers with large print. Continuing advances in computer software provide very useful products for patients with low vision. Scanners and the appropriate software enable the user to scan printed material and have it read by computer voice or enlarge the print for reading. Magnifiers can be hand-held or attached to a stand with or without illumination. Telescopic devices can be spectacle telescopes or clip-on or hand-held loupes.

A telephone system has been developed that allows access to the Internet and e-mail using voice commands (Chart 58-3). A mobile telephone-based communication support system allows people with poor eyesight to communicate by mobile phone. The system consists of a low-power mobile phone (personal handyphone system; PHS) and a large screen. When the person telephones, a registered support personnel picture is displayed on the screen and the PHS telephone dials that person automatically (Ogawa, Yonezawa, Maki, et al., 2007).

Referrals to community agencies may be necessary for patients with low vision who live alone and cannot self-administer their medications. Community agencies, such as the Lighthouse National Center for Vision and Aging, offer services to patients with low vision that include training in independent living skills and the provision of occupational and recreational activities and a wide variety of assistive devices for vision enhancement and orientation and mobility.

Ophthalmologists have worked for years toward visual restoration for people who are blind. Retinal implants for those whose optic nerves are functional as well as cortical implants for those whose optic nerves are diseased are being developed but are still experimental (Zaqloul & Boahen, 2006). The rapid changes in technology and miniaturization of computer chips may enable dramatic advances in synthetic vision in the future.

Chart 58-3 • Web Access for the Visually Impaired

People with impaired vision need not be left behind in the computer age. Various technologies are available. A list of general equipment needs follows:

- Computer: software specifically developed for people with visual impairment.
- Internet service provider (eg, AOL, Netscape, Earthlink, Comcast)
- Screen-reader program: converts text on the computer screen to synthesized speech (eg, JAWS for Windows, Windows Eyes, Slimware Window Bridge, ProTalk 32, Hal Screen Reader, WinVision, WYNN, outSPOKEN for Windows)
- Browser program to navigate the World Wide Web (eg, Microsoft Internet Explorer, IBM Home Page Reader)

The following Web sites provide extensive information about low vision resources for people with vision loss, vision impairment, and blindness:

- www.lowvision.org
- www.magnifiers.org

Researchers are developing graphic tactile displays that provide information for people with visual impairment using the sense of touch. Efficient, low-cost tactile displays are not yet available. At this time, most of these devices are research prototypes (Vidal-Verdu & Hafez, 2007).

Nursing Management

Coping with blindness involves three types of adaptation: emotional, physical, and social. The emotional adjustment to blindness or severe visual impairment determines the success of the physical and social adjustments of the patient. Successful emotional adjustment means acceptance of blindness or severe visual impairment.

Promoting Coping Efforts

Effective coping may not occur until the patient recognizes the permanence of the low vision or blindness. Clinging to false hopes of regaining vision hampers effective adaptation to blindness. A patient who is newly visually impaired and his or her family members (especially those who live with the patient) undergo the various steps of grieving: denial and shock, anger and protest, restitution, loss resolution, and acceptance. The ability to accept the changes that must come with visual loss and willingness to adapt to those changes influence the successful rehabilitation of the patient who is blind. Additional aspects to consider are value changes, independence–dependence conflicts, coping with stigma, and learning to function in social settings without visual cues and landmarks.

Promoting Spatial Orientation and Mobility

A person who is blind or severely visually impaired requires strategies for adapting to the environment. ADLs, such as walking to a chair from a bed, require spatial concepts. The person needs to know where he or she is in relation to the rest of the room, to understand the changes that may occur, and to know how to approach the desired location safely. This requires a collaborative effort between the patient and the responsible adult who serves as the sighted guide.

A patient whose visual impairment results from a chronic progressive eye disorder, such as glaucoma, has better cognitive mapping skills than the patient who loses vision suddenly. Patients with progressive eye disorders develop the use of spatial and topographic concepts early and gradually; hence, remembering a room layout is easier for them. Patients who lose vision suddenly have more difficulty in adjusting, and emotional and behavioral issues of coping with loss of vision may hinder their learning. These patients require intensive emotional support. The nurse must assess the degree of physical assistance the person with vision loss requires and communicate this to other health care personnel.

In the hospital, the bedside table and the call button must always be within reach. The parts of the call button are explained, and the patient is taught to touch and press the buttons or dials until the activity is mastered. The patient must be familiarized with the location of the telephone, water pitcher, and other objects on the bedside table. The food tray's composition is likened to the face of a clock; for example, the main plate may be described as being at 12 o'clock or the coffee cup at 3 o'clock. All articles and furniture must remain in the same positions throughout the patient's hospitalization. The nurse should introduce himself or herself on entering a patient's room and alert the patient to his or her departure. Such behaviors are always polite and help in the care of a patient with vision loss.

The nurse should be aware of the importance of techniques in providing physical assistance, encouraging independence, and ensuring safety. Specific guidelines for interacting with the patient with vision loss are presented in Chart 58-4. The readiness of the patient and his or her family to learn must be assessed before initiating orientation and mobility training.

Promoting Home and Community-Based Care

The nurse, social worker, family, and others collaborate to assess the patient's home condition and support system. If available, a low-vision specialist or occupational therapist should be consulted, particularly for patients for whom identifying and administering medications pose problems. The level of visual acuity and patient preference help determine appropriate interventions. Some private and non-profit services are identified in the Resources section at the end of this chapter.

Other interventions that are appropriate for some people with low vision or blindness include Braille and service animals. Recent rapid advances in technology have led to the erroneous conclusion by some that Braille is an outmoded communication tool. There has been an ever-increasing reliance on print magnification technology as well as computer-assisted speech output. However, although the use of Braille may be less important for adults who have already learned language and grammar skills, educators and low-vision specialists have continued to advocate that children who are legally blind be given the opportunity to learn Braille.

Guide dogs, also known as seeing-eye dogs or service dogs, are dogs that are specially bred, raised, and rigorously trained to assist people who are blind. The guide dog is a constant companion to the person who is blind (also

Chart 58-4 • Guidelines for Interacting With People Who Are Blind Or Have Low Vision

- Remember that the only difference between you and people who are blind or have low vision is that they are not able to see through their eyes what you are able to see through yours.
- Do not be uncomfortable when in the company of a person who is blind or has low vision. Talk with the person as you would talk with any other individual, honestly and without pity; do not be concerned about using words like “see” and “look.” There is no need to raise your voice unless the person asks you to do so.
- Identify yourself as you approach the person and before you make physical contact. Tell the person your name and your role. If another person approaches, introduce him or her. When you leave the room, be sure to tell the person that you are leaving and if anyone else remains in the room.
- It is often appropriate to touch the person’s hand or arm lightly to indicate that you are about to speak.
- When talking, face the person and speak directly to him or her using a normal tone of voice.
- Be specific when communicating direction. Mention a specific distance or use clock cues when possible (eg, walk left about 2 yards; walk about 20 feet to the right; the telephone is at 2 o’clock). Avoid using phrases such as “over there.”
- When you offer to assist someone, allow the person to hold on to your arm just above the elbow and to walk a half-step behind you.
- When offering the person a seat, place the person’s hand on the back or the arm of the seat.
- When you are about to go up or down a flight of stairs, tell the person and place his or her hand on the banister.
- Make sure that the environment is free of obstacles; close doors and cabinets so they are not in the path.
- Offer to read written information, such as a menu.
- If you serve food to the person, use clock cues to specify where everything is on the plate.
- When the person who is blind or who has low vision is a patient in a health care facility:
 - Make sure all objects the person will need are close at hand.
 - Identify the location of objects that the person may need (eg, “The call light is near your right hand”; “The telephone is on the table on the left side of your bed.”)
 - Remove obstacles that may be in the person’s pathway and could cause a fall.
 - Place all assistive devices the person uses close at hand; let the person feel the devices so that he or she knows their location.
- Do not distract the service animal unless the owner has given permission.
- Ask the person, “How can I help you?” At some times the person needs help, but at other times help may not be needed.

This material is adapted from and based in part on *Achieving Physical and Communication Accessibility*, a publication of the National Center for Access Unlimited; *Community Access Facts*, an Adaptive Environments Center publication; and *The Ten Commandments of Interacting with People with Mental Health Disabilities*, a publication of The Ability Center of Greater Toledo.

referred to as the animal’s handler) and is allowed on airplanes and in restaurants, stores, hotels, and other public places. With the assistance of the guide dog, the person who is blind can be extremely mobile and accomplish normal activities both within and outside of the home and workplace. A dog in harness is a working dog, not a pet. The dog should not be distracted from his job by well-intentioned strangers who want to pet, feed, or play with the animal. The dog’s handler should always be consulted before approaching the working guide dog. Most health care facilities have a service animal policy that outlines the responsibilities of the handler with regard to the care of the animal.

Glaucoma

The term *glaucoma* is used to refer to a group of ocular conditions characterized by optic nerve damage. In the past, glaucoma was seen more as a condition of elevated IOP than of optic neuropathy. Increasingly, that is no longer the case. There is no doubt that increased IOP damages the optic nerve and nerve fiber layer, but the degree of harm is highly variable (McKinnon, Goldberg, Peeples, et al., 2008). The optic nerve damage is related to the IOP caused by congestion of aqueous humor in the eye. A range of IOPs are considered “normal,” but these may be associated with vision loss in some patients.

Glaucoma is the second leading cause of blindness in adults in the United States. It is estimated that at least 2.2

million Americans have glaucoma and that 3 to 6 million more are at risk for the disease (Bressler, et al., 2008). Glaucoma is more prevalent in people older than 40 years of age, and it is the third most common age-related eye disease in the United States. It also occurs more frequently in African Americans than Caucasians (Chart 58-5). There is no cure for glaucoma, but the disease can be controlled (Sharts-Hopko & Glynn-Milley, 2009).

Physiology

Aqueous humor flows between the iris and the lens, nourishing the cornea and lens. Most (90%) of the fluid then flows out of the anterior chamber, draining through the spongy trabecular meshwork into the canal of Schlemm and

CHART
58-5

Risk Factors for Glaucoma

- Family history of glaucoma
- Thin cornea
- African American race
- Older age
- Diabetes mellitus
- Cardiovascular disease
- Migraine syndromes
- Nearsightedness (myopia)
- Eye trauma
- Prolonged use of topical or systemic corticosteroids

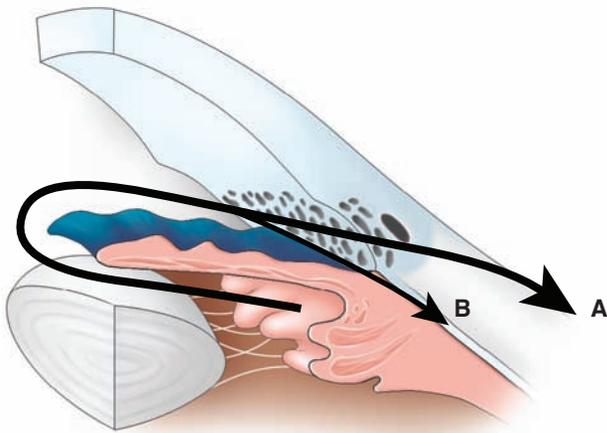

Figure 58-7 Normal outflow of aqueous humor. **A**, Trabecular meshwork. **B**, Uveoscleral route. From Kanski, J. J. (2007). *Clinical ophthalmology*. Oxford: Butterworth-Heinemann.

the episcleral veins (Fig. 58-7). About 10% of the aqueous fluid exits through the ciliary body into the suprachoroidal space and then drains into the venous circulation of the ciliary body, choroid, and sclera. Unimpeded outflow of aqueous fluid depends on an intact drainage system and an open angle (about 45 degrees) between the iris and the cornea. A narrower angle places the iris closer to the trabecular meshwork, diminishing the angle. The amount of aqueous humor produced tends to decrease with age, in systemic diseases such as diabetes, and in ocular inflammatory conditions.

IOP is determined by the rate of aqueous production, the resistance encountered by the aqueous humor as it flows out of the passages, and the venous pressure of the episcleral veins that drain into the anterior ciliary vein. When aqueous fluid production and drainage are in balance, the IOP is between 10 and 21 mm Hg. When aqueous fluid is inhibited from flowing out, pressure builds up within the eye. Fluctuations in IOP occur with time of day, exertion, diet, and medications. IOP tends to increase with blinking, tight lid squeezing, and upward gazing. Systemic conditions such as diabetes and intraocular conditions such as uveitis and retinal detachment have been associated with elevated IOP. Glaucoma may not be recognized in people with thin corneas because measurement of the IOP may be falsely low as a result of this thinness (Bressler, et al., 2008).

Pathophysiology

There are two accepted theories regarding how increased IOP damages the optic nerve in glaucoma. The direct mechanical theory suggests that high IOP damages the retinal layer as it passes through the optic nerve head. The indirect ischemic theory suggests that high IOP compresses the microcirculation in the optic nerve head, resulting in cell injury and death. Some glaucomas appear as exclusively mechanical, and some are exclusively ischemic types. Typically, most cases are a combination of both. Regardless of the cause of damage, glaucomatous changes typically evolve through clearly discernible stages (Chart 58-6).

Chart 58-6 • Stages of Glaucoma

- 1. Initiating events.** Precipitating factors include illness, emotional stress, congenital narrow angles, long-term use of corticosteroids, and use of mydriatics (ie, medications causing pupillary dilation). These events may lead to the second stage.
- 2. Structural alterations in the aqueous outflow system.** Tissue and cellular changes caused by factors that affect aqueous humor dynamics lead to structural alterations and may lead to the third stage.
- 3. Functional alterations.** Conditions such as increased intraocular pressure or impaired blood flow create functional changes that may lead to the fourth stage.
- 4. Optic nerve damage.** Atrophy of the optic nerve is characterized by loss of nerve fibers and blood supply. This fourth stage inevitably progresses to the fifth stage.
- 5. Visual loss.** Progressive loss of vision is characterized by visual field defects.

Classification of Glaucoma

There are several types of glaucoma. Although glaucoma classification is changing as knowledge increases, current clinical forms of glaucoma are identified as open-angle glaucoma, angle-closure glaucoma (also called pupillary block), congenital glaucoma, and glaucoma associated with other conditions, such as developmental anomalies or corticosteroid use. Glaucoma can be primary or secondary, depending on whether associated factors contribute to the rise in IOP. The two common clinical forms of glaucoma encountered in adults are primary open-angle glaucoma (POAG) and angle-closure glaucoma, which are differentiated by the mechanisms that cause impaired aqueous outflow. Table 58-3 summarizes the characteristics of the different types of open-angle and angle-closure glaucoma.

Clinical Manifestations

Glaucoma is often called the “silent thief of sight” because most patients are unaware that they have the disease until they have experienced visual changes and vision loss. The patient may not seek health care until he or she experiences blurred vision or “halos” around lights, difficulty focusing, difficulty adjusting eyes in low lighting, loss of peripheral vision, aching or discomfort around the eyes, and headache.

Assessment and Diagnostic Findings

The purpose of a glaucoma workup is to establish the diagnostic category, assess the optic nerve damage, and formulate a treatment plan. The patient’s ocular and medical history must be detailed to investigate the history of predisposing factors. Four major types of examinations are used in glaucoma evaluation, diagnosis, and management: tonometry to measure the IOP, ophthalmoscopy to inspect the optic nerve, gonioscopy to examine the filtration angle of the anterior chamber, and perimetry to assess the visual fields.

The changes in the optic nerve related to glaucoma are pallor and cupping of the optic nerve disc. The pallor of the optic nerve is caused by a lack of blood supply that results from cellular destruction. Cupping is characterized by exaggerated bending of the blood vessels as they cross the optic

Table 58-3 GLAUCOMA TYPES, CLINICAL MANIFESTATION, AND TREATMENT

Types of Glaucoma	Clinical Manifestations	Treatment
Open-Angle Glaucoma		
Usually bilateral, but one eye may be more severely affected than the other. In all three types of open-angle glaucoma, the anterior chamber angle is open and appears normal.		
Primary open-angle glaucoma (POAG)	Optic nerve damage, visual field defects, IOP >21 mm Hg. May have fluctuating IOPs. Usually no symptoms but possible ocular pain, headache, and halos.	Decrease IOP 20% to 50%. Additional topical and oral agents added as necessary. If medical treatment is unsuccessful, laser trabeculoplasty (LT) can decrease intraocular pressure by 20%. Glaucoma filtering surgery if continued optic nerve damage despite medication therapy and LT.
Normal tension glaucoma	IOP ≤21 mm Hg. Optic nerve damage, visual field defects.	Treatment similar to POAG, however, the best management for normal tension glaucoma management is yet to be established. Goal is to lower the IOP by at least 30%. Decrease IOP by at least 20%.
Ocular hypertension	Elevated IOP. Possible ocular pain or headache.	
Angle-Closure (Pupillary Block) Glaucoma		
Obstruction in aqueous humor outflow due to the complete or partial closure of the angle from the forward shift of the peripheral iris to the trabecula. The obstruction results in an increased IOP.		
Acute angle-closure glaucoma (AACG)	Rapidly progressive visual impairment, periocular pain, conjunctival hyperemia, and congestion. Pain may be associated with nausea, vomiting, bradycardia, and profuse sweating. Reduced central visual acuity, severely elevated IOP, corneal edema. Pupil is vertically oval, fixed in a semidilated position, and unreactive to light and accommodation.	Ocular emergency; administration of hyperosmotics, acetazolamide, and topical ocular hypotensive agents, such as pilocarpine and beta-blockers (betaxolol). Possible laser incision in the iris (iridotomy) to release blocked aqueous and reduce IOP. Other eye is also treated with pilocarpine eye drops and/or surgical management to avoid a similar spontaneous attack.
Subacute angle-closure glaucoma	Transient blurring of vision, halos around lights; temporal headaches and/or ocular pain; pupil may be semidilated.	Prophylactic peripheral laser iridotomy. Can lead to acute or chronic angle-closure glaucoma if untreated.
Chronic angle-closure glaucoma	Progression of glaucomatous cupping and significant visual field loss; IOP may be normal or elevated; ocular pain and headache.	Management similar to that for POAG: includes laser iridotomy and medications.

IOP, intraocular pressure.

disc, resulting in an enlarged optic cup that appears more basinlike compared with a normal cup. The progression of cupping in glaucoma is caused by the gradual loss of retinal nerve fibers accompanied by the loss of blood supply, resulting in increased pallor of the optic disc.

As the optic nerve damage increases, visual perception in the area is lost. The localized areas of visual loss (ie, scotomas) represent loss of retinal sensitivity and nerve fiber damage and are measured and mapped by perimetry. The results are mapped on a graph. In patients with glaucoma, the graph has a distinct pattern that is different from other ocular diseases and is useful in establishing the diagnosis. Figure 58-8 shows the progression of visual field defects caused by glaucoma.

Medical Management

The aim of all glaucoma treatment is prevention of optic nerve damage. Lifelong therapy is almost always necessary because glaucoma cannot be cured. Treatment focuses on pharmacologic therapy, laser procedures, surgery, or a combination of these approaches, all of which have potential complications and side effects. The object is to achieve the greatest benefit at the least risk, cost, and inconvenience to the patient. Although treatment cannot reverse optic nerve damage, further damage can be controlled. The goal is to maintain an IOP within a range unlikely to cause further damage.

The initial target for IOP among patients with elevated IOP and those with low-tension glaucoma with progressive visual field loss is typically set at 30% lower than the current pressure. The patient is monitored for changes in the appearance of the optic nerve. If there is evidence of progressive damage, the target IOP is again lowered until the optic nerve shows stability.

Pharmacologic Therapy

Medical management of glaucoma relies on systemic and topical ocular medications that lower IOP. Periodic follow-up examinations are essential to monitor IOP, the appearance of the optic nerve, the visual fields, and side effects of medications. Therapy takes into account the patient's health and stage of glaucoma. Comfort, affordability, convenience, lifestyle, and personality are factors to consider in the patient's adherence to the medical regimen.

The patient is usually started on the lowest dose of topical medication and then advanced to increased concentrations until the desired IOP level is reached and maintained. Because of their efficacy, minimal dosing (can be used once each day), and low cost, beta-blockers are the preferred initial topical medications. One eye is treated first, with the other eye used as a control in determining the efficacy of the medication; once efficacy has been established, treatment of

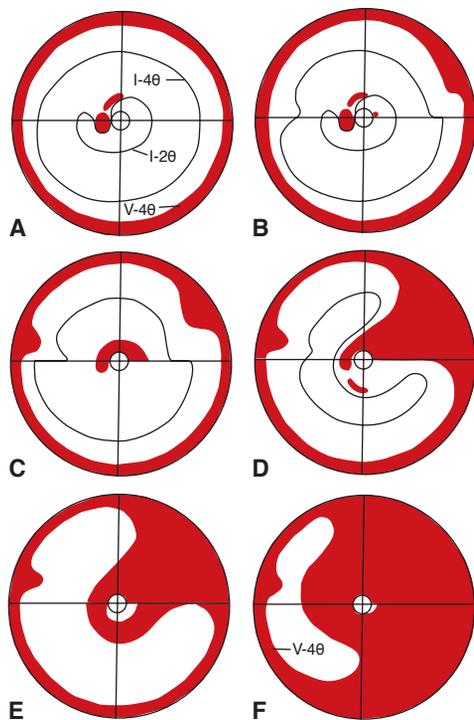

Figure 58-8 Progression of glaucomatous visual field defects. A central scotoma at 10 to 20 degrees of fixation near the blind spot is the initial significant finding (A, B). As the glaucoma progresses, the scotomas enlarge and deepen, resulting in peripheral vision loss. C, Defect within 5 degrees of fixation point nasally. D, Peripheral involvement enlarges. E, Ringlike scotoma. F, Eventually, vision is lost. The resulting “island of vision” becomes the characteristic visual field appearance of glaucoma and correlates with the “tunnel vision,” in which peripheral vision is lost. From Kanski, J. J. (2007). *Clinical ophthalmology*. Oxford: Butterworth-Heinemann.

the other eye is started. If the IOP is elevated in both eyes, both are treated. When results are not satisfactory, a new medication is substituted. The main markers of the efficacy of the medication in glaucoma control are lowering of the IOP to the target pressure, appearance of the optic nerve head, and the visual field.

Several types of ocular medications are used to treat glaucoma (Table 58-4), including **miotics** (medications that cause pupillary constriction), **adrenergic agonists** (ie, sympathomimetic agents), **beta-blockers**, **alpha₂-agonists** (ie, adrenergic agents), **carbonic anhydrase inhibitors**, and **prostaglandins**. **Cholinergics** (ie, miotics) increase the outflow of the aqueous humor by affecting ciliary muscle contraction and pupil constriction, allowing flow through a larger opening between the iris and the trabecular meshwork. **Adrenergic agonists** increase aqueous outflow but primarily decrease aqueous production with an action similar to beta-blockers and carbonic anhydrase inhibitors. **Prostaglandin analogues** reduce IOP by increasing aqueous humor outflow. They can be used once daily and do not affect pupil size.

Surgical Management

In **laser trabeculoplasty** for glaucoma, laser burns are applied to the inner surface of the trabecular meshwork to open the intratrabecular spaces and widen the canal of

Schlemm, thereby promoting outflow of aqueous humor and decreasing IOP. The procedure is indicated when IOP is inadequately controlled by medications, and it is contraindicated when the trabecular meshwork cannot be fully visualized because of narrow angles. A serious complication of this procedure is a transient increase in IOP (usually 2 hours after surgery) that may become persistent. IOP assessment in the immediate postoperative period is essential.

In **laser iridotomy** for pupillary block glaucoma, an opening is made in the iris to eliminate the pupillary block. Laser iridotomy is contraindicated in patients with corneal edema, which interferes with laser targeting and strength. Potential complications are burns to the cornea, lens, or retina; transient elevated IOP; closure of the iridotomy; uveitis; and blurring. Pilocarpine (Pilocar) is usually prescribed to prevent closure of the iridotomy.

Filtering procedures for chronic glaucoma are used to create an opening or fistula in the trabecular meshwork to drain aqueous humor from the anterior chamber to the subconjunctival space into a bleb (fluid collection on the outside of the eye), thereby bypassing the usual drainage structures. This allows the aqueous humor to flow and exit by different routes (ie, absorption by the conjunctival vessels or mixing with tears). **Trabeculectomy** is the standard filtering technique used to remove part of the trabecular meshwork. Complications include hemorrhage, an extremely low (hypotony) or extremely elevated IOP, uveitis, cataracts, bleb failure, bleb leak, and endophthalmitis. Unlike other surgical procedures, the goal of the filtering procedure is to achieve incomplete healing of the surgical wound. The outflow of aqueous humor in a newly created drainage fistula is circumvented by the granulation of fibrovascular tissue or scar tissue formation on the surgical site. Scarring is inhibited by using antifibrosis agents such as the antimetabolites fluorouracil (Efudex) and mitomycin (Mutamycin). Like all antineoplastic agents, they require special handling procedures before, during, and after the procedure. Fluorouracil can be administered intraoperatively and by subconjunctival injection during follow-up; mitomycin is much more potent and is administered only intraoperatively.

Drainage implants or **shunts** are open tubes implanted in the anterior chamber to shunt aqueous humor to the episcleral plate in the conjunctival space. These implants are used when failure has occurred with one or more trabeculectomies in which antifibrotic agents were used. A fibrous capsule develops around the episcleral plate and filters the aqueous humor, thereby regulating the outflow and controlling IOP.

Trabectome surgery is reserved for patients in whom pharmacologic treatment and/or laser trabeculoplasty do not control the IOP sufficiently (Filippopoulos & Rhee, 2008). This minimally invasive procedure is specifically designed to improve fluid drainage from the eye to balance IOP. By restoring the eye's natural fluid balance, trabectome surgery stabilizes the optic nerve and minimizes further visual field damage. The surgery is performed through a small incision and does not require creation of a permanent hole in the eye wall or an external filtering bleb or an implant.

Table 58-4  **MEDICATIONS USED IN THE MANAGEMENT OF GLAUCOMA**

Medication	Action	Side Effects	Nursing Implications
Cholinergics (miotics) (pilocarpine, carbachol)	Increases aqueous fluid outflow by contracting the ciliary muscle and causing miosis (constriction of the pupil) and opening of trabecular meshwork	Periorbital pain, blurry vision, difficulty seeing in the dark	Caution patients about diminished vision in dimly lit areas.
Adrenergic agonists (dipivefrin, epinephrine)	Reduces production of aqueous humor and increases outflow	Eye redness and burning; can have systemic effects, including palpitations, elevated blood pressure, tremor, headaches, and anxiety	Teach patients punctal occlusion to limit systemic effects (described in Chart 58-13).
Beta-blockers (betaxolol, timolol)	Decreases aqueous humor production	Can have systemic effects, including bradycardia, exacerbation of pulmonary disease, and hypotension	Contraindicated in patients with asthma, chronic obstructive pulmonary disease, second- or third-degree heart block, bradycardia, or cardiac failure; teach patients punctal occlusion to limit systemic effects.
Alpha-adrenergic agonists (apraclonidine, brimonidine)	Decreases aqueous humor production	Eye redness, dry mouth and nasal passages	Teach patients punctal occlusion to limit systemic effects.
Carbonic anhydrase inhibitors (acetazolamide, methazolamide, dorzolamide)	Decreases aqueous humor production	Oral medications (acetazolamide and methazolamide) associated with serious side effects, including anaphylactic reactions, electrolyte loss, depression, lethargy, gastrointestinal upset, impotence, and weight loss; side effects of topical form (dorzolamide) include topical allergy	Do not administer to patients with sulfa allergies; monitor electrolyte levels.
Prostaglandin analogs (latanoprost, bimatoprost)	Increases uveoscleral outflow	Darkening of the iris, conjunctival redness, possible rash	Instruct patients to report any side effects.

Nursing Management

Promoting Home and Community-Based Care

Teaching Patients Self-Care

The medical and surgical management of glaucoma slows the progression of glaucoma but does not cure it. The life-long therapeutic regimen mandates patient education. The nature of the disease and the importance of strict adherence to the medication regimen must be included in a teaching plan to help ensure compliance. A thorough discussion of the medication program, particularly the interactions of glaucoma-control medications with other medications, is essential. For example, the diuretic effect of acetazolamide (Diamox) has an additive effect on the diuretic effects of other antihypertensive medications and can result in hypokalemia. The effects of glaucoma-control medications on vision must also be explained. Miotics and sympathomimetics result in altered focus; therefore, patients need to be cautious in navigating their surroundings. Information about instilling ocular medication and preventing systemic absorption with punctal occlusion is given in the section of this chapter on ophthalmic medications.

Nurses in all settings encounter patients with glaucoma. Even patients with long-standing disease and those with glaucoma as a secondary diagnosis should be assessed for knowledge level and compliance with the therapeutic regimen. Chart 58-7 contains points to review with patients with glaucoma.

CHART

58-7

PATIENT EDUCATION

Managing Glaucoma

- Know your intraocular pressure (IOP) measurement and the desired range.
- Be informed about the extent of your vision loss and optic nerve damage.
- Keep a record of your eye pressure measurements and visual field test results to monitor your own progress.
- Review all your medications (including over-the-counter and herbal medications) with your ophthalmologist, and mention any side effects each time you visit.
- Ask about potential side effects and drug interactions of your eye medications.
- Ask whether generic or less costly forms of your eye medications are available.
- Review the dosing schedule with your ophthalmologist and inform him or her if you have trouble following the schedule.
- Participate in the decision-making process. Let your doctor know what dosing schedule works for you and other preferences regarding your eye care.
- Have the nurse observe you instilling eye medication to determine whether you are administering it properly.
- Be aware that glaucoma medications can cause adverse effects if used inappropriately. Eye drops are to be administered as prescribed, not when eyes feel irritated.
- Ask your ophthalmologist to send a report to your doctor after each appointment.
- Keep all follow-up appointments.

Continuing Care

For the patient with severe glaucoma and impaired function, referral to services that assist the patient in performing ADLs may be needed. The loss of peripheral vision impairs mobility the most. These patients need to be referred for low vision and rehabilitation services. Patients who meet the criteria for legal blindness should be offered referrals to agencies that can assist them in obtaining federal assistance.

Reassurance and emotional support are important aspects of care. A lifelong disease involving possible loss of sight has psychological, physical, social, and vocational ramifications. The family must be integrated into the plan of care, and because the disease has a familial tendency, family members should be encouraged to undergo examinations at least once every 2 years to detect glaucoma early.

Cataracts

A cataract is a lens opacity or cloudiness (Fig. 58-9). Cataracts rank behind only arthritis and heart disease as a leading cause of disability in older adults. Cataracts affect nearly 20.5 million Americans who are 40 years of age or older, or about one in six people in this age range. By 80 years of age, more than half of all Americans have cataracts. According to the World Health Organization, cataract is the leading cause of blindness in the world (Prevent Blindness America, 2008).

Pathophysiology

Cataracts can develop in one or both eyes at any age as a result of a variety of causes (Chart 58-8). Cigarette smoking, long-term use of corticosteroids, especially at high doses, sunlight and ionizing radiation, diabetes, obesity, and eye

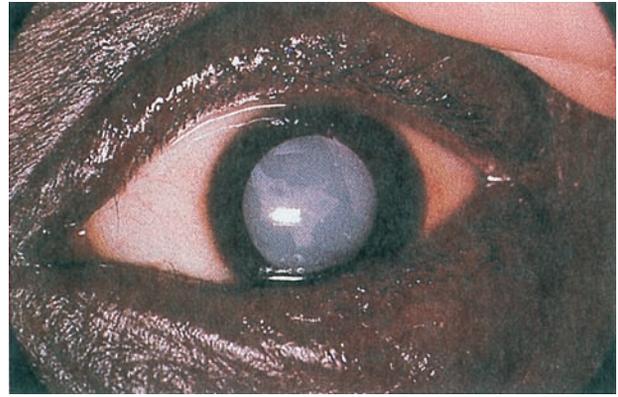

Figure 58-9 A cataract is a cloudy or opaque lens. On visual inspection, the lens appears gray or milky. From Rubin, E., Gorstein, F., Rubin, R., et al. (2005). *Pathology* (4th ed.). Philadelphia: Lippincott Williams & Wilkins.

injuries can increase the risk of cataracts. Recent studies have linked cataract risk to lower income and educational level, smoking for 35 or more pack-years, and high triglyceride levels in men (Klein, Klein, Lee, et al., 2003). The three most common types of senile (age-related) cataracts are defined by their location in the lens: nuclear, cortical, and posterior subcapsular. The extent of visual impairment depends on their size, density, and location in the lens. More than one type can be present in one eye.

A nuclear cataract is caused by central opacity in the lens and has a substantial genetic component. It is associated with myopia (ie, nearsightedness), which worsens when the cataract progresses. If dense, the cataract severely blurs vision. Periodic changes in prescription eyeglasses help manage this condition.

CHART
58-8

Risk Factors for Cataract Formation

Aging

- Loss of lens transparency
- Clumping or aggregation of lens protein (which leads to light scattering)
- Accumulation of a yellow-brown pigment due to the breakdown of lens protein
- Decreased oxygen uptake
- Increase in sodium and calcium
- Decrease in levels of vitamin C, protein, and glutathione (an antioxidant)

Associated Ocular Conditions

- Retinitis pigmentosa
- Myopia
- Retinal detachment and retinal surgery
- Infection (eg, herpes zoster, uveitis)

Toxic Factors

- Corticosteroids, especially at high doses and in long-term use
- Alkaline chemical eye burns, poisoning
- Cigarette smoking

- Calcium, copper, iron, gold, silver, and mercury, which tend to deposit in the pupillary area of the lens

Nutritional Factors

- Reduced levels of antioxidants
- Poor nutrition
- Obesity

Physical Factors

- Dehydration associated with chronic diarrhea, use of purgatives in anorexia nervosa, and use of hyperbaric oxygenation
- Blunt trauma, perforation of the lens with a sharp object or foreign body, electric shock
- Ultraviolet radiation in sunlight and x-ray

Systemic Diseases and Syndromes

- Diabetes mellitus
- Down syndrome
- Disorders related to lipid metabolism
- Renal disorders
- Musculoskeletal disorders

A cortical cataract involves the anterior, posterior, or equatorial cortex of the lens. A cataract in the equator or periphery of the cortex does not interfere with the passage of light through the center of the lens and has little effect on vision. Cortical cataracts progress at a highly variable rate. Vision is worse in very bright light. People with the highest levels of sunlight exposure have twice the risk of developing cortical cataracts as those with low-level sunlight exposure.

Posterior subcapsular cataracts occur in front of the posterior capsule. This type typically develops in younger people and, in some cases, is associated with prolonged corticosteroid use, diabetes, or ocular trauma. Near vision is diminished, and the eye is increasingly sensitive to glare from bright light (eg, sunlight, headlights). Caucasians are more likely to develop nuclear and posterior subcapsular cataracts, whereas cortical cataracts are more prevalent among African Americans.

Clinical Manifestations

Painless, blurry vision is characteristic of cataracts. The person perceives that surroundings are dimmer, as if his or her glasses need cleaning. Light scattering is common, and the person experiences reduced contrast sensitivity, sensitivity to glare, and reduced visual acuity. Other effects include myopic shift (return of ability to do close work [eg, reading fine print] without eyeglasses), astigmatism, monocular **diplopia** (double vision), color shift (the aging lens become progressively more absorbent at the blue end of the spectrum), brunescens (color values shift to yellow-brown), and reduced light transmission.

Assessment and Diagnostic Findings

Decreased visual acuity is directly proportionate to cataract density. The Snellen visual acuity test, ophthalmoscopy, and slit-lamp biomicroscopic examination are used to establish the degree of cataract formation. The degree of lens opacity does not always correlate with the patient's functional status. Some patients can perform normal activities despite clinically significant cataracts. Others with less lens opacification have a disproportionate decrease in visual acuity; hence, visual acuity is an imperfect measure of visual impairment.

Medical Management

No nonsurgical (medications, eyedrops, eyeglasses) treatment cures cataracts or prevents age-related cataracts. Results from the Age-Related Eye Disease Study Research Group (2001b), a randomized, placebo-controlled trial, found no benefit from antioxidant supplements, vitamins C and E, beta-carotene, and selenium. Results of studies that have attempted to determine the possible benefit of a once-a-day multivitamin supplement to prevent or delay the onset of cataracts have been mixed. (Clinical Trial of Nutritional Supplements and Age-Related Cataract Study Group, 2008). In the early stages of cataract development, glasses, contact lenses, strong bifocals, or magnifying lenses may improve vision.

Surgical Management

In general, if reduced vision from cataract does not interfere with normal activities, surgery may not be needed. In deciding when cataract surgery is to be performed, the patient's functional and visual status should be a primary

consideration. Surgery is performed on an outpatient basis and usually takes less than 1 hour, with the patient being discharged in 30 minutes or less afterward. Although complications from cataract surgery are uncommon, they can have significant effects on vision (Table 58-5). Restoration of visual function through a safe and minimally invasive procedure is the surgical goal, which is achieved with advances in topical anesthesia, smaller wound incision (ie, clear cornea incision), and lens design (ie, foldable and more accurate intraocular lens measurements).

Injection-free topical and intraocular anesthesia, such as 1% lidocaine gel applied to the surface of the eye, eliminates the hazards of regional (retrobulbar and peribulbar) anesthesia, such as ocular perforation, retrobulbar hemorrhage, optic injuries, diplopia, and ptosis, and is ideal for patients receiving anticoagulants. Furthermore, patients can communicate and cooperate during surgery. Intravenous (IV) moderate sedation may be used to minimize anxiety and discomfort.

When both eyes have cataracts, one eye is treated first, with at least several weeks, preferably months, separating the two procedures. Because cataract surgery is performed to improve visual functioning, the delay for the other eye gives time for the patient and the surgeon to evaluate whether the results from the first surgery are adequate to preclude the need for a second operation. The delay also provides time for the first eye to recover; if there are any complications, the surgeon may decide to perform the second procedure differently.

Phacoemulsification

In this method of extracapsular cataract surgery, a portion of the anterior capsule is removed, allowing extraction of the lens nucleus and cortex while the posterior capsule and zonular support are left intact. An ultrasonic device is used to liquefy the nucleus and cortex, which are then suctioned out through a tube. An intact zonular-capsular diaphragm provides the needed safe anchor for the posterior chamber intraocular lens (IOL). After the pupil has been dilated and the surgeon has made a small incision on the upper edge of the cornea, a viscoelastic substance (clear gel) is injected into the space between the cornea and the lens. This prevents the space from collapsing and facilitates insertion of the IOL. Because the incision is smaller than the manual extracapsular cataract extraction, the wound heals more rapidly, and there is early stabilization of refractive error and less astigmatism. New phaco needles that are used to cut and aspirate the cataract permit safe and efficient removal of nearly all cataracts through a clear cornea incision (Hoffman, Fine & Packer, 2005). With increasing frequency, self-sealing (sutureless) clear corneal incisions in the temporal part of the cornea are performed with phacoemulsification, minimizing postoperative astigmatism and thus decreasing bleeding and subconjunctival hemorrhage while speeding recovery of visual acuity.

Lens Replacement

After removal of the crystalline lens, the patient is referred to as *aphakic* (ie, without lens). The lens, which focuses light on the retina, must be replaced for the patient to see clearly. There are three lens replacement options: aphakic eyeglasses, contact lenses, and IOL implants.

Aphakic glasses, although effective, are rarely used. Objects are magnified by 25%, making them appear closer than

Table 58-5 POTENTIAL COMPLICATIONS OF CATARACT SURGERY		
Complication	Effects	Management and Outcome
Immediate Preoperative		
Retrobulbar hemorrhage: can result from retrobulbar infiltration of anesthetic agents if the short ciliary artery is located by the injectia	Increased IOP, proptosis, lid tightness, and subconjunctival hemorrhage with or without edema	Emergent lateral canthotomy (slitting of the canthus) is performed to stop central retinal perfusion when the IOP is dangerously elevated. If this procedure fails to reduce IOP, a puncture of the anterior chamber with removal of fluid is considered. The patient must be closely monitored for at least a few hours. Postponement of cataract surgery for 2 to 4 weeks is advised. Complications such as iris prolapse, vitreous loss, and choroidal hemorrhage could result in a catastrophic visual outcome.
Intraoperative Complications		
Rupture of the posterior capsule	May result in loss of vitreous	Anterior vitrectomy is required if vitreous loss occurs.
Suprachoroidal (expulsive) hemorrhage: profuse bleeding into the suprachoroidal space	Extrusion of intraocular contents from the eye or opposition of retinal surfaces	Closure of the incision and administration of a hyperosmotic agent to reduce IOP or corticosteroids to reduce intraocular inflammation. Vitrectomy is performed 1 to 2 weeks later. Visual prognosis is poor; some useful vision may be salvaged on rare occasions.
Early Postoperative Complications		
Acute bacterial endophthalmitis: devastating complication that occurs in about 1 in 1000 cases; the most common causative organisms are <i>Staphylococcus epidermidis</i> , <i>S. aureus</i> , <i>Pseudomonas</i> and <i>Proteus</i> species	Characterized by marked visual loss, pain, lid edema, hypopyon, corneal haze, and chemosis	Managed by aggressive antibiotic therapy. Broad-spectrum antibiotics are administered while awaiting culture and sensitivity results. Once results are obtained, the appropriate antibiotics are administered via intravitreal injection. Corticosteroid therapy is also administered. If there is no growth of microorganisms, the treatment is topical steroids alone.
Toxic anterior segment syndrome: non-infectious inflammation that is a complication of anterior chamber surgery; caused by a toxic agent such as an agent used to sterilize surgical instruments	Corneal edema occurs less than 24 hours after surgery; symptoms include reduced visual acuity and pain	
Late Postoperative Complications		
Suture-related problems	Toxic reactions or mechanical injury from broken or loose sutures	Suture removal relieves the symptoms. Topical corticosteroids are used when the incision is not healed and sutures cannot be removed.
Malposition of the IOL	Results in astigmatism, sensitivity to glare, or appearance of halos	Miotics are used for mild cases, whereas IOL removal and replacement is necessary for severe cases.
Chronic endophthalmitis	Persistent, low-grade inflammation and granuloma	Corticosteroids and antibiotics are administered systemically. If the condition persists, removal of the IOL and capsular bag, vitrectomy, and intravitreal injection of antibiotics are required.
Opacification of the posterior capsule (most common late complication of extracapsular cataract extraction)	Visual acuity is diminished	YAG laser is used to create a hole in the posterior capsule. Blurred vision is cleared immediately.

IOL, intraocular lens; IOP, intraocular pressure.

they actually are. This magnification creates distortion. Peripheral vision is also limited, and **binocular vision** (ie, ability of both eyes to focus on one object and fuse the two images into one) is impossible if the other eye is phakic (normal).

Contact lenses provide patients with almost normal vision, but because contact lenses need to be removed occasionally, the patient also needs a pair of aphakic glasses. Contact lenses are not advised for patients who have difficulty inserting, removing, and cleaning them. Frequent handling and improper disinfection increase the risk of infection.

Insertion of IOLs during cataract surgery is the usual approach to lens replacement. After cataract extraction, or phacoemulsification, the surgeon implants an IOL. Cataract extraction and posterior chamber IOLs are associated with a relatively low incidence of complications (eg, hyphema, macular edema, secondary glaucoma, damage to the corneal endothelium). IOL implantation is contraindicated in patients with recurrent uveitis, proliferative diabetic retinopathy, neovascular glaucoma, or rubeosis iridis.

The most common IOL is the single-focus lens or monofocal IOL. Eyeglasses are still needed for distant or close vision, because the single-focus lens, unlike the natural lens of the eye, cannot alter its shape to bring objects at different distances into focus. Multifocal IOLs reduce the need for eyeglasses (near, intermediate, or far vision). Accommodative IOLs mimic the accommodative response of the youthful, phakic eye and are also known as presbyopia-correcting IOLs (Fong, 2007). A combined surgical approach using customized IOLs and refractive surgery for a customized vision correction is now proving beneficial for elderly patients (Fine, Hoffman & Packer, 2007).

Toxic Anterior Segment Syndrome

Toxic anterior segment syndrome (TASS), which is also known as toxic endothelial cell destruction or sterile endophthalmitis, is a noninfectious anterior segment inflammation caused by a toxic agent within days of an uncomplicated and uneventful cataract surgery. In recent years, TASS has emerged as a complication of increasing frequency. Investigations have shown that it may be caused by toxins from improperly rinsed surgical instruments soaked in enzymatic detergents, residue from instruments sterilized with plasma gas, abnormalities in the pH or ionic composition of irrigation solutions, ophthalmic viscoelastic devices, intraocular medications, or even the finish of the IOL (Mamalis, Edelhauser, Dawson, et al., 2006). Specific intraoperative causes have been identified such as endotoxin contamination of balanced salt solution and antibiotic ointment penetrating the anterior chamber (Holland, Morck & Lee, 2007). Decontamination and cleaning of ophthalmic instruments should follow recommended procedures, in particular use of enzymatic solutions and rinsing with copious amounts of deionized or distilled water.

TASS is characterized by corneal edema that occurs less than 24 hours after surgery, compared with classic endophthalmitis, which appears 48 to 72 hours after surgery and is bacterial in nature. Like classic endophthalmitis, the symptoms include reduction in visual acuity and pain. In the absence of micro-organism growth, improvement has occurred with topical steroid treatment alone.

Nursing Management

The patient with cataracts should receive the usual preoperative care for ambulatory surgical patients undergoing eye surgery. The standard battery of preoperative tests (eg, complete blood count, electrocardiogram, urinalysis) that were once required in all cases are prescribed only if they are indicated by the patient's medical history.

Providing Preoperative Care

It has been common practice to withhold any anticoagulant therapy (eg, aspirin, warfarin [Coumadin]) to reduce the risk of retrobulbar hemorrhage (after retrobulbar injection) for 5 to 7 days before surgery. However, a recent study showed that the risk of adverse events for patients who continued anticoagulant therapy before cataract surgery was very low (0.1% to 0.8%). The researchers speculated that regular users of aspirin or warfarin are already at higher risk for transient ischemic attacks or angina and suggest that patients may not need to discontinue these medications prior to surgery (Katz, Feldman, Bass, et al., 2003).

Dilating drops are administered every 10 minutes for four doses at least 1 hour before surgery. Additional dilating drops may be administered in the operating room (immediately before surgery). Antibiotic, corticosteroid, and anti-inflammatory drops may be administered prophylactically to prevent postoperative infection and inflammation.

Providing Postoperative Care

Before discharge, the patient receives verbal and written instructions about how to protect the eye, administer medications, recognize signs of complications, and obtain emergency care. Activities to be avoided are identified in Chart 58-9. The nurse also explains that there should be minimal discomfort after surgery and instructs the patient to take a mild analgesic agent, such as acetaminophen, as needed. Antibiotic, anti-inflammatory, and corticosteroid eye drops or ointments are prescribed postoperatively. A clinical pathway for the care of patients undergoing ambulatory cataract surgery is presented in Appendix B at the end of this textbook.

Promoting Home and Community-Based Care

Teaching Patients Self-Care

To prevent accidental rubbing or poking of the eye, the patient wears a protective eye patch for 24 hours after surgery, followed by eyeglasses worn during the day and a metal shield worn at night for 1 to 4 weeks. The nurse instructs the patient and family in applying and caring for the eye shield. Sunglasses should be worn while outdoors during the day because the eye is sensitive to light.

Slight morning discharge, some redness, and a scratchy feeling may be expected for a few days. A clean, damp washcloth may be used to remove slight morning eye discharge. Because cataract surgery increases the risk of retinal detachment, the patient must know to notify the surgeon if new floaters (dots) in vision, flashing lights, decrease in vision, pain, or increase in redness occurs.

Continuing Care

The eye patch is removed after the first follow-up appointment. The patient may experience blurring of vision for several days to weeks. Sutures, if used, are left in the eye but alter the curvature of the cornea, resulting in temporary blurring and some astigmatism. Vision gradually improves as the eye heals. Patients with IOL implants have functional vision on the first day after surgery. Vision is stabilized when the eye is completely healed, usually within 6 to 12 weeks, when final corrective prescription is completed. Visual correction may still be needed for any remaining refractive errors. Patients who choose multifocal IOLs should be aware that there may be increased night glare and contrast sensitivity.

CORNEAL DISORDERS

Corneal Dystrophies

Corneal dystrophies are inherited as autosomal dominant traits and manifest when the person is about 20 years of age. They are characterized by deposits in the corneal layers. Decreased vision is caused by the irregular corneal surface and

HOME CARE CHECKLIST

Intraocular Lens Implant

At the completion of the home care instruction, the patient or caregiver will be able to:	PATIENT	CAREGIVER
• Wear glasses or metal eye shield at all times following surgery as instructed by the physician.	✓	
• Always wash hands before touching or cleaning the postoperative eye.	✓	✓
• Clean postoperative eye with a clean tissue; wipe the closed eye with a single gesture from the inner canthus outward.	✓	✓
• Bathe or shower; shampoo hair cautiously or seek assistance.	✓	
• Avoid lying on the side of the affected eye the night after surgery.	✓	
• Keep activity light (eg, walking, reading, watching television). Resume the following activities only as directed by the physician: driving, sexual activity, unusually strenuous activity.	✓	
• Avoid lifting, pushing, or pulling objects heavier than 15 lb.	✓	
• Avoid bending or stooping for an extended period.	✓	
• Be careful when climbing or descending stairs.	✓	
• Know when to contact the physician.*	✓	✓

*Contact the physician immediately if any of the following problems occur before the next physician's appointment: (1) vision changes; (2) continuous flashing lights appear to the affected eye; (3) redness, swelling, or pain increase in the eye; (4) the amount or type of eye drainage changes; (5) the eye is injured in any way; (6) significant pain is not relieved by acetaminophen.

corneal deposits. Corneal endothelial decompensation leads to corneal edema and blurring of vision. Persistent edema leads to **bullous keratopathy** (formation of blisters that cause pain and discomfort on rupturing). This condition is usually associated with primary open-angle glaucoma.

A bandage contact lens is used to flatten the bullae, protect the exposed corneal nerve endings, and relieve discomfort. Symptomatic treatments, such as hypertonic drops or ointment (5% sodium chloride), may reduce epithelial edema; lowering the IOP also reduces stromal edema.

Keratoconus

Keratoconus is a condition characterized by a conical protrusion of the cornea with progressive thinning on protrusion and irregular astigmatism. This hereditary condition has a higher incidence among women. Onset occurs at puberty; the condition may progress for more than 20 years and is bilateral. Corneal scarring occurs in severe cases. Blurred vision is a prominent symptom. Rigid, gas-permeable contact lenses correct irregular astigmatism and improve vision. Advances in contact lens design have reduced the need for surgery. Penetrating keratoplasty is indicated when contact lens correction is no longer effective.

Corneal Surgeries

Among the surgical procedures used to treat diseased corneal tissue are phototherapeutic keratectomy, penetrating keratoplasty and corneal endothelial transplantation, and Descemet's stripping endothelial keratoplasty.

Phototherapeutic Keratectomy

Phototherapeutic keratectomy (PTK) is a laser procedure that is used to treat diseased corneal tissue by removing or reducing corneal opacities and smoothing the anterior corneal surface to improve functional vision. PTK is a safer, more effective (when indicated) alternative than penetrating or lamellar keratoplasty. PTK is contraindicated in patients with active herpetic keratitis because the ultraviolet rays may reactivate latent virus. Common side effects are induced hyperopia and stromal haze. Complications are delayed reepithelization (particularly in patients with diabetes) and bacterial keratitis. Postoperative management consists of oral analgesics for eye pain. Reepithelization is promoted with a pressure patch or therapeutic soft contact lens. Antibiotic and corticosteroid ointments and nonsteroidal anti-inflammatory agents (NSAIDs) are prescribed postoperatively. Follow-up examinations are required for up to 2 years.

Penetrating Keratoplasty

Penetrating keratoplasty (PKP; corneal transplantation or corneal grafting) involves replacing abnormal host tissue with healthy donor (cadaver) corneal tissue. Common indications are keratoconus, corneal dystrophy, corneal scarring from herpes simplex keratitis, and chemical burns.

Several factors affect the success of the graft: the condition of the ocular structures (eg, lids, conjunctiva), quality of the tears, adequacy of blinking, and viability of the donor endothelium. Tissue that is typically not used for grafting (Chart 58-10) includes tissue that may be the source of disease transmission from donor to recipient; corneas with functionally compromised endothelium; and corneas from donors who have undergone LASIK, because the cornea is no longer intact. Conditions such as glaucoma, retinal

disease, and **strabismus** (deviation in ocular alignment) can negatively affect the outcome.

In PKP, the surgeon determines the graft size before the procedure, and the appropriate size is marked on the surface of the cornea. The surgeon prepares the donor cornea and the recipient bed, removes the diseased cornea, places the donor cornea on the recipient bed, and sutures it in place. Sutures remain in place for 12 to 18 months and are then removed. Potential complications include early graft failure due to poor quality of donor tissue, surgical trauma, acute infection, and persistently increased IOP and late graft failure due to rejection.

Postoperatively, the patient receives **mydriatics** (medications causing pupillary dilation) for 2 weeks and topical corticosteroids for 12 months (daily doses for 6 months and tapered doses thereafter). These mydriatics and corticosteroid drops should be preservative free to prevent a reactive inflammation. Patients typically describe a sensation of postoperative eye discomfort rather than acute pain.

Descemet's Stripping Endothelial Keratoplasty

For the past 50 years, PKP has been the standard of care for patients with corneal endothelial failure but with poor refractive results. Recently, a technique known as Descemet's stripping endothelial keratoplasty (DSEK) has been developed. Layers of the cornea are dissected and selectively replaced by donor cornea tissue. DSEK offers several advantages such as less postoperative astigmatism, faster visual recovery, and stronger wound integrity. Theoretically, the risk of rejection is less because less of the patient's tissue is replaced.

Nursing Management

For corneal surgeries, the nurse reinforces the surgeon's recommendations and instructions regarding visual rehabilitation and visual improvement. A technically successful graft may initially produce disappointing results because the

procedure has produced a new optical surface. Only after several months do patients start seeing the natural and true colors of their environment. Correction of a resultant refractive error with eyeglasses or contact lenses determines the final visual outcome. The nurse assesses the patient's support system and his or her ability to comply with long-term follow-up, which includes frequent clinic visits for several months for tapering of topical corticosteroid therapy, selective suture removal, and ongoing evaluation of the graft site and visual acuity. The nurse also initiates appropriate referrals to community services when indicated.

Because graft failure is an ophthalmic emergency that can occur at any time, the primary goal of nursing care is to teach the patient to identify signs and symptoms of graft failure. The early symptoms are blurred vision, discomfort, tearing, or redness of the eye. Decreased vision results after graft destruction. The patient must contact the ophthalmologist as soon as symptoms occur. Treatment of graft rejection involves prompt administration of hourly topical corticosteroids and periocular corticosteroid injections. Systemic immunosuppressive agents may be necessary for severe, resistant cases.

In DSEK, the nurse keeps the patient in a supine position postoperatively for 1 hour and instructs the patient to remain supine until the first postoperative day (Pramanik, Goins & Sutphin, 2007). Patients are maintained on low-dose topical corticosteroids indefinitely (Price & Price, 2007).

Refractive Surgeries

Refractive surgeries are cosmetic, elective procedures performed to recontour corneal tissue and correct refractive errors so that eyeglasses or contact lenses are no longer needed. Both photorefractive keratectomy (PRK) and LASIK use an excimer laser (193-nm wavelength argon fluoride laser), which can evaporate corneal tissue very cleanly with almost no damage to the epithelial cells. Newer excimer lasers have a smaller spot size, a robust tracking system for eye movements, and wavefront custom ablation technology. These advances have minimized or eliminated aberrations induced by conventional laser vision correction as well as preexisting aberrations; they have improved treatment accuracy and therefore have provided for better vision, including the reduction of postoperative night vision problems.

Laser vision correction alters the major optical function of the eye and thereby carries certain surgical risks. The patient must fully understand the benefits, potential risks and complications, common side effects, and limitations of the procedure. Refractive surgery does not alter the normal aging process of the eye. If the reason for the procedure is to meet vision requirements for the patient's occupation, the results must satisfy both the patient and the employer. Precise visual outcome cannot be guaranteed. Typically, patients must be at least 18 years of age.

The corneal structure must be normal and the refractive error must be stable. The patient is required to discontinue using contact lenses for a period before the procedure (2 to 3 weeks for soft lenses and 4 weeks for hard lenses). Patients with conditions that are likely to adversely affect corneal wound healing (eg, corticosteroid use, immunosuppression, elevated IOP) are not good candidates for the procedure.

Any superficial eye disease must be diagnosed and fully treated before a refractive procedure.

Patient satisfaction is the ultimate goal; therefore, patient education and counseling about potential risks, complications, and postoperative follow-up are critical. Minimal postoperative care includes topical corticosteroid or NSAID and antibiotic drops.

Laser Vision Correction Photorefractive Keratectomy

PRK is used to treat myopia and hyperopia with or without astigmatism. The excimer laser is applied directly to the cornea according to carefully calculated measurements. For myopia, the relative curvature is decreased; for hyperopia, the relative curvature is increased. A bandage contact lens is placed over the cornea to promote epithelial healing and reduce pain, which is similar to that of a severe corneal abrasion. The major limitations of this procedure are postoperative pain, corneal haze, and prolonged recovery of vision.

Laser-Assisted In Situ Keratomileusis

An improvement over PRK, particularly for correcting high (severe) myopia, LASIK involves flattening the anterior curvature of the cornea by removing a stromal lamella or layer. The surgeon creates a corneal flap with a microkeratome, which is an automatic corneal shaper similar to a carpenter's plane. The surgeon retracts a flap of corneal tissue less than one-third the thickness of a human hair to access the corneal stroma and then uses the excimer laser on the stromal bed to reshape the cornea according to calculated measurements (Fig. 58-10). LASIK causes less postoperative discomfort, has fewer side effects, and is safer than PRK. The patient has no corneal haze and requires less postoperative care. However, with LASIK, the cornea has been invaded at a deeper level, and any complications are more significant than those that can occur with PRK. With the increasing success and popularity of LASIK, PRK is now reserved for patients who are unsuitable for LASIK, such as people with very thin corneas.

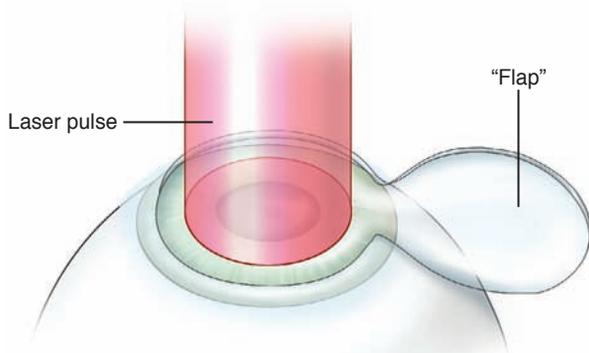

Figure 58-10 LASIK combines delicate surgical procedures and laser treatment. A flap is surgically created and lifted to one side. A laser is then applied to the cornea to reshape it. With permission from The Wilmer Laser Vision Center, Lutherville, MD.

Perioperative Complications

Surgically Induced Abnormalities

Corneal surface irregularities can occur after LASIK treatment. These include central islands (central areas of stiffness or elevation), decentered ablations resulting from misalignment of the laser treatment or from involuntary eye movement during laser treatment, and forms of irregular astigmatism. Symptoms of central islands and decentered ablations include monocular diplopia or ghost images, halos, glare, and decreased visual acuity.

Diffuse Lamellar Keratitis

As LASIK is performed more frequently, the vision-threatening complication known as diffuse lamellar keratitis (DLK) is reported more often. DLK is a peculiar, noninfectious, inflammatory reaction in the lamellar interface after LASIK. DLK seems to be strongly associated with a decrease of contrast sensitivity up to 6 months postoperatively (Han, Wee, Lee, et al., 2007). Depending on the severity of the condition, treatment methods range from administering corticosteroid drops to intervening surgically.

Phakic Intraocular Lenses

Because the results of refractive surgery on high (severe) myopia, hyperopia, and astigmatism are less predictable, there has been increasing interest in the use of phakic IOL implantation in patients who retain their natural lens. These phakic IOLs may be used in either the anterior or posterior chamber. The implantation of such devices is reversible because the natural lens is left in place and the normal architecture of the cornea is preserved. This procedure may provide more predictable refractive results than procedures that alter the corneal curvature. Potential complications include cataract, iritis or uveitis, endothelial cell loss, and increased IOP.

Although phakic IOL implantation provides a more predictable alternative to corneal refractive surgery, more controlled, longitudinal multicenter trials are needed to evaluate its long-term safety. The design of phakic IOLs continues to improve.

Conductive Keratoplasty

A recent innovation in refractive surgery for the correction of low to mild hyperopia uses the principles of thermal keratoplasty by applying radiofrequency current to the peripheral cornea using a thin, hand-held probe. It does not involve the removal of cornea tissue. Clinical trials have shown that postprocedure visual acuity, predictability, and stability are as good as, if not better than, with other refractive procedures (Du, Fan & Asbell, 2007).

RETINAL DISORDERS

Although the retina is composed of multiple microscopic layers, the two innermost layers, the sensory retina and the retinal pigment epithelium (RPE), are the most relevant to common retinal disorders. Just as the film in a camera captures an image, so does the retina, the neural tissue of the eye. The rods and cones, the photoreceptor cells, are found

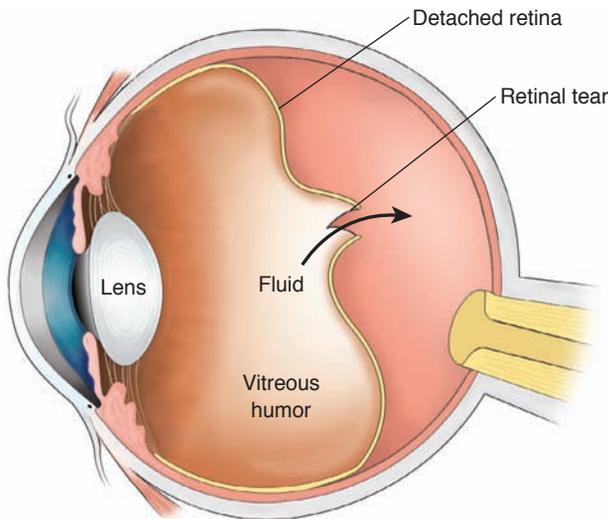

Figure 58-11 Retinal detachment.

in the sensory layer of the retina. Beneath the sensory layer lies the RPE, the pigmented layer. When the rods and cones are stimulated by light, an electrical impulse is generated, and the image is transmitted to the brain.

Retinal Detachment

Retinal detachment refers to the separation of the RPE from the sensory layer. The four types of retinal detachment are rhegmatogenous, traction, a combination of rhegmatogenous and traction, and exudative. *Rhegmatogenous detachment* is the most common form. In this condition, a hole or tear develops in the sensory retina, allowing some of the liquid vitreous to seep through the sensory retina and detach it from the RPE (Fig. 58-11). People at risk for this type of detachment include those with high myopia or **aphakia** after cataract surgery. Trauma may also play a role in rhegmatogenous retinal detachment. Between 5% and 10% of all rhegmatogenous retinal detachments are associated with proliferative retinopathy, a retinopathy associated with diabetic neovascularization (see Chapter 41).

Tension, or a pulling force, is responsible for *traction retinal detachment*. An ophthalmologist must ascertain all of the areas of retinal break and identify and release the scars or bands of fibrous material providing traction on the retina. Generally, patients with this condition have developed fibrous scar tissue from conditions such as diabetic retinopathy, vitreous hemorrhage, or the retinopathy of prematurity. The hemorrhages and fibrous proliferation associated with these conditions exert a pulling force on the delicate retina.

Patients can have both rhegmatogenous and traction retinal detachment. *Exudative retinal detachments* are the result of the production of a serous fluid under the retina from the choroid. Conditions such as uveitis and macular degeneration may cause the production of this serous fluid.

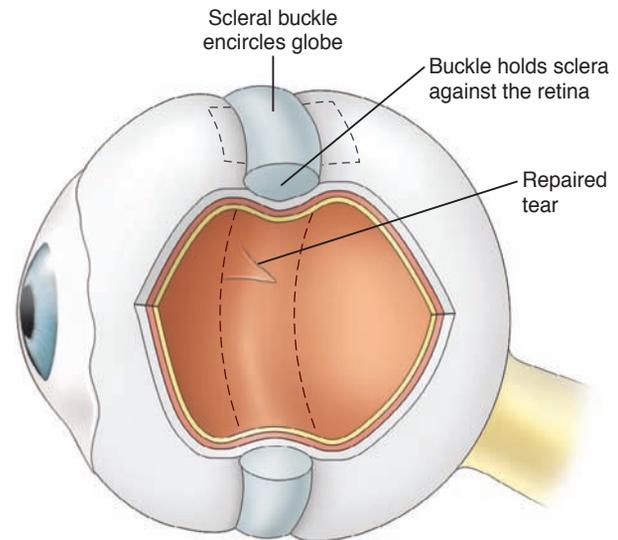

Figure 58-12 Scleral buckle.

Clinical Manifestations

Patients may report the sensation of a shade or curtain coming across the vision of one eye, cobwebs, bright flashing lights, or the sudden onset of a great number of floaters. Patients do not complain of pain.

Assessment and Diagnostic Findings

After visual acuity is determined, the patient must have a dilated fundus examination using an indirect ophthalmoscope as well as slit-lamp biomicroscopy. Stereo fundus photography and fluorescein angiography are commonly used during the evaluation.

Increasingly, optical coherence tomography and ultrasound are used for the complete retinal assessment, especially if the view is obscured by a dense cataract or vitreal hemorrhage. All retinal breaks, all fibrous bands that may be causing traction on the retina, and all degenerative changes must be identified.

Surgical Management

In rhegmatogenous detachment, an attempt is made to surgically reattach the sensory retina to the RPE. In traction detachment, the source of traction must be removed and the sensory retina reattached. New surgical techniques as well as advances in instrumentation have led to an increased rate of success of surgical reattachment and better visual outcomes. The most commonly used surgical interventions are the scleral buckle, the pars plana vitrectomy, and pneumatic retinopexy. A recently developed procedure is the 25-gauge transconjunctival sutureless vitrectomy.

Scleral Buckle

The retinal surgeon compresses the sclera (often with a scleral buckle or a silicone band; Fig. 58-12) to indent the scleral wall from the outside of the eye and bring the two retinal layers in contact with each other. This type of surgery has a high success rate in the hands of experienced retinal surgeons. It causes less damage to the lens of the eye in

phakic patients, and there is a low risk of endophthalmitis. However, there is an increased incidence of diplopia and other complications, such as induced myopia and increased postoperative pain.

Pars Plana Vitrectomy

A vitrectomy is an intraocular procedure in which 1- to 4-mm incisions are made at the pars plana. One incision allows the introduction of a light source, and another incision serves as the portal for the vitrectomy instrument. The surgeon dissects preretinal membranes under direct visualization while the retina is stabilized by an intraoperative vitreous substitute.

This surgical technique was originally introduced as a treatment for eyes with conditions that were previously inoperable (eg, vitreous hemorrhage, proliferative diabetic retinopathy). Technologic improvements, including the use of operating microscopes, microinstrumentation, and instruments that combine vitreous cutting, aspiration, and illumination capabilities in one device, have advanced vitreoretinal surgery. The techniques of vitreoretinal surgery can be used in various procedures, including the removal of foreign bodies, vitreous opacities such as blood, and dislocated lenses. Traction on the retina may be relieved through vitrectomy and may be combined with scleral buckling to repair retinal breaks. Treatment of macular holes includes vitrectomy, laser photocoagulation, air-fluid-gas exchanges, and the use of growth factor.

Pneumatic Retinopexy

This technique is used for the repair of a rhegmatogenous retinal detachment. It is the least invasive of the three procedures described. A gas bubble, silicone oil, or perfluorocarbon and liquids may be injected into the vitreous cavity to help push the sensory retina up against the RPE. Argon laser photocoagulation or cryotherapy is also used to “spot-weld” small holes.

Transconjunctival Sutureless Vitrectomy

The 25-gauge transconjunctival sutureless vitrectomy is a significant advancement in vitreoretinal surgery. Replacement of the larger 20-gauge approach with the less invasive 25-gauge technique allows for self-sealing transconjunctival pars plana sclerotomies. As a result, postoperative inflammation is decreased, thus promoting rapid wound healing and patient recovery. The 25-gauge microcannula maintains the alignment between the entry site of the conjunctiva and the sclera (Chen, 2007) (Fig. 58-13).

Complications such as hypotony and endophthalmitis may be related to the unsutured sclerotomy. However, clinical experience has shown that this sutureless system is both safe and effective with decreased surgical times, reduced postoperative inflammation, and more rapid recovery (Chen, 2007).

Nursing Management

For the most part, nursing interventions consist of educating the patient and providing supportive care. For pneumatic retinopexy, postoperative positioning of the patient is critical because the injected bubble must float into a position overlying the area of detachment, providing consistent

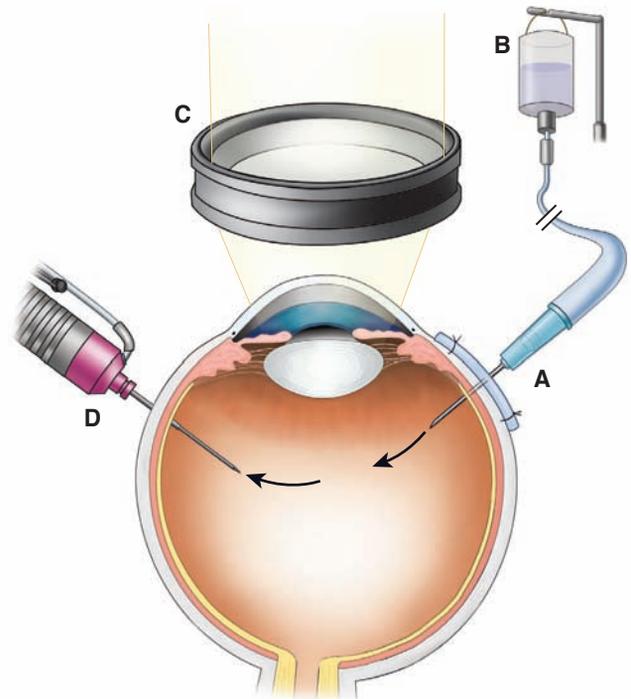

Figure 58-13 25-gauge transconjunctival pars plana sutureless vitrectomy with simultaneous suction and infusion. **A**, Infusion of fluid through a 25-gauge needle secured by passing through a block of plastic sutured to the eye. **B**, Balanced salt solution is fed into the eye by gravity. **C**, Illumination and observation are provided with the indirect ophthalmoscope. **D**, The vitreous is aspirated into the port of the sharp-tipped vitreous cutter.

pressure to reattach the sensory retina. The patient must maintain a prone position that would allow the gas bubble to act as a tamponade for the retinal break (Ross & Lavina, 2008). Patients and family members should be made aware of these special needs beforehand so that the patient can be made as comfortable as possible.

Teaching About Complications

In many cases, vitreoretinal procedures are performed on an outpatient basis, and the patient is seen the next day for a follow-up examination and closely monitored thereafter as required. Postoperative complications may include increased IOP, endophthalmitis, development of other retinal detachments, development of cataracts, and loss of turgor of the eye. Patients must be taught the signs and symptoms of complications, particularly of increasing IOP and postoperative infection. Patients should be provided with telephone numbers of members of the ophthalmic team and encouraged to call immediately if discomfort escalates.

Retinal Vascular Disorders

Loss of vision can occur from occlusion of a retinal artery or vein. Such occlusions may result from atherosclerosis, cardiac valvular disease, venous stasis, hypertension, or increased blood viscosity. Associated risk factors include diabetes mellitus, glaucoma, and aging.

Central Retinal Vein Occlusion

Blood supply to and from the ocular fundus is provided by the central retinal artery and vein. Central retinal vein occlusions (CRVOs) are relatively common and found most often in people older than 50 years of age. Patients who have suffered a CRVO report decreased visual acuity, which may range from mild blurring to vision that is severely limited.

Direct ophthalmoscopy of the retina shows optic disc swelling, venous dilation and tortuosity, retinal hemorrhages, cotton-wool spots, and a “blood and thunder” (extremely bloody) appearance of the retina. The better the initial visual acuity, the better the general prognosis.

Fluorescein angiography may show extensive areas of capillary closure. The patient should be monitored carefully over the ensuing several months for signs of neovascularization and neovascular glaucoma. Laser panretinal photocoagulation may be necessary to treat the abnormal neovascularization. Neovascularization of the iris may cause neovascular glaucoma, which may be difficult to control. Macular edema, macular nonperfusion, and vitreous hemorrhage from the neovascularization are among the potential complications of CRVO. In addition, CRVO is a significant cause of vision loss (Mohamed, McIntosh, Seang, et al., 2007).

Branch Retinal Vein Occlusion

Some patients with branch retinal vein occlusion (BRVO) are symptom free, whereas others complain of a sudden loss of vision if the macular area is involved. A more gradual loss of vision may occur if macular edema associated with BRVO develops. Studies have shown that a gridlike pattern of laser burns reduces macular edema and improves visual acuity by two or more lines on the Snellen chart (Esrick, Subramanian, Heier, et al., 2005).

On examination, the ocular fundus appears similar to that found in CRVO; however, only those portions of the retina affected by the obstructive veins have what is known as a “blood and thunder” appearance. The occlusions generally occur at the arteriovenous crossings. The diagnostic evaluation and follow-up assessments are the same as for CRVO. Potential complications are similar. Associated conditions include glaucoma, systemic hypertension, diabetes mellitus, hyperlipidemia, and hyperviscosity syndrome.

Central Retinal Artery Occlusion

Patients with central retinal artery occlusion, a relatively rare disorder that accounts for approximately 1 in 10,000 ophthalmologic visits, present with a sudden loss of vision. Visual acuity is reduced to being able to count the examiner's fingers, or the field of vision is tremendously restricted. A relative afferent pupillary defect is present. Examination of the ocular fundus reveals a pale retina with a cherry-red spot at the fovea. The retinal arteries are thin, and emboli are occasionally seen in the central retinal artery or its branches. Central retinal artery occlusion is a true ocular emergency. Various treatments are used: ocular massage, anterior chamber paracentesis, IV administration of hyperosmotic agents such as acetazolamide (Diamox), and high concentrations of oxygen. An aggressive stepwise approach may be beneficial, depending on the underlying cause of the occlusion and the amount of time from onset of

occlusion to treatment. Most visual loss associated with central retinal artery occlusion is severe and permanent.

Age-Related Macular Degeneration

Age-related macular degeneration (AMD) is the most common cause of visual loss in people older than 60 years of age in developed countries (Seddon & Chen, 2004). In the United States alone, the number of cases is expected to reach almost 3 million by the year 2020 (Bressler, et al., 2008). AMD is characterized by tiny, yellowish spots called drusen (Fig. 58-14) beneath the retina. Most people older than 60 years of age have at least a few small drusen. These drusen are small clusters of debris or waste material that lie deep within the RPE. When these drusen are located in the macular area, they can affect vision. Patients with AMD have a wide range of visual loss, but most do not experience total blindness. Central vision is generally the most affected, with most patients retaining peripheral vision (Fig. 58-15). There are two types of AMD, commonly known as the dry type and wet type.

Between 85% and 90% of people with AMD have the dry (nonneovascular, nonexudative) type of the condition, in which the outer layers of the retina slowly break down (Fig. 58-16). With this breakdown comes the appearance of drusen. When the drusen occur outside of the macular area, patients generally have no symptoms. When the drusen occur within the macula, however, there is a gradual blurring of vision that patients may notice when they try to read.

The second type of AMD, the wet (neovascular, exudative) type, may have an abrupt onset. Patients report that straight lines appear crooked and distorted or that letters in words appear broken. This effect results from proliferation of abnormal blood vessels growing under the retina, within the choroid layer of the eye, a condition known as choroidal neovascularization. The affected vessels can leak fluid and blood, elevating the retina. Some patients can be treated with the argon laser to stop the leakage from these vessels. However, this treatment is not ideal because vision may be affected by the laser treatment and abnormal vessels often grow back after treatment.

Medical Management

There is no known cure for the dry (nonexudative, non-neovascular) type of AMD. The Age-Related Eye Disease Study (2001a), a multicenter clinical trial, has provided promising information about the prevention and treatment of AMD. The study was designed to determine whether large doses of macronutrients are effective in preventing or slowing the course of the disease. The study revealed that use of antioxidants (vitamin C, vitamin E, and beta-carotene) and minerals (zinc oxide) in megadoses can slow the progression of AMD and vision loss for people at high risk for developing advanced AMD. Research continues; the National Eye Institute (NEI) is sponsoring an ongoing clinical trial, Age-Related Eye Disease Study II (AREDS II), to study the effect of lutein and zeaxanthin (carotenoids) or fish oils in protecting the macula and preventing the progression of AMD (NEI, 2008).

Antiangiogenic Therapy

An important component of treatment of neovascular (wet, exudative) AMD targets development and progression of

angiogenesis (abnormal blood vessel formation). Studies continue toward identification of agents that can be used to inhibit angiogenesis. This has implications for ocular neovascularization (Andreoli & Miller, 2007).

Vasoproliferation in exudative AMD is believed to be caused by an underlying angiogenic stimulus known as vascular endothelial growth factor (VEGF). Research has resulted in the development of agents that inhibit the development of VEGF and therefore angiogenesis. Pegaptanib sodium (Macugen), a VEGF antagonist, is designed to inhibit the ability of VEGF to bind to cellular receptors. This agent is no longer widely used because visual acuity has improved in only a limited number of patients as a result of this treatment (Jager, Mieler & Miller, 2008). Ranibizumab (Lucentis) is designed to bind and inactivate all isoforms of VEGF. Approved in 2006, it is administered by intravitreal injection once a month. Studies have shown that, on average, patients may gain one to two lines of vision on the Snellen chart after a year of treatment (Bressler, et al., 2008). This is a dramatic positive step; in the early days of photocoagulation therapy, the best that could be achieved was a slowing of visual loss that was accompanied by a treatment-related scotoma.

The monoclonal antibody bevacizumab (Avastin) has been found to be helpful in the treatment of neovascular AMD. Originally developed for the treatment of colon cancer, it has been used “off-label” by many ophthalmologists for AMD, with results that rival those of the more expensive ranibizumab.

Nursing Management

Amsler grids are given to patients to use in their homes to monitor for a sudden onset or distortion of vision. These may provide the earliest sign that macular degeneration is getting worse. Patients should be encouraged to look at these grids, one eye at a time, several times each week with glasses on. If there is a change in the grid (eg, if the lines or squares appear distorted or faded), the patient should notify the ophthalmologist immediately and should arrange to be seen promptly.

ORBITAL AND OCULAR TRAUMA

Whether affecting the eye or the orbit, trauma to the eye and surrounding structures may have devastating consequences for vision. It is preferable to prevent injury rather than treat it. Chart 58-11 details safety measures to prevent orbital and ocular trauma.

Orbital Trauma

Injury to the orbit is usually associated with a head injury; hence, the patient’s general medical condition must first be stabilized before conducting an ocular examination. Only then is the globe assessed for soft tissue injury. During inspection, the face is meticulously assessed for underlying fractures, which should always be suspected in cases of blunt trauma. To establish the extent of ocular injury, visual acuity is assessed as soon as possible, even if it is only a rough

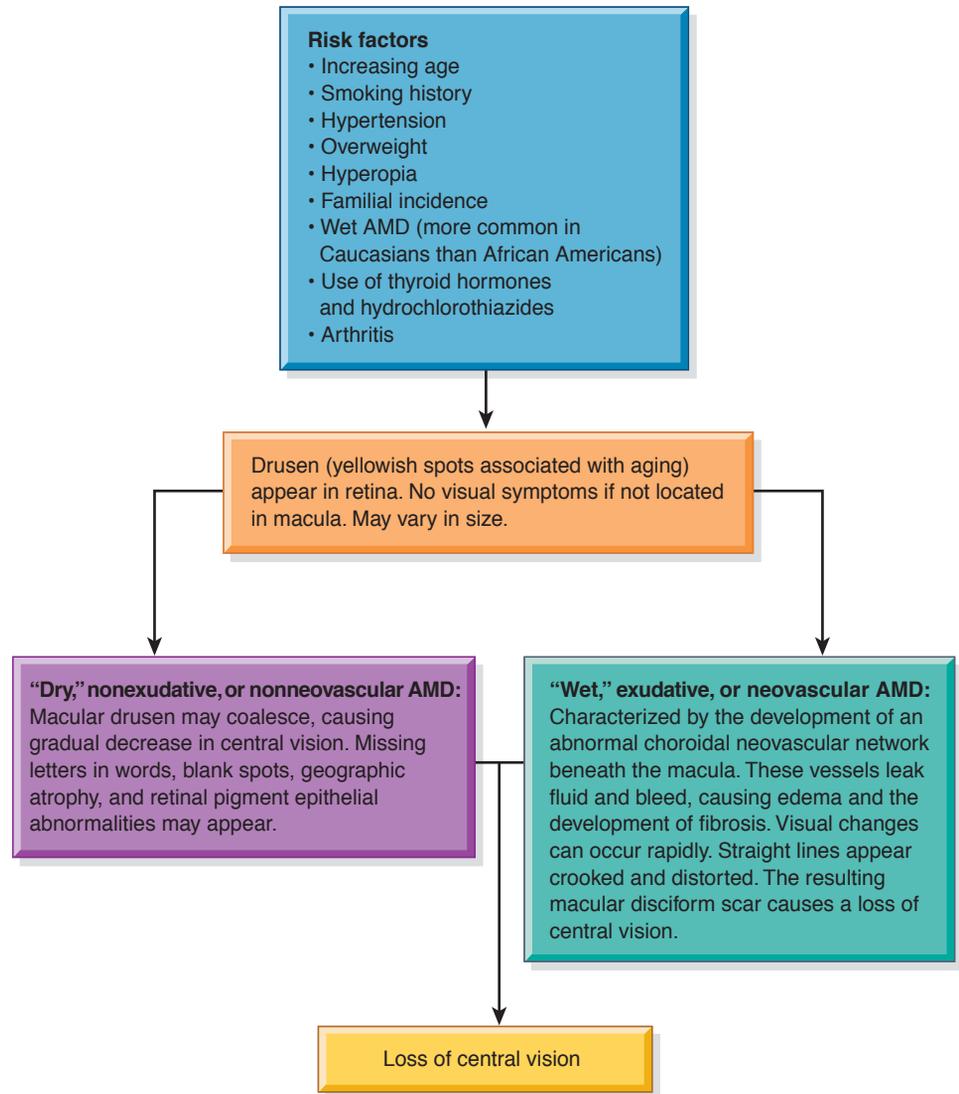

Figure 58-16 Progression of age-related macular degeneration (AMD): pathways to vision loss.

estimate. Soft tissue orbital injuries often result in damage to the optic nerve. Major ocular injuries indicated by a soft globe, prolapsing tissue, ruptured globe, and hemorrhage require immediate surgical attention.

Soft Tissue Injury and Hemorrhage

The signs and symptoms of soft tissue injury from blunt or penetrating trauma include tenderness, ecchymosis, lid swelling, **proptosis** (ie, downward displacement of the eyeball), and hemorrhage. Closed injuries lead to contusions with subconjunctival hemorrhage, commonly known as a *black eye*. Blood accumulates in the tissues of the conjunctiva. Hemorrhage may be caused by a soft tissue injury to the eyelid or by an underlying fracture.

Management of soft tissue hemorrhage that does not threaten vision is usually conservative and consists of thorough inspection, cleansing, and repair of wounds. Cold compresses are used in the early phase, followed by warm compresses. Hematomas that appear as swollen, fluctuating areas may be surgically drained or aspirated; if they are

causing significant orbital pressure, they may be surgically evacuated.

Penetrating injuries or a severe blow to the head can result in severe optic nerve damage. Visual loss can be sudden or delayed and progressive. Immediate loss of vision after an ocular injury is usually irreversible. Delayed visual loss has a better prognosis. Corticosteroid therapy is indicated to reduce optic nerve swelling. Surgery, such as optic nerve decompression, may be performed.

Orbital Fractures

Orbital fractures are detected by facial x-rays. Depending on the orbital structures involved, orbital fractures can be classified as blowout, zygomatic or tripod, maxillary, midfacial, orbital apex, and orbital roof fractures. Blowout fractures result from compression of soft tissue and the sudden increase in orbital pressure when the force is transmitted to the orbital floor, the area of least resistance.

The inferior rectus and inferior oblique muscles, with their fat and fascial attachments, or the nerve that courses

CHART
58-11

PATIENT EDUCATION

*Advice for Patients About Preventing Eye Injuries***In and Around the House**

- Make sure that all spray nozzles are directed away from themselves before pressing down on the handle.
- Read instructions carefully before using cleaning fluids, detergents, ammonia, or harsh chemicals, and to wash hands thoroughly after use.
- Use grease shields on frying pans to decrease spattering.
- Wear special goggles to shield their eyes from fumes and splashes when using powerful chemicals.
- Use opaque goggles to avoid burns from sunlamps.

In the Workshop

- Protect their eyes from flying fragments, fumes, dust particles, sparks, and splashed chemicals by wearing safety glasses.
- Read instructions thoroughly before using tools and chemicals, and follow precautions for their use.

Around Children

- Pay attention to age and maturity level of a child when selecting toys and games, and to avoid projectile toys, such as darts and pellet guns.
- Supervise children when they are playing with toys or games that can be dangerous.
- Teach children the correct way to handle potentially dangerous items, such as scissors and pencils.

In the Garden

- Avoid letting anyone stand at the side of or in front of a moving lawn mower.
- Pick up rocks and stones before going over them with the lawn mower (stones can be hurled out of the rotary blades

and rebound off curbs or walls, causing severe injury to the eye).

- Direct pesticide spray can nozzles away from the face.
- Avoid low-hanging branches.

Around the Car

- Put out all smoking materials and matches before opening the hood of the car.
- Use a flashlight, not a match or lighter, to look at the battery at night.
- Wear goggles when grinding metal or striking metal against metal while performing auto body repair.
- Take standard safety precautions when using jumper cables (wear goggles; make sure the cars are not touching one another; make sure the jumper cable clamps never touch each other; never lean over the battery when attaching cables; and never attach a cable to the negative terminal of a dead battery).

In Sports

- Wear protective safety glasses, especially for sports such as racquetball, squash, tennis, baseball, and basketball.
- Wear protective caps, helmets, or face protectors when appropriate, especially for sports such as ice hockey.

Around Fireworks

- Wear eye glasses or safety goggles.
- Avoid explosive fireworks.
- Never allow children to ignite fireworks.
- Avoid standing near others when lighting fireworks.
- Douse duds in water instead of attempting to relight them.

along the inferior oblique muscle may become entrapped, and the globe may be displaced inward (ie, enophthalmos). Computed tomography (CT) can identify the muscle and its auxiliary structures that are entrapped. These fractures are usually caused by blunt small objects, such as a fist, knee, elbow, or tennis or golf ball.

Orbital roof fractures are dangerous because of potential complications to the brain. Surgical management of these fractures requires a neurosurgeon and an ophthalmologist. The most common indications for surgical intervention are displacement of bone fragments disfiguring the normal facial contours, interference with normal binocular vision caused by extraocular muscle entrapment, interference with mastication in zygomatic fracture, and obstruction of the nasolacrimal duct. Surgery is usually nonemergent, and a period of 10 to 14 days gives the ophthalmologist time to assess ocular function, especially the extraocular muscles and the nasolacrimal duct. Emergency surgical repair is usually not performed unless the globe is displaced into the maxillary sinus. Surgical repair is primarily directed at freeing the entrapped ocular structures and restoring the integrity of the orbital floor.

Foreign Bodies

Foreign bodies that enter the orbit are usually tolerated, except for copper, iron, and vegetable materials such as those from plants or trees, which may cause purulent infec-

tion. X-rays and CT scans are used to identify the foreign body. A careful history is important, especially if the foreign body has been in the orbit for a period of time and the incident forgotten. It is important to identify metallic foreign bodies because they prohibit the use of magnetic resonance imaging (MRI) as a diagnostic tool.

After the extent of the orbital damage is assessed, the decision to use conservative treatment or surgical removal is made. In general, orbital foreign bodies are removed if they are superficial and anterior in location; have sharp edges that may affect adjacent orbital structures; or are composed of copper, iron, or vegetable material. Surgical intervention is directed at preventing further ocular injury and maintaining the integrity of the affected areas. Cultures are usually obtained, and the patient is placed on prophylactic IV antibiotics that are later changed to oral antibiotics.

Ocular Trauma

Ocular trauma is the leading cause of blindness among children and young adults, especially male trauma victims. The most common circumstances of ocular trauma are occupational injuries (eg, construction industry), sports (eg, baseball, basketball, racquet sports, boxing), weapons (eg, air guns, BB guns), assault, motor vehicle

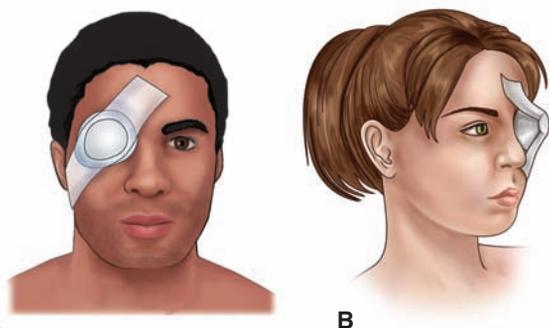

Figure 58-17 Two kinds of eye patches. **A**, Aluminum shield. **B**, Stiff paper cup shield (innovative substitute when aluminum shield is unavailable).

crashes (eg, broken windshields), and explosions (eg, blast fragments).

There are two types of ocular trauma in which the first response is critical: chemical burn and foreign object in the eye. With a chemical burn, the eye should be immediately irrigated with tap water or normal saline. With a foreign body, no attempt should be made to remove the foreign object. The object should be protected from jarring or movement to prevent further ocular damage. No pressure or patch should be applied to the affected eye. All traumatic eye injuries should be protected using a metal shield if available or a stiff paper cup until medical treatment can be obtained (Fig. 58-17).

Assessment and Diagnostic Findings

A thorough history is obtained, particularly assessing the patient's ocular history, such as preinjury vision in the affected eye or past ocular surgery. Details related to the injury that help in the diagnosis and assessment of need for further tests include the nature of the ocular injury (ie, blunt or penetrating trauma); the type of activity that caused the injury to determine the nature of the force striking the eye; and whether onset of vision loss was sudden, slow, or progressive. For chemical eye burns, the chemical agent must be identified and tested for pH if the agent is available. The corneal surface is examined for foreign bodies, wounds, and abrasions, after which the other external structures of the eye are examined. Pupillary size, shape, and light reaction of the pupil of the affected eye are compared with the other eye. Ocular motility (ability of the eyes to move synchronously up, down, right, and left) is also assessed.

Medical Management

Splash Injuries

Splash injuries are irrigated with normal saline solution before further evaluation occurs. In cases of a ruptured globe, cycloplegic agents (agents that paralyze the ciliary muscle) or topical antibiotics must be deferred because of potential toxicity to exposed intraocular tissues. Further manipulation of the eye must be avoided until the patient is under general anesthesia. Parenteral, broad-spectrum antibiotics are initiated. Tetanus antitoxin is administered, if indicated, as well as analgesics. (Tetanus prophylaxis is recommended for full-thickness ocular and skin wounds.) Any

topical ophthalmic medication (eg, anesthetic, dyes) must be sterile.

Foreign Bodies and Corneal Abrasions

After removal of a foreign body from the surface of the eye, an antibiotic ointment is applied and the eye is patched. The eye is examined daily for evidence of infection until the wound is completely healed.

Contact lens wear is a common cause of corneal abrasion. The patient experiences severe pain and **photophobia** (ocular pain on exposure to light). Corneal epithelial defects are treated with antibiotic ointment and a pressure patch to immobilize the eyelids. Topical anesthetic eye drops must not be given to the patient to take home for repeated use after corneal injury because their effects mask further damage, delay healing, and can lead to permanent corneal scarring. Corticosteroids are avoided while the epithelial defect exists.

Penetrating Injuries and Contusions of the Eyeball

Sharp penetrating injury or blunt contusion force can rupture the eyeball. When the globe, cornea, and sclera rupture, rapid decompression or herniation of the orbital contents into adjacent sinuses can occur. In general, blunt traumatic injuries (with an increased incidence of retinal detachment, intraocular tissue avulsion, and herniation) have a worse prognosis than penetrating injuries. Most penetrating injuries result in marked loss of vision with the following signs: hemorrhagic **chemosis** (edema of the conjunctiva), conjunctival laceration, shallow anterior chamber with or without an eccentrically placed pupil, **hyphema** (hemorrhage within the chamber), or vitreous hemorrhage.

Hyphema is caused by contusion forces that tear the vessels of the iris and damage the anterior chamber angle. Preventing rebleeding and prolonged increased IOP are the goals of treatment for hyphema. In severe cases, the patient is hospitalized with moderate activity restriction. An eye shield is applied. Topical corticosteroids are prescribed to reduce inflammation. An antifibrinolytic agent, aminocaproic acid (Amicar), stabilizes clot formation at the site of hemorrhage. Aspirin is contraindicated.

A ruptured globe and severe injuries with intraocular hemorrhage require surgical intervention. Vitrectomy is performed for traumatic retinal detachments. Primary **enucleation** (complete removal of the eyeball and part of the optic nerve) is considered only if the globe is irreparable and has no light perception. It is a general rule that enucleation is performed within 2 weeks of the initial injury (in an eye that has no useful vision after sustaining penetrating injury) to prevent the risk of **sympathetic ophthalmia** (an inflammation created in the uninjured eye by the affected eye that can result in blindness of the uninjured eye).

Intraocular Foreign Bodies

A patient who complains of blurred vision and discomfort should be questioned carefully about recent injuries and exposures. Patients may be injured in a number of different situations and experience an intraocular foreign body (IOFB). Precipitating circumstances can include working in construction; striking metal against metal; being involved in a

motor vehicle crash with facial injury; a gunshot wound; grinding-wheel work; and an explosion.

IOFB is diagnosed and localized by slit-lamp biomicroscopy and indirect ophthalmoscopy, as well as CT or ultrasonography. MRI is contraindicated because most foreign bodies are metallic and magnetic. It is important to determine the composition, size, and location of the IOFB and affected eye structures. Every effort should be made to identify the type of IOFB and whether it is magnetic. Iron, steel, copper, and vegetable matter cause intense inflammatory reactions. The incidence of endophthalmitis is also high. If the cornea is perforated, tetanus prophylaxis and IV antibiotics are administered. The extraction route (ie, surgical incision) of the foreign body depends on its location and composition and associated ocular injuries. Specially designed IOFB forceps and magnets are used to grasp and remove the foreign body. Any damaged area of the retina is treated to prevent retinal detachment.

Ocular Burns

Alkali, acid, and other chemically active organic substances, such as Mace and tear gas, cause chemical burns. Alkali burns (eg, lye, ammonia) result in the most severe injury because they penetrate the ocular tissues rapidly and continue to cause damage long after the initial injury is sustained. They also cause an immediate rise in IOP. Acids (eg, bleach, car batteries, refrigerant) generally cause less damage because the precipitated necrotic tissue proteins form a barrier to further penetration and damage. Chemical burns may appear as superficial punctate keratopathy (ie, spotty damage to the cornea), subconjunctival hemorrhage, or complete marbling of the cornea.

In treating chemical burns, every minute counts. Immediate tap-water irrigation should be started on site before transport of the patient to an emergency department. Only a brief history and examination are performed. Critical information, if available, is the name of the substance that went into the eye (the actual container is best). Material Safety Data Sheets (MSDS) should be accessed for reference. The corneal surfaces and conjunctival fornices are immediately and copiously irrigated with normal saline or any neutral solution. A local anesthetic is instilled, and a lid speculum is applied to overcome blepharospasm (ie, spasms of the eyelid muscles that result in closure of the lids). Particulate matter must be removed from the fornices using moistened, cotton-tipped applicators and minimal pressure on the globe. Irrigation continues until the conjunctival pH normalizes (between 7.3 and 7.6). The pH of the corneal surface is checked by placing a pH paper strip in the fornix. Antibiotics are instilled, and the eye is patched.

The goal of intermediate treatment is to prevent tissue ulceration and promote reepithelization. Intense lubrication using nonpreserved (ie, without preservatives to avoid allergic reactions) artificial tears is essential. Reepithelization is promoted with patching or therapeutic soft lenses, both of which act to keep the eye quiet by preventing blinking, thus retarding replication of corneal cells. The patient is usually monitored daily for several days. Prognosis depends on the type of injury and adequacy of the irrigation immediately after exposure. Long-term treatment consists

of two phases: restoration of the ocular surface through grafting procedures and surgical restoration of corneal integrity and optical clarity.

Thermal injury is caused by exposure to a hot object (eg, curling iron, tobacco, ash), whereas photochemical injury results from ultraviolet irradiation or infrared exposure (eg, exposure to the reflections from snow, sun gazing, viewing an eclipse of the sun without an adequate filter). These injuries can cause corneal epithelial defect, corneal opacity, conjunctival chemosis and **injection** (congestion of blood vessels), and burns of the eyelids and periorbital region. Antibiotics and a pressure patch for 24 hours constitute the treatment of mild injuries. Scarring of the eyelids may require oculoplastic surgery, whereas corneal scarring may require corneal surgery.

INFECTIOUS AND INFLAMMATORY CONDITIONS

Inflammation and infections of eye structures are common. Eye infection is a leading cause of blindness worldwide. Table 58-6 summarizes selected common infections and their treatment.

Dry Eye Syndrome

Dry eye syndrome, or keratoconjunctivitis sicca, is a deficiency in the production of any of the aqueous, mucin, or lipid tear film components; lid surface abnormalities; or epithelial abnormalities related to systemic diseases or conditions (eg, thyroid disorders, Parkinson's disease), menopause, infection, injury, or complications of medications (eg, antihistamines, oral contraceptives, phenothiazines).

Clinical Manifestations

The most common complaint in dry eye syndrome is a scratchy or foreign body sensation. Other symptoms include itching, excessive mucus secretion, inability to produce tears, a burning sensation, redness, pain, and difficulty moving the lids.

Assessment and Diagnostic Findings

Slit-lamp examination shows an absent or interrupted tear meniscus at the lower lid margin, and the conjunctiva is thickened, edematous, and hyperemic and has lost its luster. A tear meniscus is the crescent-shaped edge of the tear film in the lower lid margin. Chronic dry eyes may result in chronic conjunctival and corneal irritation that can lead to corneal erosion, scarring, ulceration, thinning, or perforation that can seriously threaten vision. Secondary bacterial infection can occur.

Management

Management of dry eye syndrome requires the complete cooperation of the patient with a regimen that needs to be followed at home for a long period; otherwise, complete relief of symptoms is unlikely. Instillation of artificial tears during the day and an ointment at night is the usual regimen to

Table 58-6 COMMON INFECTIONS AND INFLAMMATORY DISORDERS OF EYE STRUCTURES

Disorder	Description	Management
Hordeolum (stye)	Acute suppurative infection of the glands of the eyelids caused by <i>Staphylococcus aureus</i> . The lid is red and edematous with a small collection of pus in the form of an abscess. There is considerable discomfort.	Warm compresses are applied directly to the affected lid area three to four times a day for 10–15 minutes. If the condition is not improved after 48 hours, incision and drainage may be indicated. Application of topical antibiotics may be prescribed thereafter.
Chalazion	Sterile inflammatory process involving chronic granulomatous inflammation of the meibomian glands; can appear as a single granuloma or multiple granulomas in the upper or lower eyelids.	Warm compresses applied three to four times a day for 10–15 minutes may resolve the inflammation in the early stages. Most often, however, surgical excision is indicated. Corticosteroid injection to the chalazion lesion may be used for smaller lesions.
Blepharitis	Chronic bilateral inflammation of the eyelid margins. There are two types: staphylococcal and seborrheic. Staphylococcal blepharitis is usually ulcerative and is more serious due to the involvement of the base of hair follicles. Permanent scarring can result.	The seborrheic type is chronic and is usually resistant to treatment, but the milder cases may respond to lid hygiene. Staphylococcal blepharitis requires topical antibiotic treatment. Instructions on lid hygiene (to keep the lid margins clean and free of exudates) are given to the patient.
Bacterial keratitis	Infection of the cornea by <i>Staphylococcus aureus</i> , <i>Streptococcus pneumoniae</i> , and <i>Pseudomonas aeruginosa</i> .	Fortified (high-concentration) antibiotic eyedrops are administered every 30 minutes around the clock for the first few days, then every 1–2 hours. Systemic antibiotics may be administered. Cycloplegics are administered to reduce pain caused by ciliary spasm. Corticosteroid therapy and subconjunctival injections of antibiotics are controversial.
Herpes simplex keratitis	Leading cause of corneal blindness in the United States. Symptoms are severe pain, tearing, and photophobia. The dendritic ulcer has a branching, linear pattern with feathery edges and terminal bulbs at its ends. Herpes simplex keratitis can lead to recurrent stromal keratitis and persist to 12 months with residual corneal scarring.	Many lesions heal without treatment and residual effects. The treatment goal is to minimize the damaging effect of the inflammatory response and eliminate viral replication within the cornea. Penetrating keratoplasty is indicated for corneal scarring and must be performed when the herpetic disease has been inactive for many months.

hydrate and lubricate the eye and preserve a moist ocular surface. Cyclosporine ophthalmic emulsion (Restasis) is an effective agent that increases tear production and is used once daily. Anti-inflammatory medications are also used, and moisture chambers (eg, moisture chamber spectacles, swim goggles) may provide additional relief.

Patients may become hypersensitive to chemical preservatives such as benzalkonium chloride and thimerosal. For these patients, preservative-free ophthalmic solutions are used. Management of the dry eye syndrome also includes the concurrent treatment of infections, such as chronic blepharitis and acne rosacea, and treating the underlying systemic disease, such as Sjögren syndrome (an autoimmune disease).

In advanced cases of dry eye syndrome, surgical treatment that includes punctal occlusion, grafting procedures, and lateral tarsorrhaphy (uniting the edges of the lids) are options. Punctal plugs are made of silicone material for the temporary or permanent occlusion of the puncta. This helps preserve the natural tears and prolongs the effects of artificial tears. Short-term occlusion is performed by inserting punctal or silicone rods in all four puncta. If tearing is induced by the occlusion, the upper plugs are removed, and the remaining lower plugs are removed in another week. Permanent occlusion is performed only in severe cases in adults who do not develop tearing after partial occlusion and who have results on a repeated Schirmer’s test of 2 mm or less (filter paper is used to measure tear production).

Conjunctivitis

Conjunctivitis (inflammation of the conjunctiva) is the most common ocular disease worldwide. It is characterized by a pink appearance (hence the common term *pink eye*) because of subconjunctival blood vessel congestion.

Clinical Manifestations

General symptoms include foreign body sensation, scratching or burning sensation, itching, and photophobia. Conjunctivitis may be unilateral or bilateral, but the infection usually starts in one eye and then spreads to the other eye by hand contact.

Assessment and Diagnostic Findings

The four main clinical features important to evaluate are the type of discharge (watery, mucoid, purulent, or mucopurulent), type of conjunctival reaction (follicular or papillary), presence of pseudomembranes or true membranes, and presence or absence of lymphadenopathy (enlargement of the preauricular and submandibular lymph nodes where the eyelids drain). Pseudomembranes consist of coagulated exudate that adheres to the surface of the inflamed conjunctiva. True membranes form when the exudate adheres to the superficial layer of the conjunctiva, and removal results in bleeding. Follicles are multiple, slightly elevated lesions encircled by tiny blood vessels; they look like grains of rice. Papillae are hyperplastic conjunctival epithelium in

numerous projections that are usually seen as a fine mosaic pattern under slit-lamp examination. Diagnosis is based on the distinctive characteristics of ocular signs, acute or chronic presentation, and identification of any precipitating events. Positive results of swab smear preparations and cultures confirm the diagnosis.

Types of Conjunctivitis

Conjunctivitis is classified according to its cause. The major causes are microbial infection, allergy, and irritating toxic stimuli. A wide spectrum of organisms can cause conjunctivitis, including bacteria (eg, *Chlamydia*), viruses, fungus, and parasites. Conjunctivitis can also result from an existing ocular infection or can be a manifestation of a systemic disease.

Microbial Conjunctivitis

Bacterial Conjunctivitis

Bacterial conjunctivitis can be acute or chronic. The acute type can develop into a chronic condition. Signs and symptoms can vary from mild to severe. Chronic bacterial conjunctivitis is usually seen in patients with lacrimal duct obstruction, chronic dacryocystitis, and chronic blepharitis. The most common causative microorganisms are *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Staphylococcus aureus*.

Bacterial conjunctivitis manifests with an acute onset of redness, burning, and discharge. There is papillary formation, conjunctival irritation, and injection in the fornices. The exudates are variable but are usually present on waking in the morning. The eyes may be difficult to open because of adhesions caused by the exudate. Purulent discharge occurs in severe acute bacterial infections, whereas mucopurulent discharge appears in mild cases. In gonococcal conjunctivitis, the symptoms are more acute. The exudate is profuse and purulent, and there is lymphadenopathy. Pseudomembranes may be present.

Chlamydial conjunctivitis includes **trachoma** (a bilateral chronic follicular conjunctivitis of childhood that leads to blindness during adulthood if left untreated) and inclusion conjunctivitis. Trachoma is an ancient disease and is the leading cause of preventable blindness in the world. It is prevalent in areas with hot, dry, and dusty climates and in areas with poor living conditions. It is spread by direct contact or fomites, and the vectors can be insects such as flies and gnats. The onset of trachoma in children is usually insidious, but it can be acute or subacute in adults. The initial symptoms include red inflamed eyes, tearing, photophobia, ocular pain, purulent exudates, preauricular lymphadenopathy, and lid edema. Initial ocular signs include follicular and papillary formations. At the middle stage of the disease, there is an acute inflammation with papillary hypertrophy and follicular necrosis, after which trichiasis (turning inward of hair follicles) and entropion begin to develop. The lashes that are turned in rub against the cornea and, after prolonged irritation, cause corneal erosion and ulceration. The late stage of the disease is characterized by scarred conjunctiva, subepithelial keratitis, abnormal vascularization of the cornea (pannus), and residual scars from the follicles that look like depressions in the conjunctiva (Herbert's

pits). Severe corneal ulceration can lead to perforation and blindness.

Inclusion conjunctivitis affects sexually active people who have genital chlamydial infection. Transmission is by oral-genital sex or hand-to-eye transmission. Indirect transmission can occur in inadequately chlorinated swimming pools. The eye lesions usually appear a week after exposure and may be associated with a nonspecific urethritis or cervicitis. The discharge is mucopurulent, follicles are present, and there is lymphadenopathy.

Viral Conjunctivitis

Viral conjunctivitis can be acute and chronic. The discharge is watery, and follicles are prominent. Severe cases include pseudomembranes. The common causative organisms are adenovirus and herpes simplex virus. Conjunctivitis caused by adenovirus is highly contagious. The condition is usually preceded by symptoms of upper respiratory infection. Corneal involvement causes extreme photophobia. Symptoms include extreme tearing, redness, and foreign body sensation that can involve one or both eyes. There is lid edema, ptosis, and conjunctival **hyperemia** (dilation of the conjunctival blood vessels) (Fig. 58-18). These signs and symptoms vary from mild to severe and may last for 2 weeks. Viral conjunctivitis, although self-limited, tends to last longer than bacterial conjunctivitis.

Epidemic keratoconjunctivitis (EKC) is a highly contagious viral conjunctivitis that is easily transmitted from one person to another among household members, schoolchildren, and health care workers. The outbreak of epidemics is seasonal, especially during the summer when people use swimming pools. EKC is most often accompanied by preauricular lymphadenopathy and occasionally periorbital pain. There are marked follicular and papillary formations. This type of conjunctivitis can lead to keratopathy.

Allergic Conjunctivitis

Immunologic or allergic conjunctivitis is a hypersensitivity reaction that occurs as part of allergic rhinitis (hay fever), or it can be an independent allergic reaction. The patient usually has a history of an allergy to pollens and other environmental allergens. There is extreme pruritus, epiphora (ie, excessive secretion of tears), injection, and usually severe

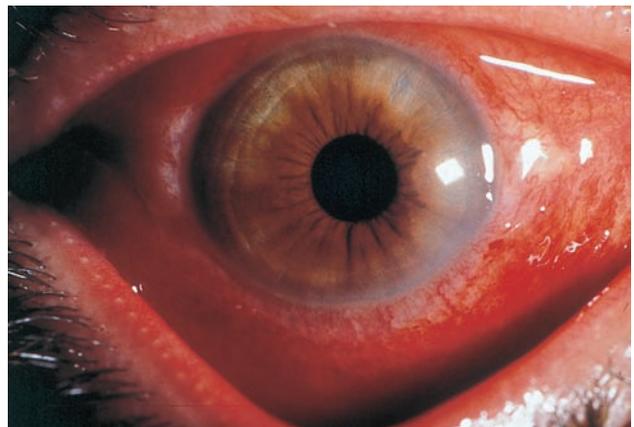

Figure 58-18 Conjunctival hyperemia in viral conjunctivitis.

CHART
58-12

PATIENT EDUCATION

Instructions for Patients With Viral Conjunctivitis

Viral conjunctivitis is a highly contagious eye infection. It can easily spread from one person to another. The symptoms can be alarming, but they are not serious. The following information will help you understand this eye condition and how to take care of yourself and/or your family member at home.

- Your eyes will look red and will have watery discharge, and your lids will be swollen for about a week.
- You will experience eye pain, a sandy sensation in your eye, and sensitivity to light.
- Symptoms will resolve after about 1 week.
- You may use light cold compresses over your eyes for about 10 minutes four to five times a day to soothe the pain.
- You may use artificial tears for the sandy sensation in your eye and mild pain medications such as acetaminophen (Tylenol).
- You need to stay at home. Children must not play outside. You may return to work or school after 7 days when the

redness and discharge have cleared. You may obtain a doctor's note to return to work or school.

- Do not share towels, linens, makeup, or toys.
- Wash your hands thoroughly with soap and water frequently, including and before and after you apply artificial tears or cold compresses.
- Use a new tissue every time you wipe the discharge from your eye. You may dampen the tissue with clean water to clean the outside of the eye.
- You may wash your face and take a shower as you normally do.
- Discard all of your makeup articles. You must not apply makeup until the infection has resolved.
- Wear dark glasses if bright lights bother you.
- If the discharge from your eye turns yellowish and puslike or you experience changes in your vision, you need to return to the health care provider for an examination.

photophobia. The stringlike mucoid discharge is usually associated with rubbing the eyes because of severe pruritus. Vernal conjunctivitis is also known as seasonal conjunctivitis because it appears mostly during warm weather. There may be large formations of papillae that have a cobblestone appearance. It is more common in children and young adults. Most affected people have a history of asthma or eczema.

Toxic Conjunctivitis

Chemical conjunctivitis can be the result of medications; chlorine from swimming pools; exposure to toxic fumes among industrial workers; or exposure to other irritants such as smoke, hair sprays, acids, and alkalis.

Management

The management of conjunctivitis depends on the type. Most types of mild and viral conjunctivitis are self-limiting, benign conditions that may not require treatment and laboratory procedures. For more severe cases, topical antibiotics, eye drops, or ointments are prescribed. Patients with gonococcal conjunctivitis require urgent antibiotic therapy. If left untreated, this ocular disease can lead to corneal perforation and blindness. The systemic complications can include meningitis and generalized septicemia.

Bacterial Conjunctivitis

Acute bacterial conjunctivitis is almost always self-limiting, lasting 2 weeks if left untreated. If treated with antibiotics, it may last a few days, except for gonococcal and staphylococcal conjunctivitis.

For trachoma, usually broad-spectrum antibiotics are administered topically and systemically. Surgical management includes the correction of trichiasis (eyelashes growing inward toward the conjunctiva and cornea) to prevent conjunctival scarring.

Adult inclusion conjunctivitis requires 1 week of antibiotics. Prevention of reinfection is important, and affected people and their sexual partners must seek treatment for sexually transmitted disease, if indicated.

Viral Conjunctivitis

Viral conjunctivitis is not responsive to any treatment. Cold compresses may alleviate some symptoms. It is extremely important to remember that viral conjunctivitis, especially epidemic keratoconjunctivitis, is highly contagious. Patients must be made aware of the contagious nature of the disease, and adequate instructions must be given (Chart 58-12). These instructions should include an emphasis on hand hygiene and avoiding sharing of hand towels, face cloths, and eye drops. Tissues should be directly discarded into a covered trash can.

Proper steps must be taken to avoid nosocomial infections. Frequent hand hygiene and procedures for environmental cleaning and disinfection of equipment used for eye examination must be strictly followed at all times. To prevent spread during outbreaks of conjunctivitis caused by adenovirus, health care facilities must set aside specified areas for treating patients with or suspected of having conjunctivitis caused by adenovirus to prevent spread. All forms of tonometry must be avoided unless medically indicated. All multidose ophthalmic medications must be discarded at the end of each day or when contaminated. Infected employees and others must not be allowed to work or attend school until symptoms have resolved, which can take 3 to 7 days.

Allergic Conjunctivitis

Patients with allergic conjunctivitis, especially recurrent vernal or seasonal conjunctivitis, are usually given corticosteroids in ophthalmic preparations. Depending on the severity of the disease, they may be given oral preparations. Use of vasoconstrictors, such as topical epinephrine solution, cold compresses, ice packs, and cool ventilation usually provide comfort by decreasing swelling.

Toxic Conjunctivitis

For conjunctivitis caused by chemical irritants, the eye must be irrigated immediately and profusely with saline or sterile water.

Uveitis

Inflammation of the uveal tract (uveitis) can affect the iris, the ciliary body, or the choroid. There are two types of uveitis: nongranulomatous and granulomatous.

The more common type of uveitis is the nongranulomatous type, which manifests as an acute condition with pain, photophobia, and a pattern of conjunctival injection, especially around the cornea. The pupil is small or irregular, and vision is blurred. There may be small, fine precipitates on the posterior corneal surface and cells in the aqueous humor (ie, cell and flare). If the uveitis is severe, a **hypopyon** (accumulation of pus in the anterior chamber) may develop. The condition may be unilateral or bilateral and may be recurrent. Repeated attacks of nongranulomatous anterior uveitis can cause anterior synechiae (peripheral iris adheres to the cornea and impedes outflow of aqueous humor). Posterior synechiae (adherence of the iris and lens) block aqueous outflow from the posterior chamber. Secondary glaucoma can result from either anterior or posterior synechiae. Cataracts may also occur as a sequela to uveitis.

Granulomatous uveitis can have a more insidious onset and can involve any portion of the uveal tract. It tends to be chronic. Symptoms such as photophobia and pain may be minimal. Vision is markedly and adversely affected. Conjunctival injection is diffuse, and there may be vitreous clouding. In a severe posterior uveitis, such as chorioretinitis, there may be retinal and choroidal hemorrhages.

Management

Because photophobia is a common symptom, patients should wear dark glasses outdoors. Ciliary spasm and synechia are best avoided through mydriasis; cyclopentolate (Cyclogyl) and atropine are commonly used. Local corticosteroid drops, such as Pred Forte 1% and Flarex 0.1%, instilled four to six times a day are also used to decrease inflammation. In very severe cases, systemic corticosteroids, as well as intravitreal corticosteroids, may be used. Daclizumab (Zenapax), a monoclonal antibody, is designed to prevent a specific chemical interaction needed by immune cells, such as lymphocytes, to produce inflammation. The National Eye Institute of the National Institutes of Health has conducted a preliminary clinical trial to examine the safety and effectiveness of treating uveitis with daclizumab with positive results. Larger-scale trials are planned (Yeh, Wroblewski, Buggage, et al., 2008).

If the uveitis is recurrent, a careful history should be initiated to discover any underlying causes. This evaluation should include a complete history, physical examination, and diagnostic tests, including a complete blood cell count, erythrocyte sedimentation rate, antinuclear antibodies, and Venereal Disease Research Laboratory (VDRL) and Lyme disease titers. Underlying causes include autoimmune disorders such as ankylosing spondylitis and sarcoidosis as well as toxoplasmosis, herpes zoster virus, ocular candidiasis, histoplasmosis, herpes simplex virus, tuberculosis, and syphilis.

Orbital Cellulitis

Orbital cellulitis is inflammation of the tissues surrounding the eye and may result from bacterial, fungal, or viral inflammatory conditions of contiguous structures, such as the face, oropharynx, dental structures, or intracranial structures. It can also result from foreign bodies and from a pre-existing ocular infection, such as dacryocystitis and panophthalmitis, or from generalized septicemia. Infection of the sinuses is the most frequent cause. Infection originating in the sinuses can spread easily to the orbit through the thin bony walls and foramina or by means of the interconnecting venous system of the orbit and sinuses. The most common causative organisms are staphylococci and streptococci in adults and *H. influenzae* in children. The symptoms include pain, lid swelling, conjunctival edema, proptosis, and decreased ocular motility. With such edema, optic nerve compression can occur and IOP may increase.

The severe intraorbital tension caused by abscess formation and the impairment of optic nerve function in orbital cellulitis can result in permanent visual loss. Because of the orbit's proximity to the brain, orbital cellulitis can lead to life-threatening complications, such as intracranial abscess and cavernous sinus thrombosis.

Management

Immediate administration of high-dose, broad-spectrum, systemic antibiotics is indicated. Cultures and Gram-stained smears are obtained. Monitoring changes in visual acuity, degree of proptosis, central nervous system function (eg, nausea, vomiting, fever, cognitive changes), displacement of the globe, extraocular movements, pupillary signs, and the fundus is extremely important. Consultation with an otolaryngologist is necessary, especially when rhinosinusitis is suspected. In the event of abscess formation or progressive loss of vision, surgical drainage of the abscess or sinus is performed. Sinusotomy and antibiotic irrigation are also performed.

ORBITAL AND OCULAR TUMORS

Benign Tumors of the Orbit

Benign tumors can develop from infancy and grow rapidly or slowly and present in later life. Some benign tumors are superficial and are easily identifiable by external presentation, palpation, and x-rays, but some are deep and may require a CT scan for a more thorough and precise diagnosis. There can be a significant proptosis, and visual function may be jeopardized. Benign tumors are masses characterized by the lack of infiltration in the surrounding tissues. Examples are cystic dermoid cysts and mucocele, hemangiomas, lymphangiomas, lacrimal tumors, and neurofibromas.

To prevent recurrence, benign masses are excised completely when possible. Sometimes, excision is difficult because of the involvement of some portions of the orbital bones, such as deep dermoid cysts, in which dissection of the bone is required. Subtotal resection may be indicated in deep benign tumors that intertwine with other orbital structures,

such as optic nerve meningiomas. Complete removal of the tumor may endanger visual function.

Benign Tumors of the Eyelids

Benign tumors include a wide variety of neoplasms and increase in frequency with age. Nevi may be unpigmented at birth and may enlarge and darken in adolescence or may never acquire any pigment at all. Hemangiomas are vascular capillary tumors that may be bright, superficial, strawberry-red lesions (ie, strawberry nevus) or bluish and purplish deeper lesions. Milia are small, white, slightly elevated cysts of the eyelid that may occur in multiples. Xanthelasma are yellowish, lipid deposits on both lids near the inner angle of the eye that commonly appear as a result of the aging of the skin or a lipid disorder. Molluscum contagiosum lesions are flat, symmetric growths along the lid margin caused by a virus that can result in conjunctivitis and keratitis if debris gets into the conjunctival sac.

Treatment of benign congenital lid lesions is rarely indicated, except when visual function is affected. Corticosteroid injection to the hemangioma lesion is usually effective, but surgical excision may be performed. Benign lid lesions usually present aesthetic problems rather than visual function problems. Surgical excision, or electrocautery, is primarily performed for cosmetic reasons, except for cases of molluscum contagiosum, for which surgical intervention is performed to prevent an infectious process that may ensue.

Benign Tumors of the Conjunctiva

Conjunctival nevus, a congenital, benign neoplasm, is a flat, slightly elevated, brown spot that becomes pigmented during late childhood or adolescence. This should be differentiated from the pigmented lesion melanosis acquired at middle age, which tends to wax and wane and become malignant melanoma. Keratin- and sebum-containing dermoid cysts are congenital and can be found in the conjunctiva. Dermolipoma is a congenital tumor that manifests as a smooth, rounded growth in the conjunctiva near the lateral canthus. Papillomas are usually soft with irregular surfaces and appear on the lid margins. Treatment consists of surgical excision.

Malignant Tumors of the Orbit

Rhabdomyosarcoma is the most common malignant primary orbital tumor in childhood, but it can also develop in elderly people. The symptoms of rhabdomyosarcoma include sudden painless proptosis of one eye followed by lid swelling, conjunctival chemosis, and impairment of ocular motility. Imaging of these tumors establishes the size, configuration, location, and stage of the disease; delineates the degree of bone destruction; and is useful in estimating the field for radiation therapy, if needed. The most common site of metastasis is the lung.

Management of these primary malignant orbital tumors involves three major therapeutic modalities: surgery, radiation therapy, and adjuvant chemotherapy. The degree of

orbital destruction is important in planning the surgical approach. Resection often involves removal of the eyeball. The psychological needs of the patient and family are paramount in planning the management approach.

Malignant Tumors of the Eyelid

Basal cell carcinoma is the most common malignant tumor of the eyelid. Squamous cell carcinoma occurs less frequently but is considered the second most common malignant tumor. Malignant melanoma is rare. Malignant eyelid tumors occur more frequently among people with a fair complexion who have a history of chronic exposure to the sun.

Basal cell carcinoma appears as a painless nodule that may ulcerate. The lesion is invasive, spreads to the surrounding tissues, and grows slowly but does not metastasize. It usually appears on the lower lid margin near the inner canthus with a pearly white margin. Squamous cell carcinoma of the eyelids may resemble basal cell carcinoma initially because it also grows slowly and painlessly. It tends to ulcerate and invade the surrounding tissues, but it can metastasize to the regional lymph nodes. Malignant melanoma may not be pigmented and can arise from nevi. It spreads to the surrounding tissues and metastasizes to other organs.

Complete excision of these carcinomas is followed by reconstruction with skin grafting if the surgical excision is extensive. The ocular postoperative site and the graft donor site are monitored for bleeding. Donor graft sites may include the buccal mucosa, the thigh, or the abdomen. The patient is referred to an oncologist for evaluation of the need for radiation therapy and monitoring for metastasis. Early diagnosis and surgical management are the basis of a good prognosis. These conditions have life-threatening consequences, and surgical excisions may result in facial disfigurement. Emotional support is an extremely important aspect of nursing management.

Malignant Tumors of the Conjunctiva

Conjunctival carcinoma most often grows in the exposed areas of the conjunctiva. The typical lesions are usually gelatinous and whitish due to keratin formation. They grow gradually, and deep invasion and metastasis are rare. Malignant melanoma is rare but may arise from a preexisting nevus or acquired melanosis during middle age. Squamous cell carcinoma is also rare but invasive.

The management is surgical incision. Some benign tumors and most malignant tumors recur. To avoid recurrences, patients usually undergo radiation therapy and cryotherapy after the excision of malignant tumors. Cosmetic disfigurement may result from extensive excision when deep invasion by the malignant tumor is involved.

Malignant Tumors of the Globe

Retinoblastoma, a malignant tumor of the retina, occurs in childhood and is hereditary, found in 1 of 15,000 live births. It is hereditary in 30% to 40% of cases. All bilateral

cases are hereditary. The retinoblastoma gene is found on chromosome 13, region q14. If this gene is inhibited, the growth in retinal cells is unchecked and the retinoblastoma results. Signs and symptoms include an initial leukocoria or “white” pupil with a peculiar light reflection and possible strabismus as well. Less frequent signs are uveitis, glaucoma, hyphema, nystagmus, and periorbital cellulitis. Treatment for this life-threatening tumor is enucleation, if the tumor is large and unilateral. If the eye is removed before cancer spreads to the optic nerve, the cure rate is greater than 90%.

Ocular melanoma, another cancer, primarily occurs in adults. This rare, malignant choroidal tumor is often discovered on a retinal examination. In its early stages, it could be mistaken for a nevus. Many ophthalmologists may practice for decades and never encounter this lesion. For this reason, any patient who is suspected of having ocular melanoma should be immediately referred to an ocular oncologist with experience in this disease.

Although many patients do not have symptoms in the early stages, some patients complain of blurred vision or a change in eye color. A number of such tumors have been found in people with blindness who have painful eyes. In addition to a complete physical examination to discover any evidence of metastasis (to the liver, lung, and breast), retinal fundus photography, fluorescein angiography, and ultrasonography are performed. The diagnosis is confirmed at biopsy after enucleation.

Tumors are classified according to boundary lines (apical height and basal diameter) as small, medium, or large. Small tumors are generally monitored, whereas medium and large tumors require treatment. Treatment consists of radiation, enucleation, or both. Radiation therapy may be achieved by external beam performed in repeated episodes over several days or through the implantation of a small plaque that contains radioactive iodine (I-125) pellets over the tumor.

SURGICAL PROCEDURES AND ENUCLEATION

Orbital Surgeries

Orbital surgeries may be performed to repair fractures, remove a foreign body, or remove benign or malignant growths. Surgical procedures involving the orbit and lids affect facial appearance (cosmesis). The goals are to recover and preserve visual function and to maintain the anatomic relationship of the ocular structures to achieve cosmesis. During the repair of orbital fractures, the orbital bones are realigned to follow the anatomic positions of facial structures.

Orbital surgical procedures involve working around delicate structures of the eye, such as the optic nerve, retinal blood vessels, and ocular muscles. Complications of orbital surgical procedures may include blindness as a result of damage to the optic nerve and its blood supply. Sudden pain and loss of vision may indicate intraorbital hemorrhage or compression of the optic nerve. Ptosis and diplopia may result from trauma to the extraocular muscles during the surgical

procedure, but these conditions typically resolve after a few weeks.

Prophylaxis with IV antibiotics is the usual postoperative regimen after orbital surgery, especially with repair of orbital fractures and intraorbital foreign body removal. IV corticosteroids are used if there is a concern about optic nerve swelling. Topical ocular antibiotics are typically instilled, and antibiotic ointments are applied externally to the skin suture sites.

For the first 24 to 48 hours postoperatively, ice compresses are applied over the periocular area to decrease peri-orbital swelling, facial swelling, and hematoma. The head of the patient's bed should be elevated to a comfortable position (30 to 45 degrees).

Discharge teaching should include medication instructions for oral antibiotics, instillation of ophthalmic medications, and application of ocular compresses.

Enucleation

Enucleation is the removal of the entire eye and part of the optic nerve. It may be performed for the following conditions:

- Severe injury resulting in prolapse of uveal tissue or loss of light projection (the ability to identify the direction of the light source) or perception
- An irritated, blind, painful, deformed, or disfigured eye, usually caused by glaucoma, retinal detachment, or chronic inflammation
- An eye without useful vision that is producing or has produced sympathetic ophthalmia in the other eye
- Intraocular tumors that are untreatable by other means

The procedure for enucleation involves the separation and cutting of each of the ocular muscles, dissection of the Tenon's capsule (fibrous membrane covering the sclera), and cutting of the optic nerve from the eyeball. The insertion of an orbital implant typically follows, and the conjunctiva is closed. A large pressure dressing is applied over the area.

Evisceration involves the surgical removal of the intraocular contents through an incision or opening in the cornea or sclera. Evisceration may be performed to treat severe ocular trauma with ruptured globe, severe ocular inflammation, or severe ocular infection. The optic nerve, sclera, extraocular muscles, and sometimes the cornea are left intact. The main advantage of evisceration over enucleation is that the final cosmetic result and motility after fitting the ocular prosthesis are enhanced. This procedure would be more acceptable to a patient whose body image is severely threatened. The main disadvantage is the high risk of sympathetic ophthalmia.

Exenteration is the removal of the eyelids, the eye, and various amounts of orbital contents. It is indicated in malignancies in the orbit that are life-threatening or when more conservative modalities of treatment have failed or are inappropriate. An example is squamous cell carcinoma of the paranasal sinuses, skin, and conjunctiva with deep orbital involvement. In its most extensive form, exenteration may include the removal of all orbital tissues and resection of the orbital bones.

Ocular Prostheses

Orbital implants and conformers (ocular prostheses usually made of silicone rubber) maintain the shape of the eye after enucleation or evisceration to prevent a contracted, sunken appearance. The temporary conformer is placed over the conjunctival closure after the implantation of an orbital implant. A conformer is placed after the enucleation or evisceration procedure to protect the suture line, maintain the fornices, prevent contracture of the socket in preparation for the ocular prosthesis, and promote the integrity of the eyelids.

All ocular prosthetics have limitations in their motility. There are two designs of eye prostheses. The anophthalmic ocular prostheses are used in the absence of the globe. Scleral shells look just like the anophthalmic prosthesis (Fig. 58-19) but are thinner and fit over a globe with intact corneal sensation. An eye prosthesis usually lasts about 6 years, depending on the quality of fit, comfort, and cosmetic appearance. When the anophthalmic socket is completely healed, conformers are replaced with prosthetic eyes.

An ocularist is a specially trained and skilled professional who makes prosthetic eyes. After the ophthalmologist is satisfied that the anophthalmic socket is completely healed and is ready for prosthetic fitting, the patient is referred to an ocularist. The healing period is usually 6 to 8 weeks. It is advisable for the patient to have a consultation with the ocularist before the fitting. Obtaining accurate information and verbalizing concerns can lessen anxiety about wearing an ocular prosthesis.

Medical Management

Removal of an eye has physical, social, and psychological ramifications for any person. The significance of loss of the eye and vision must be addressed in the plan of care. The patient's preparation should include information about the surgical procedure and placement of orbital implants and conformers and the availability of ocular prosthetics to enhance cosmetic appearance. In some cases, patients may choose to see an ocularist before the surgery to discuss ocular prosthetics.

Nursing Management

Teaching About Postsurgical and Prosthetic Care

Patients who undergo eye removal need to know that they will usually have a large ocular pressure dressing, which is

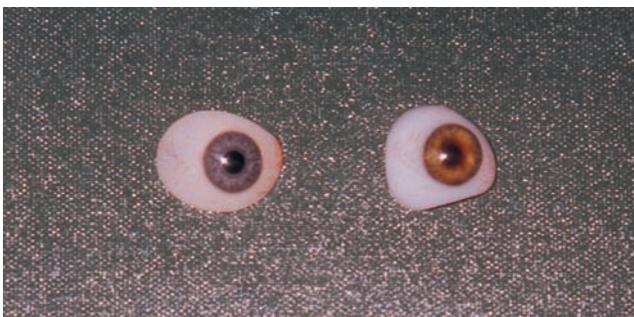

Figure 58-19 Eye prostheses. (Left) Anophthalmic ocular prosthesis. (Right) Scleral shell.

typically removed after a week, and that an ophthalmic topical antibiotic ointment is applied in the socket three times daily.

After the removal of an eye, there is a loss of depth perception. Patients must be advised to take extra caution in their ambulation and movement to avoid miscalculations that may result in injury. It may take some time to adjust to monocular vision.

The patient must be advised that conformers may accidentally fall out of the socket. If this happens, the conformer must be washed, wiped dry, and placed back in the socket.

When surgical eye removal is unexpected, such as in severe ocular trauma, leaving no time for the patient and family to prepare for the loss, the nurse's role in providing emotional support is crucial.

Promoting Home and Community-Based Care

Teaching Patients Self-Care

Patients need to be taught how to insert, remove, and care for the prosthetic eye. Proper hand hygiene must be observed before inserting and removing an ocular prosthesis. A suction cup may be used if there are problems with manual dexterity. Precautions, such as draping a towel over the sink and closing the sink drain, must be taken to avoid loss of the prosthesis. When instructing patients or family members, a return demonstration is important to assess the level of understanding and ability to perform the procedure.

Before insertion, the inner punctal or outer lateral aspects and the superior and inferior aspects of the prosthesis must be identified by locating the identifying marks, such as a reddish color in the inner punctal area. For people with low vision, other forms of identifying markers, such as dots or notches, are used. The upper lid is raised high enough to create a space; then the patient learns to slide the prosthesis up, underneath, and behind the upper eyelid. Meanwhile, the patient pulls the lower eyelid down to help put the prosthesis in place and to have its inferior edge fall back gradually to the lower eyelid. The lower eyelid is checked for correct positioning.

To remove the prosthesis, the patient cups one hand on the cheek to catch the prosthesis, places the forefinger of the free hand against the midportion of the lower eyelid, and gazes upward. Gazing upward brings the inferior edge of the prosthesis nearer the inferior eyelid margin. With the finger pushing inward, downward, and laterally against the lower eyelid, the prosthesis slides out into the cupped hand.

Continuing Care

An eye prosthesis can be worn and left in place for several months. Hygiene and comfort are usually maintained with daily irrigation of the prosthesis in place with normal saline solution, hard contact lens solution, or artificial tears. In the case of dry eye symptoms, the use of ophthalmic ointment lubricants or oil-based drops, such as vitamin E and mineral oil, can be helpful. Removing crusting and mucous discharge that accumulate overnight is performed with the prosthesis in place. Malpositions may occur when wiping or

rubbing the prosthesis in the socket. The prosthesis can be repositioned with the use of clean fingers. Proper wiping of the prosthesis should be a gentle temporal-to-nasal motion to avoid malpositions.

The prosthesis needs to be removed and cleaned when it becomes uncomfortable and when there is increased mucous discharge. The socket should also be rendered free of mucus and inspected for any signs of infection. Any unusual discomfort, irritation, or redness of the globe or eyelids may indicate excessive wear, debris under the shell, or lack of proper hygiene. Any infection or irritation that does not resolve needs medical attention.

OCULAR CONSEQUENCES OF SYSTEMIC DISEASE

Diabetic Retinopathy

Of all of the medical disorders that the nurse encounters, diabetes mellitus is one of the most common. One of the most serious complications of diabetes is retinopathy. In the United States today, diabetes is the leading cause of new cases of blindness in people between 20 and 74 years of age (Prevent Blindness America, 2008). Before the discovery of insulin in the 1920s, diabetic retinopathy was relatively rare because most people with diabetes did not survive for more than 1 or 2 years. However, with the many advancements in the treatment of diabetes, more and more patients are able to survive and enjoy relatively normal lifespans, but they are also confronted with the complications of long-term diabetes. With the rate of obesity in the United States rising, type 2 diabetes has become epidemic, and the incidence of diabetic retinopathy may be expected to increase. Chapter 41 provides a detailed discussion of diabetic retinopathy.

Cytomegalovirus Retinitis

Many ophthalmic complications have been associated with AIDS. Cytomegalovirus (CMV) is the most common cause of retinal inflammation in patients with AIDS. Early symptoms of CMV retinitis vary from patient to patient. Some patients complain of floaters or a decrease in peripheral vision. Some have a paracentral or central scotoma, whereas others have fluctuations in vision from macular edema. The retina often becomes thin and atrophic and susceptible to retinal tears and breaks.

CMV retinitis generally takes one of three forms: hemorrhagic, brushfire, or granular. In the hemorrhagic type, large areas of white, necrotic retina may be associated with retinal hemorrhage. In the brushfire type, a yellow-white margin begins at the edge of burned-out atrophic retina. This retinitis expands and, if untreated, involves the entire retina. In the granular type, white granular lesions in the periphery of the retina gradually expand. The white, feathery infiltration of the retina destroys sensory retina and leads to necrosis, optic atrophy, and retinal detachment.

Medical Management

Pharmacologic Therapy

Pharmacologic agents available for treatment of CMV retinitis include ganciclovir (Cytovene), foscarnet (Foscavir), and cidofovir (Vistide).

Ganciclovir is administered intravenously, orally, or intravitreally in the acute stage of CMV retinitis. The intravitreal form is available as a 4-mm intraocular implant or insert containing the medication embedded in a polymer-based system that slowly releases the medication. The insert is surgically placed in the posterior segment of the eye, and the medication diffuses locally to the site of the infection over a period of 5 to 8 months before the insert must be replaced. When administered systemically, ganciclovir is a very potent medication; it can cause neutropenia, thrombocytopenia, anemia, and elevated serum creatinine levels. The surgically implanted sustained-release insert enables higher concentrations of ganciclovir to reach the CMV retinitis, but there are risks and complications associated with the inserts, including endophthalmitis, retinal detachment, and hypotony.

Foscarnet inhibits viral DNA replication. It may be the medication of choice when ganciclovir is ineffective. It may be administered by IV or intravitreal injections. The combination of foscarnet and ganciclovir has been more effective than either medication alone. Nephrotoxicity may occur with systemic foscarnet, and renal function must be monitored carefully.

Cidofovir impedes CMV replication and is administered by IV. Cidofovir has been shown to delay the progression of CMV retinitis significantly. Nephrotoxicity, proteinuria, and increased serum creatinine levels are significant side effects.

In the late 1990s, the routine management of patients with AIDS, including those with CMV retinitis, changed with the introduction of highly active antiretroviral therapy (HAART). HAART is a combination of two or three medications of different categories. For example, a nucleoside analogue such as zidovudine (Retrovir) administered in combination with one or more protease inhibitors such as ritonavir (Norvir) has led to a suppression of human immunodeficiency virus (HIV) replication for sustained periods. The immune system can then recover to a functional level. Several patients who had been treated for CMV retinitis have been able to discontinue treatment for CMV retinitis as their immune systems rebounded. However, some patients develop immune recovery uveitis, characterized by intraocular inflammation, cystoid macular edema, and the formation of epiretinal membranes. Immune recovery uveitis is managed by corticosteroids or by injection of corticosteroids into the sub-Tenon's area of the eye.

Hypertension-Related Eye Changes

Hypertension can shorten the lifespan by as many as 20 years and affects the eye as well as the heart, brain, and kidneys. Long-standing hypertension goes hand in hand

with atherosclerosis, and the associated retinal changes are evidenced by the development of retinal arteriolar changes, such as tortuosity, narrowing, and a change in light reflex. Funduscopic examination reveals a copper or silver coloration of the arterioles and venous compression (arteriovenous nicking) at the arteriolar and venous crossings. Intraretinal hemorrhages from hypertension appear flame-shaped because they occur in the nerve fiber layer of the retina.

Hypertension can also occur as an acute consequence of conditions such as pheochromocytoma, acute renal failure, and pregnancy-induced hypertension. The retinopathy associated with these crisis states is extensive, and the manifestations include cotton-wool spots, retinal hemorrhages, retinal edema, and retinal exudates, often clustered around the macula.

The choroid is also affected by the profound and abrupt rise in blood pressure and resulting vasoconstriction, and ischemia may result in serous retinal detachments and infarction of the RPE. Ischemic optic neuropathy and **papilledema** (swelling of the optic disc due to increased IOP) may also result. Blood pressure in these more severe stages should be lowered in a controlled gradual fashion to avoid ischemia of the optic nerve and brain secondary to a too-rapid fall in blood pressure. For further information about hypertension, see Chapter 32.

CONCEPTS IN OCULAR MEDICATION ADMINISTRATION

The main objective of ocular medication delivery is to maximize the amount of medication that reaches the ocular site of action in sufficient concentration to produce a beneficial therapeutic effect. This is determined by the dynamics of ocular pharmacokinetics: absorption, distribution, metabolism, and excretion.

Topical administration of ocular medications results in only a 1% to 7% absorption rate by the ocular tissues. Ocular absorption involves the entry of a medication into the aqueous humor through the different routes of ocular medication administration. The rate and extent of aqueous humor absorption are determined by the characteristics of the medication and the anatomy and physiology of the eye. Natural barriers of absorption that diminish the efficacy of ocular medications include the following:

- *Limited size of the conjunctival sac.* The conjunctival sac can hold only 50 μL , and any excess is wasted. The volume of one eye drop from commercial topical ocular solutions typically ranges from 20 to 35 μL .
- *Corneal membrane barriers.* The epithelial, stromal, and endothelial layers are barriers to absorption.
- *Blood–ocular barriers.* Blood–ocular barriers prevent high ocular tissue concentration of most ophthalmic medications because they separate the bloodstream from the ocular tissues and keep foreign substances from entering the eye, thereby limiting a medication's efficacy.
- *Tearing, blinking, and drainage.* Increased tear production and drainage due to ocular irritation or an ocular

condition may dilute or wash out an instilled eye drop; blinking expels an instilled eye drop from the conjunctival sac.

Distribution of an ocular medication into the various ocular tissues varies by tissue type; the various tissues (eg, conjunctiva, cornea, lens, iris, ciliary body, choroids) absorb medications to varying degrees. Medications penetrate the corneal epithelium by diffusion by passing through the cells (intracellular) or by passing between the cells (intercellular). Water-soluble (hydrophilic) medications diffuse through the intracellular route, and fat-soluble (lipophilic) medications diffuse through the intercellular route. Topical administration usually does not reach the retina in significant concentrations. Because the space between the ciliary process and the lens is small, medication diffusion in the vitreous is slow. When high concentrations of medication in the vitreous are required, intraocular injection is often chosen to bypass the natural ocular anatomic and physiologic barriers.

Aqueous solutions are most commonly used for the eye. They are the least expensive medications and interfere least with vision. However, corneal contact time is brief because tears dilute the medication. Ophthalmic ointments have extended retention time in the conjunctival sac and provide a higher concentration than eye drops. The major disadvantage of ointments is the blurred vision that results after application. In general, eyelids and eyelid margins are best treated with ointments. The conjunctiva, limbus, cornea, and anterior chamber are treated most effectively with instilled solutions or suspensions. Subconjunctival injection may be necessary for better absorption in the anterior chamber. If high medication concentrations are required in the posterior chamber, intravitreal injections or systemically absorbed medications are considered. Contact lenses and collagen shields soaked in antibiotics are alternative delivery methods for treating corneal infections.

Of all these delivery methods, the topical route of administration—instilled eye drops and applied ointments—remains the most common. Topical instillation, which is the least invasive method, permits self-administration of medication and produces fewer side effects.

Preservatives are commonly used in ocular medications. Benzalkonium chloride, for example, prevents the growth of organisms and enhances the corneal permeability of most medications; however, some patients are allergic to this preservative. This may be suspected even if the patient had never before experienced an allergic reaction to systemic use of the medication in question. Eye drops without preservatives can be prepared by pharmacists.

Commonly Used Ocular Medications

Common ocular medications include topical anesthetic, mydriatic, and cycloplegic agents that reduce IOP; anti-infective medications; corticosteroids; NSAIDs; antiallergy medications; eye irrigants; and lubricants.

Topical Anesthetics

One or two drops of proparacaine hydrochloride (Ophthaine 0.5%) and tetracaine hydrochloride (Pontocaine 0.5%) are

instilled before diagnostic procedures such as tonometry and gonioscopy and in minor ocular procedures such as removal of sutures or conjunctival or corneal scrapings. Topical anesthetics are also used for severe eye pain to allow the patient to open his or her eyes for examination or treatment (eg, eye irrigation for chemical burns). Anesthesia occurs within 20 seconds to 1 minute and lasts 10 to 20 minutes. The nurse must instruct the patient not to rub his or her eyes while anesthetized because this may result in corneal damage.

Most patients are not allowed to take topical anesthetics home because of the risk of overuse. Patients with corneal abrasions and erosions experience severe pain and are often tempted to overuse topical anesthetic eye drops. Overuse of these drops results in softening of the cornea. Prolonged use of anesthetic drops can delay wound healing and can lead to permanent corneal opacification and scarring, resulting in visual loss.

Mydriatics and Cycloplegics

Mydriasis, or pupil dilation, is the main objective of the administration of mydriatic and cycloplegic agents (Table 58-7). These two types of medications function differently and are used in combination to achieve the maximal dilation that is needed during surgery and fundus examinations to give the ophthalmologist a better view of the internal eye structures. Mydriatics potentiate alpha-adrenergic sympathetic effects that result in the relaxation of the ciliary muscle. This causes the pupil to dilate. However, this sympathetic action alone is not enough to sustain mydriasis because of its short duration of action. The strong light used during an eye examination also stimulates miosis (ie, pupillary contraction). Cycloplegic medications are administered to paralyze the iris sphincter.

The patient is instructed about the temporary effects of mydriasis on vision, such as glare and the inability to focus properly. The patient may have difficulty reading. The effects of the various mydriatics and cycloplegics can last 3 hours to several days. The patient is advised to wear sunglasses (most eye clinics provide protective sunglasses). The ability to drive is dependent on the person's age, vision, and comfort level. Some patients can drive safely with the use of sunglasses, whereas others may need to be driven home.

Mydriatic and cycloplegic agents affect the central nervous system. Their effects are most prominent in children and elderly patients; these patients must be assessed closely for symptoms, such as increased blood pressure, tachycardia, dizziness, ataxia, confusion, disorientation, incoherent speech, and hallucination. These medications are contraindicated in patients with narrow angles or shallow anterior chambers and in patients taking monoamine oxidase inhibitors or tricyclic antidepressants.

Medications Used to Treat Glaucoma

Therapeutic medications for glaucoma are used to lower IOP by decreasing aqueous production or increasing aqueous outflow. Because glaucoma calls for lifetime therapy, the patient must be instructed regarding both the ocular and systemic side effects of the medications.

Most antiglaucoma medications affect the accommodation of the lens and limit light entry through a constricted pupil. Visual acuity and the ability to focus may be affected. Some drops (eg, prostaglandin analogues) may cause iris color change as well as eyelash hypertrichosis (excessive growth of hair). Factors to consider in selecting glaucoma medications are efficacy, systemic and ocular side effects, convenience, and cost.

Medication	Available Preparation/ Concentration	Indication/Dosage	Peak		Recovery Time	
			Mydriasis	Cycloplegia	Mydriasis	Cycloplegia
phenylephrine (Neo-Synephrine)	Solutions (2.5%, 10%)	Administered with cycloplegics in pupillary dilation for ophthalmoscopy and surgical procedures every 5–10 min × 3 or until the pupils are fully dilated	10–60 min	—	3–6 h	—
atropine (Atropine Ophthalmic)	Ointment (0.5%–2%) Solutions (0.5%–3%)	In glaucoma, uveitis, or after surgery, 2× to 4× daily	30–40 min	60–180 min	7–10 d	6–12 d
scopolamine (Isopto Hyoscine Ophthalmic)	Solution (0.25%)	Same as atropine	20–30 min	30–60 min	3–7 d	3–7 d
homatropine (Homatropine HBR)	Solution (5%–2.5%)	Same as atropine and scopolamine	40–60 min	30–60 min	1–3 d	1–3 d
cyclopentolate (AK-Pentolate)	Solution (0.5%–2%)	Administered with mydriatics every 5–10 min × 3 or until the pupils are fully dilated for ophthalmoscopy and surgical procedures	30–60 min	25–75 min	1 d	6–24 h
tropicamide (Mydracil)	Solution (0.25%–1%)	Administered with mydriatics every 5–10 min × 3 or until the pupils are fully dilated for ophthalmoscopy and surgical procedures	20–40 min	20–35 min	6 h	<6 h

Anti-Infective Medications

Anti-infective medications include antibiotic, antifungal, and antiviral agents. Most are available as drops, ointments, or subconjunctival or intravitreal injections. Antibiotics include penicillin, cephalosporins, aminoglycosides, and fluoroquinolones. The main antifungal agent is amphotericin B. Side effects of amphotericin are serious and include severe pain, conjunctival necrosis, iritis, and retinal toxicity. Antiviral medications include acyclovir (Zovirax) and ganciclovir. They are used to treat ocular infections associated with herpesvirus and CMV. Patients receiving ocular anti-infective agents are subject to the same side effects and adverse reactions as those receiving oral or parenteral medications.

Corticosteroids and Nonsteroidal Anti-Inflammatory Drugs

The topical preparations of corticosteroids are commonly used in inflammatory conditions of the eyelids, conjunctiva, cornea, anterior chamber, lens, and uvea. In posterior segment diseases that involve the posterior sclera, retina, and optic nerve, the topical agents are less effective, and parenteral and oral routes are preferred. Because these topical eye drop preparations are suspensions, the patient is instructed to shake the bottle several times to promote mixture of the medication and maximize its therapeutic effect. The most common ocular side effects of long-term topical corticosteroid administration are glaucoma, cataracts, susceptibility to infection, impaired wound healing, mydriasis, and ptosis. High IOP may develop, which is reversible after corticosteroid use is discontinued. To avoid the side effects of corticosteroids, NSAIDs are used as an alternative in controlling inflammatory eye conditions and postoperatively to reduce inflammation. NSAID therapy in combination with topical and oral preparations is an important adjunct therapy in managing uveitis.

Antiallergy Medications

Ocular hypersensitivity reactions, such as allergic conjunctivitis, are extremely common. These conditions result primarily from responses to environmental allergens. Most allergens are airborne or carried to the eye by the hand or by other means, although allergic reactions may also be drug induced. Corticosteroids are commonly used as anti-inflammatory and immunosuppressive agents to control ocular hypersensitivity reactions.

Ocular Irrigants and Lubricants

Most irrigating solutions are used to cleanse the external lids to maintain lid hygiene, to irrigate the external corneal surface to regain normal pH (eg, in chemical burns), to irrigate the corneal surface to eliminate debris, or to inflate the globe intraoperatively. These solutions have various compositions that include sodium, potassium, magnesium, calcium, bicarbonate, glucose, and glutathione (ie, substance found in the aqueous humor). Sterile irrigating solutions, such as Dacriose, for lid hygiene are available. Irrigating solutions are safe to use with an intact corneal surface; however, the corneal surface should not be irrigated in cases of

threatened corneal perforation. For patients with severe corneal ulcer, specific orders must be obtained regarding whether it is safe to irrigate the corneal surface or just to cleanse the external lids. Although it is good practice to promote hygiene, prevention of complications must be the primary concern. Normal saline solutions are commonly used to irrigate the corneal surface when chemical burns occur.

Lubricants, such as artificial tears, help alleviate corneal irritation, such as dry eye syndrome. Artificial tears are topical preparations of methyl or hydroxypropyl cellulose that are prepared as eye drop solutions, ointments, or ocular inserts (inserted at the lower conjunctival cul-de-sac once each day). The eye drops can be instilled as often as every hour, depending on the severity of symptoms.

Nursing Management

The objectives in administering ocular medications are to ensure proper administration to maximize the therapeutic effects and to ensure the safety of the patient by monitoring for systemic and local side effects. Absorption of eye drops by the nasolacrimal duct is undesirable because of the potential systemic side effects of ocular medications. To diminish systemic absorption and minimize the side effects, it is important to occlude the puncta (Chart 58-13). This is especially important for patients who are most vulnerable to medication overdose, including elderly people, children, infants, women who are lactating or are pregnant, and patients with cardiac, pulmonary, hepatic, or renal disease. A 1-minute interval between instillation of different types of ocular drops is recommended.

Before the administration of ocular medications, the nurse warns the patient that blurred vision, stinging, and a burning sensation are symptoms that ordinarily occur after instillation and are temporary. Risk for interactions of the ocular medication with other ocular and systemic medications must be emphasized; therefore, a careful patient interview regarding the medications being taken must be obtained.

Emphasis must be placed on hand hygiene techniques before and after medication instillation. The tip of the eye drop bottle or the ointment tube must never touch any part of the eye. The medication must be recapped immediately after each use. If a patient who instills his or her own medications cannot feel the eye drops when they are instilled, the eye medication may be refrigerated, because a cold drop is easier to detect. A 5-minute interval between successive administrations allows adequate drug retention and absorption. The patient or the caregiver at home should be asked to demonstrate actual eye drop or ointment instillation and punctal occlusion.

ISSUES IN OPHTHALMOLOGY

The well-being of the patient physically, emotionally, financially, socially, and spiritually can be at risk when vision is threatened. Patients with a deteriorating eye condition often worry about the impact that visual loss will have on their lives. As they experience visual

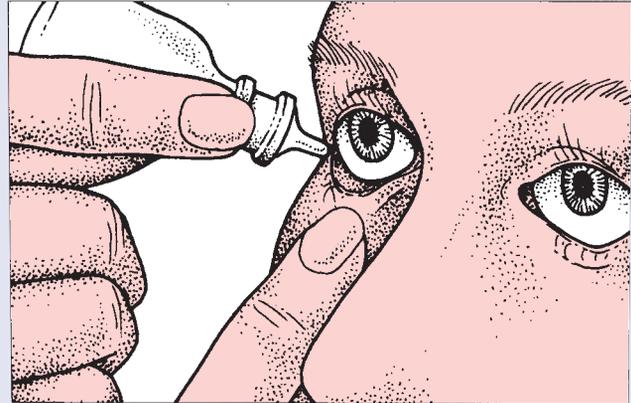

CHART
58-13

PATIENT EDUCATION

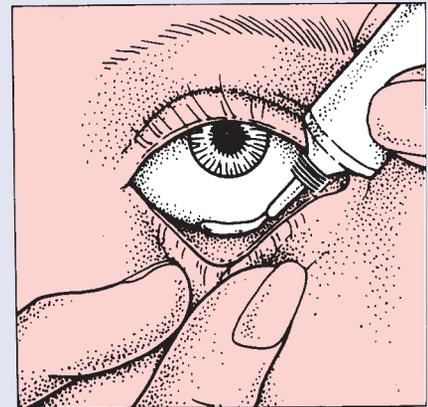

Instilling Eye Medications

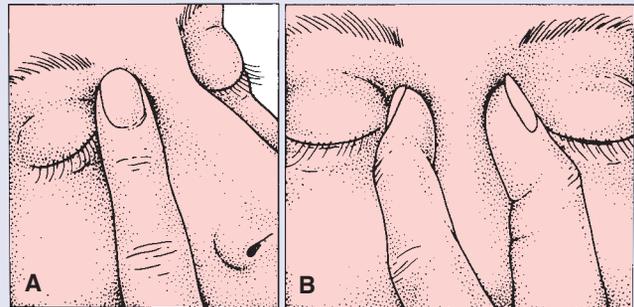

- Shake suspensions or “milky” solutions to obtain the desired medication level.
- Wash hands thoroughly before and after the procedure.
- Ensure adequate lighting.
- Read the label of the eye medication to make sure it is the correct medication.
- Assume a comfortable position.
- Do not touch the tip of the medication container to any part of the eye or face.
- Hold the lower lid down; do not press on the eyeball. Apply gentle pressure to the cheek bone to anchor the finger holding the lid.

- Instill eye drops before applying ointments.
- Apply a 1/2-inch ribbon of ointment to the lower conjunctival sac.

- Keep the eyelids closed, and apply gentle pressure on the inner canthus (punctal occlusion) near the bridge of the nose for 1 or 2 minutes immediately after instilling eyedrops.
- Using a clean tissue, gently pat skin to absorb excess eye-drops that run onto the cheeks.
- Wait 5 to 10 minutes before instilling another eye medication.

distortions, scotomas, or gradual visual loss, what was a vague worry can become a consuming preoccupation. The patient may equate a decrease in visual acuity with a loss of independence. The loss of a driver's license may force a patient to relocate or give up or change careers.

Vision Loss

Major goals should include the preservation of vision and the prevention of further visual loss in patients who have already experienced some degree of loss. Aging itself is a risk factor for many conditions such as cataracts, glaucoma,

and AMD, which may lead to visual loss. Therefore, people older than 50 years of age should have regular examinations by an eye care specialist to help detect problems at their earliest stages, when there may be more treatment options. Those with diabetes or other systemic conditions should also be proactive in obtaining regular ophthalmic care.

For patients with visual impairment, effective communication is essential to promote rehabilitation. The nurse together with the patient should establish goals. The nurse listens to the patient, tries to determine his or her level of health care need, and makes suggestions and recommendations.

Patient Safety

With the advent of the 2000 report from the Institute of Medicine on medical errors and the subsequent report of the Institute's Committee on Identifying and Preventing Medication Errors (Aspden, Wolcott, Bootman, et al., 2007), the nurse must be aware of patient safety practices unique to ophthalmology and must be an active participant in the development of a culture of safety. High-volume, efficient, fast-paced procedures characterize ophthalmic practice. This means that patient identification is critical. Active identification (asking the patient his or her name) and a second identifier (birth date, history, hospital number) must be verified before any procedure. As with other organs involving laterality, the correct eye must be verified before medication administration and surgery. Verification of the correct eye before surgery with the involvement of the patient or caregiver (for pediatric patients and adults with cognitive impairment) must be done before initiating any procedure or transferring the patient to another unit. Marking of the operative eye by the surgeon and a final verification of the correct eye by the surgeon, anesthesiologist, and nurse immediately before incision must be performed in all cases.

Cataract surgery with an IOL implant is one of the most frequently performed surgeries. Each facility must have a policy for multiple checks and verification of the IOL type, power, and diopter, as well as the operative eye. The surgeon, scrub nurse or technician, and circulating nurse should each verify the correct IOL measurements, the correct patient, and the patient's chart.

CRITICAL THINKING EXERCISES

1 An ophthalmic surgeon calls a meeting with the operating room (OR) nurse manager and you, the charge nurse of the OR where he performs surgeries. Five of 15 postoperative cataract patients in the past week have complained of blurred vision and eye pain 1 to 5 days postoperatively. The operative eye showed corneal edema and inflammation of the anterior chamber. The patients were placed on topical nonsteroidal anti-inflammatory agents and were showing some improvement. Is there a need to be alarmed? Identify the steps you plan to take to investigate what is causing the postoperative problems. What initial measures are you planning?

2 You are working in a medical unit of a community hospital. An 86-year-old woman, a cardiac patient who has previously been diagnosed with dry age-related macular degeneration, is worried about some changes in her vision that she has noticed. When checking her vision with her glasses on, you are relieved to find that her vision for distance seems satisfactory. However, the patient complains that when she reads the menu, some of the letters on some lines seem to be missing. In addition, she seems to have some visual distortion; she cannot tell the letter *D* from the letter *O*. The patient has a follow-up appointment scheduled with her ophthalmologist in 4 months. Should she be seen sooner? What additional tests do you think will be necessary? What could be the etiol-

ogy of her complaints? How can you make this patient's environment safer?

EBP 3 You are working the evening shift in the operating room and an environmental services' employee runs to you stating that he accidentally splashed his eyes with a cleaning solution. He is holding the bottle that has no label but still has some solution left in it. He has a lot of eye pain, and his vision is extremely blurred. What should you do immediately? What is the evidence base that supports the treatment of chemical burns to the eyes? What is the strength of this evidence? What critical information do you need to provide to the emergency physician? What environmental safety measures do you need to put in place?

Assessment and Management of Patients With Hearing and Balance Disorders

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

- 1 Describe methods used to assess hearing and to diagnose hearing and balance disorders.
- 2 List the manifestations that may be exhibited by a person with a hearing disorder.
- 3 Identify ways to communicate effectively with a person with a hearing disorder.
- 4 Differentiate problems of the external ear from those of the middle ear and inner ear.
- 5 Compare the various types of surgical procedures used for managing middle ear disorders and appropriate nursing care.
- 6 Describe the teaching topics that need to be addressed for patients undergoing middle ear and mastoid surgery.
- 7 Describe the different types of inner ear disorders, including the clinical manifestations, diagnosis, and management.

GLOSSARY

- acute otitis media:** inflammation in the middle ear lasting less than 6 weeks
- cholesteatoma:** tumor of the middle ear or mastoid, or both, that can destroy structures of the temporal bone
- chronic otitis media:** repeated episodes of acute otitis media causing irreversible tissue damage and persistent tympanic membrane perforation
- conductive hearing loss:** loss of hearing in which efficient sound transmission to the inner ear is interrupted by some obstruction or disease process
- deafness:** partial or complete loss of the ability to hear
- dizziness:** altered sensation of orientation in space
- endolymphatic hydrops:** dilation of the endolymphatic space of the inner ear; the pathologic correlate of Ménière's disease
- exostoses:** small, hard, bony protrusions in the lower posterior bony portion of the ear canal
- labyrinthitis:** inflammation of the labyrinth of the inner ear
- Ménière's disease:** condition of the inner ear characterized by a triad of symptoms: episodic vertigo, tinnitus, and fluctuating sensorineural hearing loss
- middle ear effusion:** fluid in the middle ear without evidence of infection
- myringotomy (ie, tympanotomy):** incision in the tympanic membrane
- nystagmus:** involuntary rhythmic eye movement
- ossiculoplasty:** surgical reconstruction of the middle ear bones to restore hearing
- otalgia:** sensation of fullness or pain in the ear
- otitis externa (ie, external otitis):** inflammation of the external auditory canal
- otorrhea:** drainage from the ear
- otosclerosis:** a condition characterized by abnormal spongy bone formation around the stapes
- presbycusis:** progressive hearing loss associated with aging
- rhinorrhea:** drainage from the nose
- sensorineural hearing loss:** loss of hearing related to damage of the end organ for hearing or cranial nerve VIII, or both
- tinnitus:** subjective perception of sound with internal origin; unwanted noises in the head or ear
- tympanoplasty:** surgical repair of the tympanic membrane
- vertigo:** illusion of movement in which the individual or the surroundings are sensed as moving

The ear is a sensory organ with dual functions—hearing and balance. The sense of hearing is essential for normal development and maintenance of speech as well as the ability to communicate with others. Balance, or equilibrium, is essential for maintaining body movement, position, and coordination.

The delicate structure and function of the ear make early detection and accurate diagnosis of disorders necessary for preservation of normal hearing and balance. The diagnosis and treatment of these disorders requires skilled health care professionals such as otolaryngologists, internists, and nurses. Nurses can become certified in the specialty of otolaryngology.

This chapter addresses the assessment and management of hearing and balance disorders common to adults. The pediatric otolaryngology literature provides information about otologic disorders that pertain to children.

ASSESSMENT OF THE EAR

Anatomic and Physiologic Overview

The cranium encloses and protects the brain and surrounding structures, providing attachment for various muscles that control head and jaw movements. Eight bones form the

cranium: the occipital bone, the frontal bone, two parietal bones, two temporal bones, the sphenoid bone, and the ethmoid bone. Some of these bones contain sinuses, which are cavities lined with mucous membranes and connected to the nasal cavity. The ears are located on either side of the cranium at approximately eye level.

Anatomy of the External Ear

The external ear includes the auricle (pinna) and the external auditory canal (Fig. 59-1). The external ear is separated from the middle ear by a disklike structure called the tympanic membrane (eardrum).

Auricle

The auricle, attached to the side of the head by skin, is composed mainly of cartilage, except for the fat and subcutaneous tissue in the earlobe. The auricle collects the sound waves and directs vibrations into the external auditory canal.

External Auditory Canal

The external auditory canal is approximately 2.5 cm long. The lateral third is an elastic cartilaginous and dense fibrous framework to which thin skin is attached. The medial two thirds is bone lined with thin skin. The external auditory canal ends at the tympanic membrane.

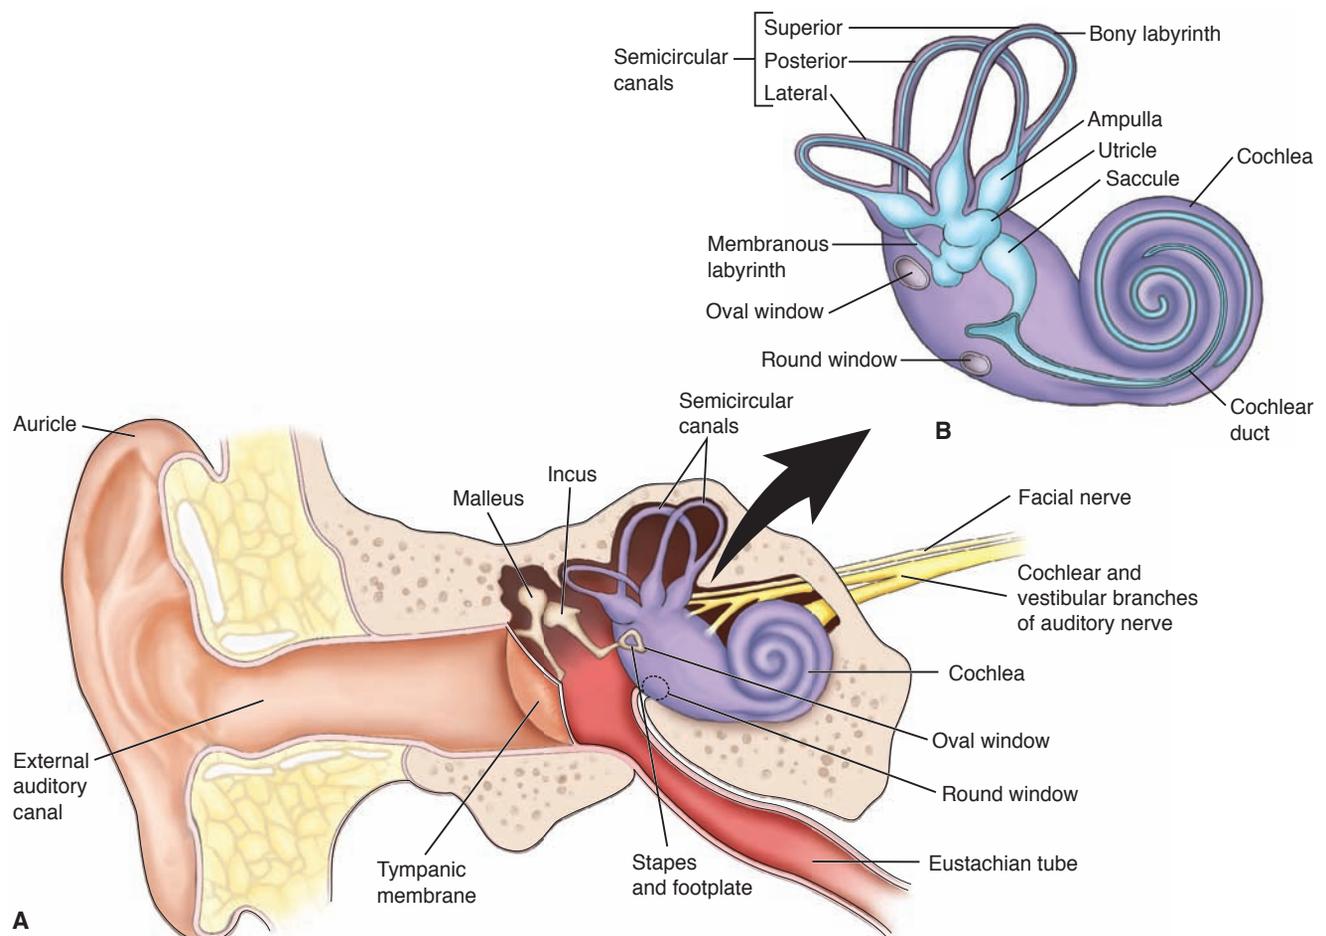

Figure 59-1 A, Anatomy of the ear. B, The inner ear.

The skin of the canal contains hair, sebaceous glands, and ceruminous glands, which secrete a brown, waxlike substance called cerumen (ear wax). The ear's self-cleaning mechanism moves old skin cells and cerumen to the outer part of the ear.

Just anterior to the external auditory canal is the temporomandibular joint. The head of the mandible can be felt by placing a fingertip in the external auditory canal while the patient opens and closes the mouth.

Anatomy of the Middle Ear

The middle ear, an air-filled cavity, includes the tympanic membrane laterally and the otic capsule medially. The middle ear cleft lies between the two. The middle ear is connected to the nasopharynx by the eustachian tube and is continuous with air-filled cells in the adjacent mastoid portion of the temporal bone.

The eustachian tube, which is approximately 1 mm wide and 35 mm long, connects the middle ear to the nasopharynx. Normally, the eustachian tube is closed, but it opens by action of the tensor veli palatini muscle when the person performs a Valsalva maneuver, yawns, or swallows. It drains normal and abnormal secretions of the middle ear and equalizes pressure in the middle ear with that of the atmosphere.

Tympanic Membrane

The tympanic membrane (eardrum), about 1 cm in diameter and very thin, is normally pearly gray and translucent. It consists of three layers of tissue: an outer layer, continuous with the skin of the ear canal; a fibrous middle layer; and an inner mucosal layer, continuous with the lining of the middle ear cavity. Approximately 80% of the tympanic membrane is composed of all three layers and is called the pars tensa. The remaining 20% lacks the middle layer and is called the pars flaccida. The absence of this fibrous middle layer makes the pars flaccida more vulnerable to pathologic disorders than the pars tensa. Distinguishing landmarks

include the annulus, the fibrous border that attaches the eardrum to the temporal bone; the short process of the malleus; the long process of the malleus; the umbo of the malleus, which attaches to the tympanic membrane in the center; the pars flaccida; and the pars tensa (Fig. 59-2).

The tympanic membrane protects the middle ear and conducts sound vibrations from the external canal to the ossicles. The sound pressure is magnified 22 times as a result of transmission from a larger area to a smaller one.

Ossicles

The middle ear contains the three smallest bones (the ossicles) of the body: the malleus, the incus, and the stapes. The ossicles, which are held in place by joints, muscles, and ligaments, assist in the transmission of sound. Two small fenestrae (oval and round windows), located in the medial wall of the middle ear, separate the middle ear from the inner ear. The footplate of the stapes sits in the oval window, secured by a fibrous annulus (ring-shaped structure). The footplate transmits sound to the inner ear. The round window, covered by a thin membrane, provides an exit for sound vibrations (see Fig. 59-1).

Anatomy of the Inner Ear

The inner ear is housed deep within the temporal bone. The organs for hearing (cochlea) and balance (semicircular canals), as well as cranial nerves VII (facial nerve) and VIII (vestibulocochlear nerve), are all part of this complex anatomy (see Fig. 59-1). The cochlea and semicircular canals are housed in the bony labyrinth. The bony labyrinth surrounds and protects the membranous labyrinth, which is bathed in a fluid called perilymph.

Membranous Labyrinth

The membranous labyrinth is composed of the utricle, the saccule, the cochlear duct, the semicircular canals, and the organ of Corti, all of which are surrounded by a fluid called

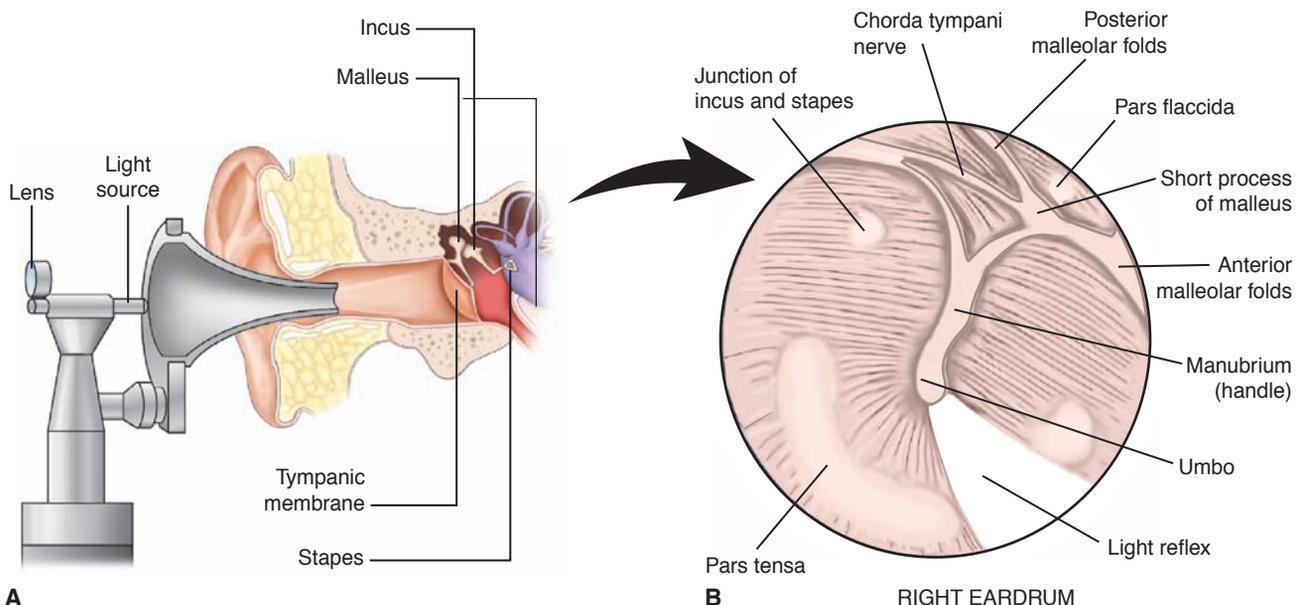

Figure 59-2 Technique for using the otoscope (A) to see the tympanic membrane (B).

endolymph. The three semicircular canals—posterior, superior, and lateral, which lie at 90-degree angles to one another—contain sensory receptor organs, arranged to detect rotational movement. These receptor end organs are stimulated by changes in the rate or direction of a person's movement. The utricle and saccule are involved with linear movements.

Organ of Corti

The organ of Corti is housed in the cochlea, a snail-shaped, bony tube about 3.5 cm long with two and a half spiral turns. Membranes separate the cochlear duct (scala media) from the scala vestibuli and the scala tympani from the basilar membrane. The organ of Corti is located on the basilar membrane that stretches from the base to the apex of the cochlea. As sound vibrations enter the perilymph at the oval window and travel along the scala vestibuli, they pass through the scala tympani, enter the cochlear duct, and cause movement of the basilar membrane. The organ of Corti, also called the end organ for hearing, transforms mechanical energy into neural activity and separates sounds into different frequencies. This electrochemical impulse travels through the acoustic nerve to the temporal cortex of the brain to be interpreted as meaningful sound. In the internal auditory canal, the cochlear (acoustic) nerve, arising from the cochlea, joins the vestibular nerve, arising from the semicircular canals, utricle, and saccule, to become the vestibulocochlear nerve (cranial nerve VIII). This canal also houses the facial nerve and the blood supply from the ear to the brain.

Function of the Ears

Hearing

Hearing is conducted over two pathways: air and bone. Sounds transmitted by air conduction travel over the air-filled external and middle ear through vibration of the tympanic membrane and ossicles. Sounds transmitted by bone conduction travel directly through bone to the inner ear, bypassing the tympanic membrane and ossicles. Normally, air conduction is the more efficient pathway.

Sound Conduction and Transmission

Sound enters the ear through the external auditory canal and causes the tympanic membrane to vibrate. These vibrations transmit sound through the lever action of the ossicles to the oval window as mechanical energy. This mechanical energy is then transmitted through the inner ear fluids to the cochlea, stimulating the hair cells, and is subsequently converted to electrical energy. The electrical energy travels through the vestibulocochlear nerve to the central nervous system, where it is interpreted in its final form as sound.

Vibrations transmitted by the tympanic membrane to the ossicles of the middle ear are transmitted to the cochlea, located in the labyrinth of the inner ear. The stapes rocks, causing vibrations (waves) in fluids contained in the inner ear. These fluid waves cause movement of the basilar membrane, stimulating the hair cells of the organ of Corti in the cochlea to move in a wavelike manner. The movements of the tympanic membrane set up electrical currents that stimulate the various areas of the cochlea. The hair cells set up

neural impulses that are encoded and then transferred to the auditory cortex in the brain, where they are decoded into a sound message.

The footplate of the stapes receives impulses transmitted by the incus and the malleus from the tympanic membrane. The round window, which opens on the opposite side of the cochlear duct, is protected from sound waves by the intact tympanic membrane, permitting motion of the inner ear fluids by sound wave stimulation. For example, in the normally intact tympanic membrane, sound waves stimulate the oval window first, and a lag occurs before the terminal effect of the stimulus reaches the round window. However, this lag phase is changed when a perforation of the tympanic membrane allows sound waves to impinge on the oval and round windows simultaneously. This effect cancels the lag and prevents the maximal effect of inner ear fluid motility and its subsequent effect in stimulating the hair cells in the organ of Corti. The result is a reduction in hearing ability (Fig. 59-3).

Balance and Equilibrium

Body balance is maintained by the cooperation of the muscles and joints of the body (proprioceptive system), the eyes (visual system), and the labyrinth (vestibular system). These areas send their information about equilibrium, or balance, to the brain (cerebellar system) for coordination and perception in the cerebral cortex. The brain obtains its blood supply from the heart and arterial system. A problem in any of these areas, such as arteriosclerosis or impaired vision, can cause a disturbance of balance. The vestibular apparatus of the inner ear provides feedback regarding the movements and the position of the head and body in space.

Assessment

Assessment of hearing and balance involves inspection of the external, middle, and inner ear. Evaluation of gross hearing acuity also is included in every physical examination.

Inspection of the External Ear

Inspection of the external ear is a simple procedure, but it is often overlooked. The external ear is examined by inspection and direct palpation; the auricle and surrounding tissues should be inspected for deformities, lesions, and discharge, as well as size, symmetry, and angle of attachment to the head. Manipulation of the auricle does not normally elicit pain. If this maneuver is painful, acute external otitis is suspected. Tenderness on palpation in the area of the mastoid may indicate acute mastoiditis or inflammation of the posterior auricular node. Occasionally, sebaceous cysts and topi (subcutaneous mineral deposits) are present on the pinna. A flaky scaliness on or behind the auricle usually indicates seborrheic dermatitis and can be present on the scalp and facial structures as well.

Otoscopic Examination

The tympanic membrane is inspected with an otoscope and indirect palpation with a pneumatic otoscope. To examine the external auditory canal and tympanic membrane, the otoscope should be held in the examiner's right hand, in a

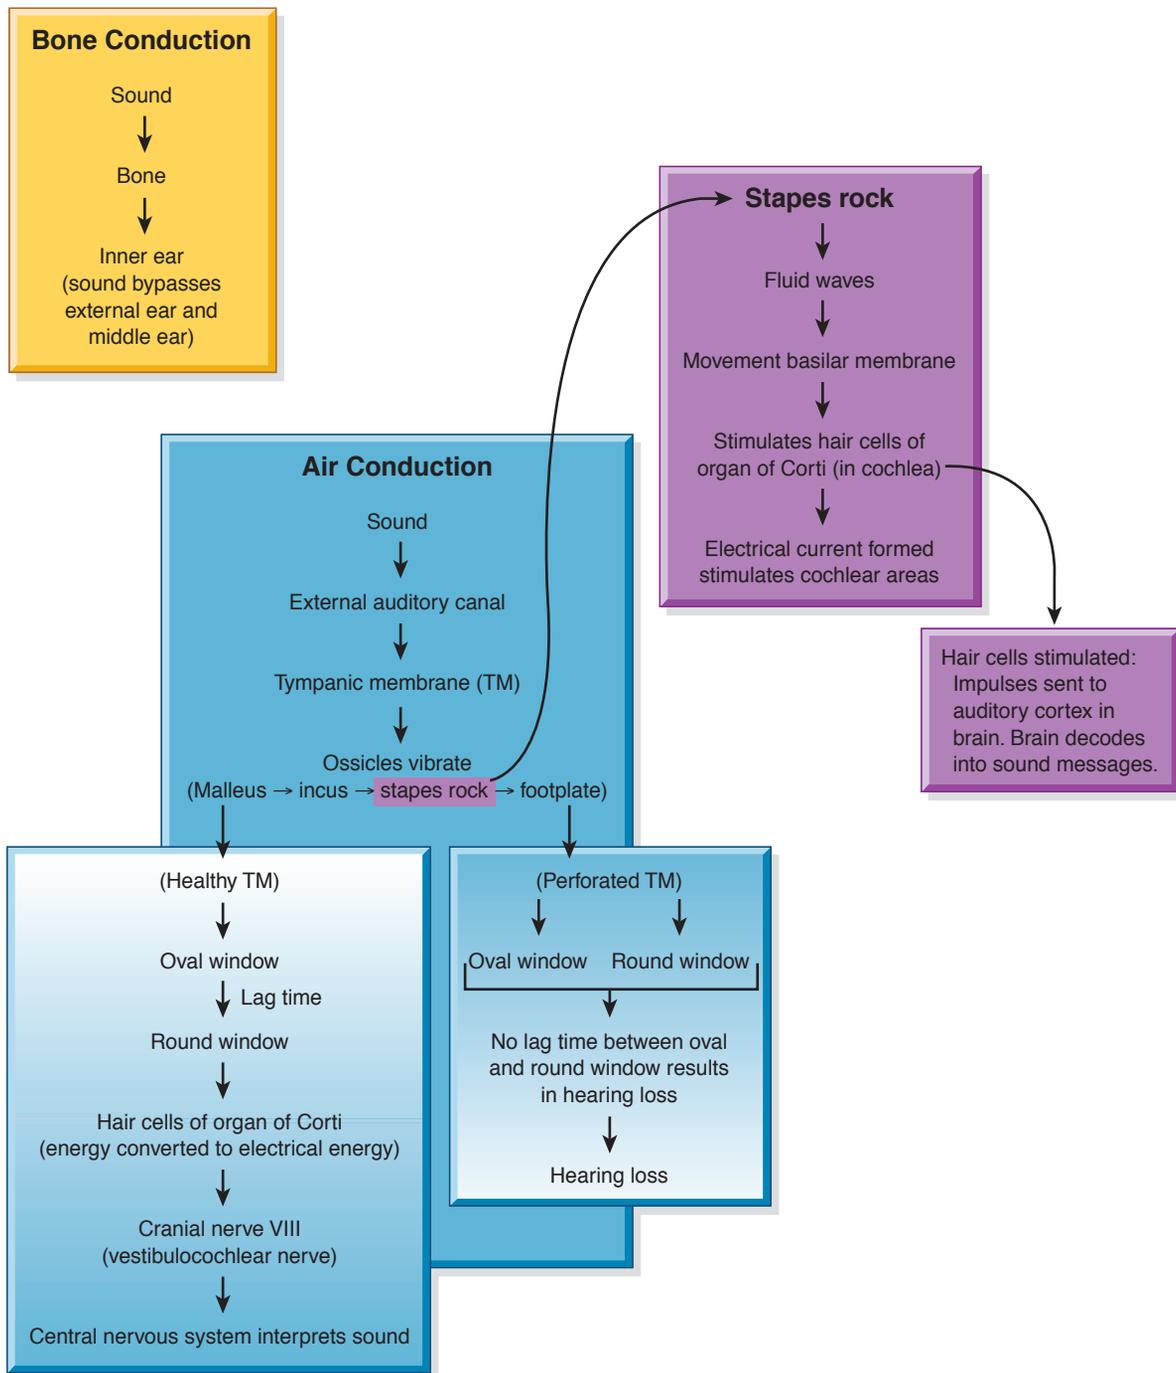

Figure 59-3 Bone conduction compared to air conduction.

pencil-hold position, with the examiner’s hand braced against the patient’s face (Fig. 59-4). This position prevents the examiner from inserting the otoscope too far into the external canal. Using the opposite hand, the auricle is grasped and gently pulled back to straighten the canal in the adult. If the canal is not straightened with this technique, the tympanic membrane is more difficult to visualize because the canal obstructs the view.

The speculum is slowly inserted into the ear canal, with the examiner’s eye held close to the magnifying lens of the

otoscope to visualize the canal and tympanic membrane. The largest speculum that the canal can accommodate (usually 5 mm in an adult) is guided gently down into the canal and slightly forward. Because the distal portion of the canal is bony and covered by a sensitive layer of epithelium, only light pressure can be used without causing pain. The external auditory canal is examined for discharge, inflammation, or a foreign body.

The healthy tympanic membrane is pearly gray and is positioned obliquely at the base of the canal. The following

Figure 59-4 Proper technique for examining the ear. Hold the otoscope in the right or left hand, in a “pencil-hold” position. Steady the hand against the patient’s head to avoid inserting the otoscope too far into the external canal.

landmarks are identified, if visible (see Fig. 59-2): the pars tensa, the umbo, the manubrium of the malleus, and its short process. A slow, circular movement of the speculum allows further visualization of the malleolar folds and periphery. The position and color of the membrane and any unusual markings or deviations from normal are documented. The presence of fluid, air bubbles, blood, or masses in the middle ear also should be noted.

Proper otoscopic examination of the external auditory canal and tympanic membrane requires that the canal be free of large amounts of cerumen. Cerumen is normally present in the external canal, and small amounts should not interfere with otoscopic examination. If the tympanic membrane cannot be visualized because of cerumen, the cerumen may be removed by gently irrigating the external canal with warm water (unless contraindicated). If adherent cerumen is present, a small amount of mineral oil or over-the-counter cerumen softener may be instilled into the ear canal and the patient instructed to return for subsequent removal of the cerumen and inspection of the ear. The use of instruments such as a cerumen curette for cerumen removal is reserved for otolaryngologists and nurses with specialized training because of the danger of perforating the tympanic membrane or excoriating the external auditory canal. Cerumen buildup is a common cause of hearing loss and local irritation.

Evaluation of Gross Auditory Acuity

A general estimate of hearing can be made by assessing the patient’s ability to hear a whispered phrase or a ticking watch, testing one ear at a time. The Weber and Rinne tests may be used to distinguish conductive loss from sensorineural loss when hearing is impaired. These tests are part of the usual screening physical examination and are useful if a more specific assessment is needed, if hearing loss

is detected, or if confirmation of audiometric results is desired.

Whisper Test

To exclude one ear from the testing, the examiner covers the untested ear with the palm of the hand. Then the examiner whispers softly from a distance of 1 or 2 feet from the unoccluded ear and out of the patient’s sight. The patient with normal acuity can correctly repeat what was whispered.

Weber Test

The Weber test uses bone conduction to test lateralization of sound. A tuning fork (ideally, 512 Hz), set in motion by grasping it firmly by its stem and tapping it on the examiner’s knee or hand, is placed on the patient’s head or forehead (Fig. 59-5A). A person with normal hearing hears the sound equally in both ears or describes the sound as centered in the middle of the head. A person with **conductive hearing loss**, such as from otosclerosis or otitis media, hears the sound better in the affected ear. A person with **sensorineural hearing loss**, resulting from damage to the cochlear or vestibulocochlear nerve, hears the sound in the better-hearing ear. The Weber test is useful for detecting unilateral hearing loss (Table 59-1).

Rinne Test

In the Rinne test (pronounced *rin-ay*), the examiner shifts the stem of a vibrating tuning fork between two positions: 2 inches from the opening of the ear canal (for air conduction) and against the mastoid bone (for bone conduction) (Fig. 59-5B). As the position changes, the patient is asked to indicate which tone is louder or when the tone is no longer audible.

The Rinne test is useful for distinguishing between conductive and sensorineural hearing loss. A person with normal hearing reports that air-conducted sound is louder than bone-conducted sound. A person with a conductive hearing loss hears bone-conducted sound as long as or longer than air-conducted sound. A person with a sensorineural hearing loss hears air-conducted sound longer than bone-conducted sound.

Diagnostic Evaluation

Many diagnostic procedures are available to measure the auditory and vestibular systems indirectly. These tests are usually performed by an audiologist who is certified by the American Speech-Language-Hearing Association. Prior to each of the following tests, the nurse explains the procedure to the patient.

Audiometry

In detecting hearing loss, audiometry is the single most important diagnostic instrument. Audiometric testing is of two kinds: pure-tone audiometry, in which the sound stimulus consists of a pure or musical tone (the louder the tone before the patient perceives it, the greater the hearing loss), and speech audiometry, in which the spoken word is used to determine the ability to hear and discriminate sounds and words.

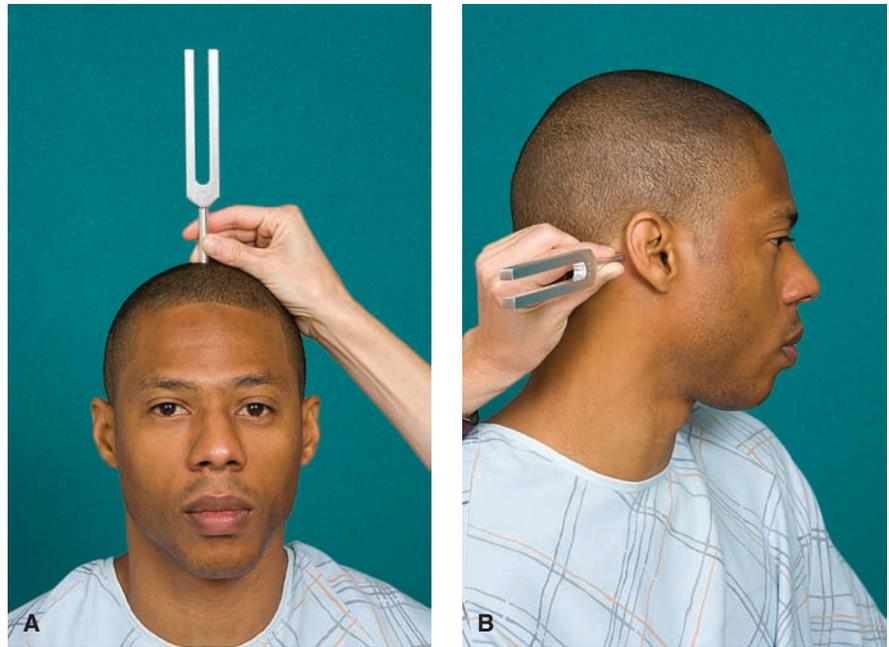

Figure 59-5 **A**, The Weber test assesses bone conduction of sound. **B**, The Rinne test assesses both air and bone conduction of sound.

When evaluating hearing, three characteristics are important: frequency, pitch, and intensity. *Frequency* refers to the number of sound waves emanating from a source per second, measured as cycles per second, or Hertz (Hz). The normal human ear perceives sounds ranging in frequency from 20 to 20,000 Hz. The frequencies from 500 to 2000 Hz are important in understanding everyday speech and are referred to as the speech range or speech frequencies. *Pitch* is the term used to describe frequency; a tone with 100 Hz is considered of low pitch, and a tone of 10,000 Hz is considered of high pitch.

The unit for measuring loudness (*intensity* of sound) is the decibel (dB), the pressure exerted by sound. Hearing loss is measured in decibels, a logarithmic function of intensity that is not easily converted into a percentage. The critical level of loudness is approximately 30 dB. The shuffling of papers in quiet surroundings is about 15 dB; a low conversation, 40 dB; and a jet plane 100 feet away, about 150 dB. Sound louder than 80 dB is perceived by the human ear to be harsh and can be damaging to the inner ear. Table 59-2 classifies hearing loss based on decibel level. In surgical treatment of patients with hearing loss, the aim is to improve the hearing level to 30 dB or better within the speech frequencies.

With audiometry, the patient wears earphones and signals to the audiologist when a tone is heard. When the tone is applied directly over the external auditory canal, air conduction is measured. When the stimulus is applied to the mastoid bone, bypassing the conductive mechanism (ie, the

ossicles), nerve conduction is tested. For accuracy, testing is performed in a soundproof room. Responses are plotted on a graph known as an audiogram, which differentiates conductive from sensorineural hearing loss.

Tympanogram

A tympanogram, or impedance audiometry, measures middle ear muscle reflex to sound stimulation and compliance of the tympanic membrane by changing the air pressure in a sealed ear canal. Compliance is impaired with middle ear disease.

Auditory Brain Stem Response

The auditory brain stem response is a detectable electrical potential from cranial nerve VIII and the ascending auditory pathways of the brain stem in response to sound stimulation. Electrodes are placed on the patient's forehead. Acoustic stimuli (eg, clicks) are made in the ear. The resulting electrophysiologic measurements can determine at which decibel level a patient hears and whether there are any impairments along the nerve pathways (eg, tumor on cranial nerve VIII).

Electronystagmography

Electronystagmography is the measurement and graphic recording of the changes in electrical potentials created by eye movements during spontaneous, positional, or calorically evoked nystagmus. It is also used to assess the

Table 59-1 COMPARISON OF WEBER AND RINNE TESTS

Hearing Status	Weber	Rinne
Normal hearing	Sound is heard equally in both ears.	Air conduction is audible longer than bone conduction.
Conductive hearing loss	Sound is heard best in affected ear (hearing loss).	Sound is heard as long or longer in affected ear (hearing loss).
Sensorineural hearing loss	Sound is heard best in normal hearing ear.	Air conduction is audible longer than bone conduction in affected ear.

Loss in Decibels	Interpretation
0–15	Normal hearing
>15–25	Slight hearing loss
>25–40	Mild hearing loss
>40–55	Moderate hearing loss
>55–70	Moderate to severe hearing loss
>70–90	Severe hearing loss
>90	Profound hearing loss

oculomotor and vestibular systems and their corresponding interaction. It helps diagnose conditions such as Ménière's disease and tumors of the internal auditory canal or posterior fossa. Any vestibular suppressants, such as sedatives, tranquilizers, antihistamines, and alcohol, are withheld for 24 hours before testing.

Platform Posturography

Platform posturography is used to investigate postural control capabilities such as vertigo. It can be used to evaluate if a person's vertigo is becoming worse or to evaluate the person's response to treatment. The integration of visual, vestibular, and proprioceptive cues (ie, sensory integration) with motor response output and coordination of the lower limbs is tested. The patient stands on a platform, surrounded by a screen, and different conditions such as a moving platform with a moving screen or a stationary platform with a moving screen are presented. The responses from the patient on six different conditions are measured and indicate which of the anatomic systems may be impaired. Preparation for the testing is the same as for electronystagmography.

Sinusoidal Harmonic Acceleration

Sinusoidal harmonic acceleration, or a rotary chair, is used to assess the vestibulo-ocular system by analyzing compensatory eye movements in response to the clockwise and counterclockwise rotation of the chair. Although such testing cannot identify the side of the lesion in unilateral disease, it helps identify disease (eg, Ménière's disease and tumors of the auditory canal) and evaluate the course of recovery. The same patient preparation is required as for electronystagmography.

Middle Ear Endoscopy

With endoscopes with very small diameters and acute angles, the ear can be examined by an endoscopist specializing in otolaryngology. Middle ear endoscopy is performed safely and effectively as an office procedure to evaluate suspected perilymphatic fistula and new-onset conductive hearing loss, the anatomy of the round window before transtympanic treatment of Ménière's disease, and the tympanic cavity before ear surgery to treat chronic middle ear and mastoid infections.

The tympanic membrane is anesthetized topically for about 10 minutes before the procedure. Then, the external auditory canal is irrigated with sterile normal saline solution. With the aid of a microscope, a tympanotomy is created with a laser beam or a myringotomy knife, so that the endoscope can be inserted into the middle ear cavity. Video

and photo documentation can be accomplished through the scope.

HEARING LOSS

Hearing impairment has been reported to occur in 3 of every 1000 births, and approximately one half of the time it is related to genetic factors (U.S. Department of Health and Human Services [USDHHS], 2007). Chart 59-1 contains more information about hearing disorders that have a genetic cause. It has been reported that approximately 73% of hospitals or birthing centers are now offering universal hearing screenings for all newborns after birth and prior to discharge.

Hearing loss is greater in men than in women. By the year 2050, about one of every five people in the United States, or almost 58 million people, will be 55 years of age or older. Of this population, almost half can expect to have a hearing impairment (USDHHS, 2007). Hearing loss is an important health issue, and as people age, hearing screening and treatment are indicated.

Approximately 10 million people in the United States have irreversible hearing loss (Mitchell, 2006). It is estimated that more than 30 million people are exposed on a daily basis to noise levels that produce hearing loss. Occupations such as carpentry, plumbing, and coal mining have the highest risk of noise-induced hearing loss. Wise Ears was developed in 1999 by the National Institute on Deafness and Other Communication Disorders (NIDCD) and the National Institute for Occupational Safety and Health. It aims to educate the public about noise-induced hearing loss and ways to prevent this hearing loss (NIDCD, 2008)

Conductive hearing loss usually results from an external ear disorder, such as impacted cerumen, or a middle ear disorder, such as otitis media or otosclerosis. In such instances, the efficient transmission of sound by air to the inner ear is interrupted. A sensorineural loss involves damage to the cochlea or vestibulocochlear nerve.

Mixed hearing loss and functional hearing loss also may occur. Patients with mixed hearing loss have conductive loss and sensorineural loss, resulting from dysfunction of air and bone conduction. A functional (or psychogenic) hearing loss is nonorganic and unrelated to detectable structural changes in the hearing mechanisms; it is usually a manifestation of an emotional disturbance.

Clinical Manifestations

Early manifestations of hearing impairment and loss may include tinnitus, increasing inability to hear when in a group, and a need to turn up the volume of the television. Hearing impairment can also trigger changes in attitude, the ability to communicate, the awareness of surroundings, and even the ability to protect oneself, affecting a person's quality of life. In a classroom, a student with impaired hearing may be uninterested and inattentive and have failing grades. A person at home may feel isolated because of an inability to hear the clock chime or to hear the telephone. A pedestrian who is hearing-impaired may attempt to cross the street and fail to hear an approaching car. People with impaired hearing may miss parts of a conversation. Many people are unaware

CHART
59-1GENETICS IN NURSING PRACTICE
Hearing Disorders**Selected Hearing Disorders Influenced by Genetic Factors**

- Autosomal dominant hearing loss
- Autosomal recessive hearing loss (eg, connexin 26 gene)
- Otosclerosis
- Pendred syndrome
- Usher syndrome
- Waardenburg syndrome

Nursing Assessments**Family History Assessment**

- Assess for other family members in several generations with hearing loss (autosomal dominant hearing loss)
- Inquire about genetic relatedness (eg, individuals who are related, such as first cousins, have a higher chance to share the same recessive genes—autosomal recessive hearing loss)
- Inquire about age at onset of hearing loss

Patient Assessment

- Assess for related genetic conditions, such as vision impairment (eg, retinitis pigmentosa in Usher syndrome; thyroid disorder in Pendred syndrome)
- Assess for iris, pigment, and hair alterations (white forelock) seen in Waardenburg syndrome

Management Issues Specific to Genetics

- Inquire whether DNA gene mutation or other genetic testing has been performed on affected family members.
- If indicated, refer for further genetic counseling and evaluation so that family members can discuss inheritance, risk to other family members, availability of genetic testing, and gene-based interventions.
- Offer appropriate genetic information and resources.
- Assess patient's understanding of genetic information.
- Provide support to families with newly diagnosed genetic-related sensorineural disorders.
- Participate in management and coordination of care of patients with genetic conditions, and individuals predisposed to develop or pass on a genetic condition.

Genetics Resources

Genetic Alliance—a directory of support groups for patients and families with genetic conditions; www.geneticalliance.org

Gene Clinics—a listing of common genetic disorders with up-to-date clinical summaries, genetic counseling and testing information; www.geneclinics.org

National Organization of Rare Disorders—a directory of support groups and information for patients and families with rare genetic disorders; www.rarediseases.org

OMIM: Online Mendelian Inheritance in Man—a complete listing of inherited genetic conditions; www.ncbi.nlm.nih.gov/omim/stats/html

of their gradual hearing impairment. Often, it is not the person with the hearing loss but the people with whom he or she is communicating who recognizes the impairment first (Chart 59-2).

For various reasons, some people with hearing loss refuse to seek medical attention or wear a hearing aid. They may feel self-conscious wearing a hearing aid. Other more in-

sightful people generally ask those with whom they are trying to communicate to let them know whether difficulties in communication exist. The attitudes and behaviors of patients who need hearing assistance should be taken into account when counseling them. The decision to wear a hearing aid is a personal one that is affected by these attitudes and behaviors.

CHART
59-2

Assessing for Hearing Loss

Be alert for the following:

Speech deterioration: The person who slurs words or drops word endings, or produces flat-sounding speech, may not be hearing correctly. The ears guide the voice, both in loudness and in pronunciation.

Fatigue: If a person tires easily when listening to conversation or to a speech, fatigue may be the result of straining to hear. Under these circumstances, the person may become irritable very easily.

Indifference: It is easy for the person who cannot hear what others say to become depressed and disinterested in life in general.

Social withdrawal: Not being able to hear what is going on causes the hearing-impaired person to withdraw from situations that might prove embarrassing.

Insecurity: Lack of self-confidence and fear of mistakes create a feeling of insecurity in many hearing-impaired people. No one likes to say the wrong thing or do anything that might appear foolish.

Indecision and procrastination: Loss of self-confidence makes it increasingly difficult for a hearing-impaired person to make decisions.

Suspiciousness: The hearing-impaired person, who often hears only part of what is being said, may suspect that others are talking about him or her, or that portions of the conversation are deliberately spoken softly so that he or she will not hear them.

False pride: The hearing-impaired person wants to conceal the hearing loss and thus often pretends to be hearing when he or she actually is not.

Loneliness and unhappiness: Although everyone wishes for quiet now and then, *enforced* silence can be boring and even somewhat frightening. People with a hearing loss often feel isolated.

Tendency to dominate the conversation: Many hearing-impaired people tend to dominate the conversation, knowing that as long as it is centered on them and they can control it, they are not so likely to be embarrassed by some mistake.

Prevention

Many environmental factors have an adverse effect on the auditory system and, with time, result in permanent sensorineural hearing loss. The most common is noise. Noise (unwanted and unavoidable sound) has been identified as one of today's environmental hazards. The volume of noise that surrounds us daily has increased into a potentially dangerous source of physical and psychological damage.

Loud, persistent noise has been found to cause constriction of peripheral blood vessels, increased blood pressure and heart rate (because of increased secretion of adrenalin), and increased gastrointestinal activity. Although research is needed to address the overall effects of noise on the human body, a quiet environment is more conducive to peace of mind. A person who is ill feels more at ease when noise is kept to a minimum.

Numerous factors contribute to hearing loss (Chart 59-3). *Noise-induced hearing loss* refers to hearing loss that follows a long period of exposure to loud noise (eg, heavy machinery, engines, artillery, rock-band music). *Acoustic trauma* refers to hearing loss caused by a single exposure to an extremely intense noise, such as an explosion. Usually, noise-induced hearing loss occurs at a high frequency (about 4000 Hz). However, with continued noise exposure, the hearing loss can become more severe and include adjacent frequencies. The minimum noise level known to cause noise-induced hearing loss, regardless of duration, is about 85 to 90 dB.

Noise exposure is inherent in many jobs (eg, mechanics, printers, pilots, flight attendants, musicians) and in hobbies such as woodworking and hunting. Noise level regulations are based on the amount of noise a person is exposed to, with the maximum legal amount being exposure to noise over an average working day or week of 80 dB, with a peak sound pressure of 135 dB (Health and Safety Executive, 2008). The Occupational Safety and Health Administration requires that workers wear ear protection to prevent noise-induced hearing loss when exposed to noise above the legal limits. Ear protection against noise is the most effective preventive measure available. Hearing loss due to noise is permanent because the hair cells in the organ of Corti are destroyed.

Gerontologic Considerations

Approximately half of all people with hearing loss or deafness are 65 years of age or older. The cause is unknown; linkages to diet, metabolism, arteriosclerosis, stress, and heredity have been inconsistent (Mitchell, 2006).

CHART
59-3

Risk Factors for Hearing Loss

- Family history of sensorineural impairment
- Congenital malformations of the cranial structure (ear)
- Low birth weight (<1500 g)
- Use of ototoxic medications (eg, gentamycin, loop diuretics)
- Recurrent ear infections
- Bacterial meningitis
- Chronic exposure to loud noises
- Perforation of the tympanic membrane

With aging, changes occur in the ear that may eventually lead to hearing deficits. Although few changes occur in the external ear, cerumen tends to become harder and drier, posing a greater chance of impaction. In the middle ear, the tympanic membrane may atrophy or become sclerotic. In the inner ear, cells at the base of the cochlea degenerate. A familial predisposition to sensorineural hearing loss is also seen, manifested by inability to hear high-frequency sounds, followed in time by the loss of middle and lower frequencies. The term **presbycusis** is used to describe this progressive hearing loss.

In addition to age-related changes, other factors can affect hearing in the elderly population, such as lifelong exposure to loud noises. Certain medications, such as aminoglycosides and aspirin, have ototoxic effects when renal changes (eg, in the older person) result in delayed medication excretion and increased levels of the medications in the blood. Many older people have taken quinine for treatment of leg cramps; this medication also can contribute to hearing loss. Psychogenic factors and other disease processes (eg, diabetes) also may be partially responsible for sensorineural hearing loss.

When hearing loss occurs, proper evaluation and treatment are warranted. *Healthy People 2010* identifies eight objectives for decreasing the problems caused by hearing loss. One of these objectives is for people diagnosed with hearing loss or deafness to use rehabilitation services and supplemental devices to improve communication with other people. Resources are available in workplaces and in schools. The Individuals with Disabilities Education Act (IDEA) was developed to ensure that children and adults, including elderly adults, receive the same opportunities in the educational system as those without hearing impairment (U.S. Department of Education, 2008).

Even with the best health care, people with hearing loss must learn to adjust to it. Care of elderly patients includes recognizing emotional reactions related to hearing loss, such as suspicion of others because of an inability to hear adequately; frustration and anger, with repeated statements such as, "I didn't hear what you said"; and feelings of insecurity because of the inability to hear the telephone or alarms. The Americans with Disabilities Act (ADA) of 1990 requires that all emergency services are accessible to people who have text message telephones (TTYs). In addition, in 1998, the Department of Justice mandated that all 911 centers in the United States be accessible to people with TTYs.

Medical Management

If a hearing loss is permanent or untreatable or if the patient elects not to be treated, aural rehabilitation (discussed at the end of the chapter) may be beneficial.

Nursing Management

Nurses who understand the different types of hearing loss are more successful in adopting a communication style to fit the needs and preferences of each patient. Trying to speak in a loud voice to a person who cannot hear high-frequency sounds only makes understanding more difficult. However, strategies such as talking into the less-impaired ear and using gestures and facial expressions can help (Chart 59-4).

A major issue for many people who are deaf or hearing-impaired is that they have other health problems that often do not receive attention, in large part because of

Chart 59-4 • Communicating With People Who Are Hearing-Impaired**For the Person Who is Hearing-impaired Whose Speech is Difficult to Understand:**

- Determine how the person prefers to communicate with others. Do not assume that writing, gestures, or other means are the best or preferred technique.
- Consider if the person uses sign language. Interpreters are available from the American Sign Language, Inc., Interpreting Service (ASLI). These specialists provide the best means of communication, providing accurate, professional services.
- Devote full attention to what the person is saying. Look and listen—do not try to attend to another task while listening.
- Engage the speaker in conversation when it is possible for you to anticipate the replies. This enables you to become accustomed to any peculiarities in speech patterns.
- Try to determine the essential context of what is being said; you can often fill in the details from context.
- Do not try to appear as if you understand if you do not.
- If you cannot understand at all or have serious doubt about your ability to understand what is being said, have the person write the message rather than risk misunderstanding. Having the person repeat the message in speech, after you know its content, also aids you in becoming accustomed to the person's pattern of speech.

- Written communication is an excellent resource. Written material should be written at a third-grade level so that the majority of people can understand it.

For the Person Who is Hearing-impaired Who Speech Reads:

- When speaking, always face the person as directly as possible.
- Make sure your face is as clearly visible as possible. Locate yourself so that your face is well lighted; avoid being silhouetted against strong light. Do not obscure the person's view of your mouth in any way; avoid talking with any object held in your mouth.
- Be sure that the patient knows the topic or subject before going ahead with what you plan to say. This enables the person to use contextual clues in speech reading.
- Speak slowly and distinctly, pausing more frequently than you would normally.
- If you question whether some important direction or instruction has been understood, check to be certain that the patient has the full meaning of your message.
- If for any reason your mouth must be covered (as with a mask) and you must direct or instruct the patient, write the message.

communication barriers with their health care practitioners. To meet the health care needs of these patients, practitioners are legally obligated to make accommodations for a patient's inability to hear. Providing interpreters for those who can communicate through sign language is essential in many situations so that the practitioner can effectively communicate with the patient.

During health care and screening procedures, the practitioner (eg, dentist, physician, nurse) must be aware that patients who are deaf or hearing-impaired are unable to read lips, see a signer, or read written materials in the dark rooms required during some diagnostic tests. The same situation exists if the practitioner is wearing a mask or is not in sight (eg, x-ray studies, magnetic resonance imaging [MRI], colonoscopy).

Nurses and other health care practitioners must work with patients who are deaf or hearing-impaired and their families to identify practical and effective means of communication. Nurses can serve as catalysts throughout the health care system to ensure that accommodations are made to meet the communication needs of these patients.

CONDITIONS OF THE EXTERNAL EAR**Cerumen Impaction**

Cerumen normally accumulates in the external canal in various amounts and colors. Although wax does not usually need to be removed, impaction occasionally occurs, causing **otalgia**, a sensation of fullness or pain in the ear, with or without a hearing loss. Accumulation of cerumen as a cause of hearing loss is especially significant in the elderly population. Attempts to clear the external auditory canal with matches, hairpins, and other implements are dangerous

because trauma to the skin, infection, and damage to the tympanic membrane can occur.

Management

Cerumen can be removed by irrigation, suction, or instrumentation. Unless the patient has a perforated eardrum or an inflamed external ear (ie, otitis externa), gentle irrigation usually helps remove impacted cerumen, particularly if it is not tightly packed in the external auditory canal. For successful removal, the water stream must flow behind the obstructing cerumen to move it first laterally and then out of the canal. To prevent injury, the lowest effective pressure should be used. However, if the eardrum behind the impaction is perforated, water can enter the middle ear, producing acute vertigo and infection. If irrigation is unsuccessful, direct visual, mechanical removal can be performed on a cooperative patient by a trained health care provider.

Instilling a few drops of warmed glycerin, mineral oil, or half-strength hydrogen peroxide into the ear canal for 30 minutes can soften cerumen before its removal. Ceruminolytic agents, such as peroxide in glyceryl (Debrox), are available; however, these compounds may cause an allergic dermatitis reaction. Using any softening solution two or three times a day for several days is generally sufficient. If the cerumen cannot be dislodged by these methods, instruments, such as a cerumen curette, aural suction, and a binocular microscope for magnification, can be used.

Foreign Bodies

Some objects are inserted intentionally into the ear by adults who may have been trying to clean the external canal or relieve itching or by children who introduce peas,

beans, pebbles, toys, and beads. Insects may also enter the ear canal. In either case, the effects may range from no symptoms to profound pain and decreased hearing.

Management

Removing a foreign body from the external auditory canal can be quite challenging. The three standard methods for removing foreign bodies are the same as those for removing cerumen: irrigation, suction, and instrumentation. The contraindications for irrigation are also the same. Foreign vegetable bodies and insects tend to swell; thus, irrigation is contraindicated. Usually, an insect can be dislodged by instilling mineral oil, which will kill the insect and allow it to be removed.

Attempts to remove a foreign body from the external canal may be dangerous in unskilled hands. The object may be pushed completely into the bony portion of the canal, lacerating the skin and perforating the tympanic membrane. In rare circumstances, the foreign body may have to be extracted in the operating room with the patient under general anesthesia.

External Otitis (Otitis Externa)

External otitis, or **otitis externa**, refers to an inflammation of the external auditory canal. Causes include water in the ear canal (swimmer's ear); trauma to the skin of the ear canal, permitting entrance of organisms into the tissues; and systemic conditions, such as vitamin deficiency and endocrine disorders. Bacterial or fungal infections are most frequently encountered. The most common bacterial pathogens associated with external otitis are *Staphylococcus aureus* and *Pseudomonas* species. The most common fungus isolated in both normal and infected ears is *Aspergillus*. External otitis is often caused by a dermatosis such as psoriasis, eczema, or seborrheic dermatitis. Even allergic reactions to hair spray, hair dye, and permanent wave lotions can cause dermatitis, which clears when the offending agent is removed.

Clinical Manifestations

Patients usually report pain, discharge from the external auditory canal, aural tenderness (usually not present in middle ear infections), and occasionally fever, cellulitis, and lymphadenopathy. Other symptoms may include pruritus and hearing loss or a feeling of fullness. On otoscopic examination, the ear canal is erythematous and edematous. Discharge may be yellow or green and foul-smelling. In fungal infections, hairlike black spores may even be visible.

Medical Management

The principles of therapy are aimed at relieving the discomfort, reducing the swelling of the ear canal, and eradicating the infection. Patients may require analgesic medications for the first 48 to 92 hours. If the tissues of the external canal are edematous, a wick should be inserted to keep the canal open so that liquid medications (eg, Burow's solution, antibiotic otic preparations) can be introduced. These medications may be administered by dropper at room temperature. Such medications usually combine

CHART
59-5

PATIENT EDUCATION Prevention of Otitis Externa

- Protect the external canal when swimming, showering, or washing hair. Ear plugs or a swim cap should be worn. Drying the external canal afterward with a hair dryer on low heat may be suggested.
- Alcohol drops may be placed in the external canal to act as an astringent to help prevent infection after water exposure.
- Prevent trauma to the external canal. Procedures, foreign objects (eg, bobby pin), scratching, or any other trauma to the canal that breaks the skin integrity may cause infection.
- If otitis externa is diagnosed, refrain from any water sport activity for approximately 7 to 10 days to allow the canal to heal completely. Recurrence is highly likely unless you allow the external canal to heal completely.

antibiotic and corticosteroid agents to soothe the inflamed tissues. For cellulitis or fever, systemic antibiotics may be prescribed. For fungal disorders, antifungal agents are prescribed.

Nursing Management

Nurses should instruct patients not to clean the external auditory canal with cotton-tipped applicators and to avoid events that traumatize the external canal such as scratching the canal with the fingernail or other objects. Trauma may lead to infection of the canal. Patients should also avoid getting the canal wet when swimming or shampooing the hair. A cotton ball can be covered in a water-insoluble gel such as petroleum jelly and placed in the ear as a barrier to water contamination. Infection can be prevented by using antiseptic otic preparations after swimming (eg, Swim Ear, Ear Dry), unless there is a history of tympanic membrane perforation or a current ear infection (Chart 59-5).

Malignant External Otitis

A more serious, although rare, external ear infection is malignant external otitis (temporal bone osteomyelitis). This is a progressive, debilitating, and occasionally fatal infection of the external auditory canal, the surrounding tissue, and the base of the skull. *Pseudomonas aeruginosa* is usually the infecting organism in patients with low resistance to infection (eg, patients with diabetes). Successful treatment includes control of the diabetes, administration of antibiotics (usually intravenously), and aggressive local wound care. Standard parenteral antibiotic treatment includes the combination of an antipseudomonal agent and an aminoglycoside, both of which have potentially serious side effects. Because aminoglycosides are nephrotoxic and ototoxic, serum aminoglycoside levels and renal and auditory function must be monitored during therapy. Local wound care includes limited débridement of the infected tissue, including bone and cartilage, depending on the extent of the infection.

Masses of the External Ear

Exostoses are small, hard, bony protrusions found in the lower posterior bony portion of the ear canal; they usually occur bilaterally. The skin covering the exostosis is normal. It is believed that exostoses are caused by an exposure to cold water, as in scuba diving or surfing. The usual treatment, if any, is surgical excision.

Malignant tumors also may occur in the external ear. Most common are basal cell carcinomas on the pinna and squamous cell carcinomas in the ear canal. If untreated, squamous cell carcinoma may spread through the temporal bone, causing facial nerve paralysis and hearing loss. Carcinomas must be treated surgically.

Gapping Earring Puncture

Gapping earring puncture results from wearing heavy pierced earrings for a long time or after an infection, or as a reaction from the earring or impurities in the earring. This deformity can only be corrected surgically.

CONDITIONS OF THE MIDDLE EAR

Tympanic Membrane Perforation

Perforation of the tympanic membrane is usually caused by infection or trauma. Sources of trauma include skull fracture, explosive injury, or a severe blow to the ear. Less frequently, perforation is caused by foreign objects (eg, cotton-tipped applicators, bobby pins, keys) that have been pushed too far into the external auditory canal. In addition to tympanic membrane perforation, injury to the ossicles and even the inner ear may result from this type of trauma. Attempts by patients to clear the external auditory canal should be discouraged. During infection, the tympanic membrane can rupture if the pressure in the middle ear exceeds the atmospheric pressure in the external auditory canal.

Medical Management

Although most tympanic membrane perforations heal spontaneously within weeks after rupture, some may take several months to heal. Some perforations persist because scar tissue grows over the edges of the perforation, preventing extension of the epithelial cells across the margins and final healing. In the case of a head injury or temporal bone fracture, a patient is observed for evidence of cerebrospinal fluid

otorrhea or **rhinorrhea**—a clear, watery drainage from the ear or nose, respectively. While healing, the ear must be protected from water.

Surgical Management

Perforations that do not heal on their own may require surgery. The decision to perform a **tympanoplasty** (surgical repair of the tympanic membrane) is usually based on the need to prevent potential infection from water entering the ear or the desire to improve the patient's hearing. Performed on an outpatient basis, tympanoplasty may involve a variety of surgical techniques. In all techniques, tissue (commonly from the temporalis fascia) is placed across the perforation to allow healing. Surgery is usually successful in closing the perforation permanently and improving hearing.

Acute Otitis Media

Ear infections can occur at any age; however, they are most commonly seen in children. **Acute otitis media (AOM)** is an acute infection of the middle ear, usually lasting less than 6 weeks. The pathogens that cause acute otitis media are usually *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Moraxella catarrhalis*, which enter the middle ear after eustachian tube dysfunction caused by obstruction related to upper respiratory infections, inflammation of surrounding structures (eg, rhinosinusitis, adenoid hypertrophy), or allergic reactions (eg, allergic rhinitis). Bacteria can enter the eustachian tube from contaminated secretions in the nasopharynx and the middle ear from a tympanic membrane perforation. A purulent exudate is usually present in the middle ear, resulting in a conductive hearing loss.

Clinical Manifestations

The symptoms of otitis media vary with the severity of the infection. The condition, usually unilateral in adults, may be accompanied by otalgia. The pain is relieved after spontaneous perforation or therapeutic incision of the tympanic membrane. Other symptoms may include drainage from the ear, fever, and hearing loss. On otoscopic examination, the external auditory canal appears normal. The tympanic membrane is erythematous and often bulging. Patients report no pain with movement of the auricle. Table 59-3 differentiates acute external otitis from AOM. Risk factors for AOM include age (younger than 12 months), chronic upper respiratory infections, medical conditions that predispose to ear infections (Down syndrome, cystic fibrosis, cleft palate), and chronic exposure to secondhand cigarette smoke.

Table 59-3 CLINICAL FEATURES OF OTITIS

Feature	Acute Otitis Externa	Acute Otitis Media
Otorrhea	May or may not be present	Present if tympanic membrane perforates; discharge is profuse
Otalgia	Persistent, may awaken patient at night	Relieved if tympanic membrane ruptures
Aural tenderness	Present on palpation of auricle	Usually absent
Systemic symptoms	Absent	Fever, upper respiratory infection, rhinitis
Edema of external auditory canal	Present	Absent
Tympanic membrane	May appear normal	Erythema, bulging, may be perforated
Hearing loss	Conductive type	Conductive type

Medical Management

The outcome of AOM depends on the efficacy of therapy (the prescribed dose of an oral antibiotic and the duration of therapy), the virulence of the bacteria, and the physical status of the patient. With early and appropriate broad-spectrum antibiotic therapy, otitis media may resolve with no serious sequelae. If drainage occurs, an antibiotic otic preparation is usually prescribed. The condition may become subacute (lasting 3 weeks to 3 months), with persistent purulent discharge from the ear. Rarely does permanent hearing loss occur. Secondary complications involving the mastoid and other serious intracranial complications, such as meningitis or brain abscess, although rare, can occur.

Surgical Management

An incision in the tympanic membrane is known as **myringotomy** (ie, **tympanotomy**). The tympanic membrane is numbed with a local anesthetic agent such as phenol or by iontophoresis (ie, electrical current flows through a lidocaine-and-epinephrine solution to numb the ear canal and tympanic membrane). The procedure is painless and takes less than 15 minutes. Under microscopic guidance, an incision is made through the tympanic membrane to relieve pressure and to drain serous or purulent fluid from the middle ear.

Normally, this procedure is unnecessary for treating AOM, but it may be performed if pain persists. Myringotomy also allows the drainage to be analyzed (by culture and sensitivity testing) so that the infecting organism can be identified and appropriate antibiotic therapy prescribed. The incision heals within 24 to 72 hours.

If AOM recurs and there is no contraindication, a ventilating, or pressure-equalizing, tube may be inserted. The ventilating tube, which temporarily takes the place of the eustachian tube in equalizing pressure, is retained for 6 to 18 months. The ventilating tube is then extruded with normal skin migration of the tympanic membrane, with the hole healing in nearly every case. Ventilating tubes are used to treat recurrent episodes of AOM.

Serous Otitis Media

Serous otitis media (**middle ear effusion**) involves fluid, without evidence of active infection, in the middle ear. In theory, this fluid results from a negative pressure in the middle ear caused by eustachian tube obstruction. When this condition occurs in adults, an underlying cause for the eustachian tube dysfunction must be sought. Middle ear effusion is frequently seen in patients after radiation therapy or barotrauma and in patients with eustachian tube dysfunction from a concurrent upper respiratory infection or allergy. Barotrauma results from sudden pressure changes in the middle ear caused by changes in barometric pressure, as in scuba diving or airplane descent. A carcinoma (eg, nasopharyngeal cancer) obstructing the eustachian tube should be ruled out in adults with persistent unilateral serous otitis media.

Clinical Manifestations

Patients may complain of hearing loss, fullness in the ear or a sensation of congestion, or popping and crackling noises that occur as the eustachian tube attempts to open. The tympanic membrane appears dull on otoscopy, and air bubbles may be visualized in the middle ear. Usually, the audiogram shows a conductive hearing loss.

Management

Serous otitis media need not be treated medically unless infection (ie, AOM) occurs. If the hearing loss associated with middle ear effusion is significant, a myringotomy can be performed, and a tube may be placed to keep the middle ear ventilated. Corticosteroids in small doses may decrease the edema of the eustachian tube in cases of barotrauma. Decongestants have not proved effective. A Valsalva maneuver, which forcibly opens the eustachian tube by increasing nasopharyngeal pressure, may be cautiously performed; this maneuver may cause worsening pain or perforation of the tympanic membrane.

Chronic Otitis Media

Chronic otitis media is the result of recurrent AOM causing irreversible tissue pathology and persistent perforation of the tympanic membrane. Chronic infections of the middle ear damage the tympanic membrane, destroy the ossicles, and involve the mastoid. Before the discovery of antibiotics, infections of the mastoid were life-threatening. Today, acute mastoiditis is rare in developed countries.

Clinical Manifestations

Symptoms may be minimal, with varying degrees of hearing loss and a persistent or intermittent, foul-smelling otorrhea. Pain is not usually experienced, except in cases of acute mastoiditis, when the postauricular area is tender and may be erythematous and edematous. Otoscopic examination may show a perforation, and cholesteatoma can be identified as a white mass behind the tympanic membrane or coming through to the external canal from a perforation.

Cholesteatoma is an ingrowth of the skin of the external layer of the eardrum into the middle ear. It is generally caused by a chronic retraction pocket of the tympanic membrane, creating a persistently high negative pressure of the middle ear. The skin forms a sac that fills with degenerated skin and sebaceous materials. The sac can attach to the structures of the middle ear or mastoid, or both.

Chronic otitis media can cause chronic mastoiditis and lead to the formation of cholesteatoma. It can occur in the middle ear, mastoid cavity, or both, often dictating the type of surgery to be performed. If untreated, cholesteatoma will continue to enlarge, possibly causing damage to the facial nerve and horizontal canal and destruction of other surrounding structures.

Cholesteatomas are common benign tumors of the inner ear (Semaan & Megerian, 2006). They usually do not cause pain; however, if treatment or surgery is delayed, they may destroy structures of the temporal bone. These fast-growing tumors may cause severe sequelae such as hearing loss or

neurologic disorders. Congenital cholesteatomas are usually found in children and may cause severe bone loss of the incus. Cholesteatomas found in elderly patients generally develop in the external canal.

Cholesteatomas may be asymptomatic or they may cause hearing loss, facial pain and paralysis, tinnitus, or vertigo. Audiometric tests often show a conductive or mixed hearing loss. Based on presenting symptoms, diagnosis may be made by visual examination or by computed tomography (CT) or MRI. Therapy includes treatment of the acute infection and surgical removal of the mass to restore hearing.

Medical Management

Local treatment of chronic otitis media consists of careful suctioning of the ear under otoscopic guidance. Instillation of antibiotic drops or application of antibiotic powder is used to treat purulent discharge. Systemic antibiotics are prescribed only in cases of acute infection.

Surgical Management

Surgical procedures, including tympanoplasty, ossiculoplasty, and mastoidectomy, are used if medical treatments are ineffective.

Tympanoplasty

The most common surgical procedure for chronic otitis media is a tympanoplasty, or surgical reconstruction of the tympanic membrane. Reconstruction of the ossicles may also be required. The purposes of a tympanoplasty are to reestablish middle ear function, close the perforation, prevent recurrent infection, and improve hearing.

There are five types of tympanoplasties. The simplest surgical procedure, type I (myringoplasty), is designed to close a perforation in the tympanic membrane. The other procedures, types II through V, involve more extensive repair of middle ear structures. The structures and the degree of involvement can differ, but all tympanoplasty procedures include restoring the continuity of the sound conduction mechanism.

Tympanoplasty is performed through the external auditory canal with a transcanal approach or through a postauricular incision. The contents of the middle ear are carefully inspected, and the ossicular chain (malleus and incus unit) is evaluated. Ossicular interruption is most frequent in chronic otitis media, but problems of reconstruction can also occur with malformations of the middle ear and ossicular dislocations due to head injuries. Dramatic improvement in hearing can result from closure of a perforation and reestablishment of the ossicles. Surgery is usually performed in an outpatient facility under moderate sedation or general anesthesia.

Ossiculoplasty

Ossiculoplasty is the surgical reconstruction of the middle ear bones to restore hearing. Prostheses made of materials such as Teflon, stainless steel, and hydroxyapatite are used to reconnect the ossicles, thereby reestablishing the sound conduction mechanism. However, the greater the damage, the lower the success rate for restoring normal hearing.

Mastoidectomy

The objectives of mastoid surgery are to remove the cholesteatoma, gain access to diseased structures, and create

a dry (noninfected) and healthy ear. If possible, the ossicles are reconstructed during the initial surgical procedure. Occasionally, extensive disease or damage dictates that this be performed as part of a two-stage operation.

A mastoidectomy is usually performed through a postauricular incision. Infection is eliminated by removing the mastoid air cells. A second mastoidectomy may be necessary to check for recurrent or residual cholesteatoma. The hearing mechanism may be reconstructed at this time. The success rate for correcting this conductive hearing loss is approximately 75%. Surgery is usually performed in an outpatient setting. The patient has a mastoid pressure dressing, which can be removed 24 to 48 hours after surgery. Although infrequently injured, the facial nerve, which runs through the middle ear and mastoid, is at some risk for injury during mastoid surgery. As the patient awakens from anesthesia, any evidence of facial paresis should be reported to the physician.

NURSING PROCESS

THE PATIENT UNDERGOING MASTOID SURGERY

Although several otologic surgical procedures are performed under moderate sedation, mastoid surgery is performed using general anesthesia.

Assessment

The health history includes a complete description of the ear disorder, including infection, otalgia, otorrhea, hearing loss, and vertigo. Data are collected about the duration and intensity of the disorder, its causes, and previous treatments. Information is obtained about other health problems and all medications that the patient is taking. Medication allergies and family history of ear disease also should be obtained.

Physical assessment addresses erythema, edema, otorrhea, lesions, and characteristics such as odor and color of discharge. The results of the audiogram are reviewed.

Nursing Diagnoses

Based on the assessment data, the major nursing diagnoses may include the following:

- Anxiety related to surgical procedure, potential loss of hearing, potential taste disturbance, and potential loss of facial movement
- Acute pain related to mastoid surgery
- Risk for infection related to mastoidectomy; placement of grafts, prostheses, and electrodes; and surgical trauma to surrounding tissues and structures
- Disturbed auditory sensory perception related to ear disorder, surgery, or packing
- Risk for trauma related to impaired balance or vertigo during the immediate postoperative period or from dislodgment of the graft or prosthesis
- Disturbed sensory perception related to potential damage to facial nerve (cranial nerve VII) and chorda tympani nerve
- Deficient knowledge about mastoid disease, surgical procedure, and postoperative care and expectations

Planning and Goals

The major goals of caring for a patient undergoing mastoidectomy include reduction of anxiety; freedom from pain and discomfort; prevention of infection; stable or improved hearing and communication; absence of vertigo and related injury; absence of or adjustment to sensory or perceptual alterations; and increased knowledge regarding the disease, surgical procedure, and postoperative care.

Nursing Interventions

Reducing Anxiety

The nurse reinforces the information discussed by the otologic surgeon with the patient, including anesthesia, the location of the incision (postauricular), and expected surgical results (eg, hearing, balance, taste, facial movement). The patient also is encouraged to discuss any anxieties and concerns about the surgery.

Relieving Pain

Although most patients complain very little about incisional pain after mastoid surgery, they do have some ear discomfort. Aural fullness or pressure after surgery is caused by residual blood or fluid in the middle ear. The prescribed analgesic medication may be taken for the first 24 hours after surgery and then only as needed.

A wick or external auditory canal packing is used if a tympanoplasty was performed at the time of the mastoidectomy. For the next 2 to 3 weeks after surgery, the patient may experience sharp, shooting pains intermittently as the eustachian tube opens and allows air to enter the middle ear. Constant, throbbing pain accompanied by fever may indicate infection and should be reported to the physician.

Preventing Infection

Measures are initiated to prevent infection in the operated ear. The external auditory canal wick, or packing, may be impregnated with an antibiotic solution before instillation. Prophylactic antibiotics are administered as prescribed, and the patient is instructed to prevent water from entering the external auditory canal for 6 weeks. A cotton ball or lamb's wool covered with a water-insoluble substance (eg, petroleum jelly) and placed loosely in the ear canal usually prevents water contamination and should be used when the patient showers or washes his or her hair, or in any situations in which water may enter the ear. The postauricular incision should be kept dry for the first 2 days. Signs of infection such as an elevated temperature and purulent drainage should be reported. Some serosanguineous drainage from the external auditory canal is normal after surgery.

Improving Hearing and Communication

Hearing in the operated ear may be reduced for several weeks because of edema, accumulation of blood and tissue fluid in the middle ear, and dressings or packing. Measures are initiated to improve hearing and communication, such as reducing environmental noise, facing the patient when speaking, speaking clearly and distinctly without shouting, providing good lighting if the patient relies on speech reading, and using nonverbal clues (eg, facial expression, pointing, gestures)

and other forms of communication. Family members or significant others are instructed about effective ways to communicate with the patient. If the patient uses assistive hearing devices, one can be used in the unaffected ear.

Preventing Injury

Vertigo may occur after mastoid surgery if the semicircular canals or other areas of the inner ear are traumatized. Antiemetic or antivertiginous medications (eg, antihistamines) can be prescribed if a balance disturbance or vertigo occurs. Safety measures such as assisted ambulation are implemented to prevent falls and injury. The patient is instructed to avoid heavy lifting, straining, exertion, and nose blowing for 2 to 3 weeks after surgery to prevent dislodging the tympanic membrane graft or ossicular prosthesis.

Preventing Altered Sensory Perception

Facial nerve injury is a potential, although rare, complication of mastoid surgery. The patient is instructed to report immediately any evidence of facial nerve (cranial nerve VII) weakness, such as drooping of the mouth on the operated side, slurred speech, decreased sensation, and difficulty swallowing. A more frequent occurrence is a temporary disturbance in the chorda tympani nerve, a small branch of the facial nerve that runs through the middle ear. Patients experience a taste disturbance and dry mouth on the side of surgery for several months until the nerve regenerates.

Promoting Home and Community-Based Care

TEACHING PATIENTS SELF-CARE. Patients require instruction about medication therapy, such as analgesic and antivertiginous agents (eg, antihistamines) prescribed for balance disturbance. Teaching includes information about the expected effects and potential side effects of the medication. Patients also need instruction about any activity restrictions. Possible complications such as infection, facial nerve weakness, or taste disturbances, including the signs and symptoms to report immediately, should be addressed (Chart 59-6).

CONTINUING CARE. Some patients, particularly elderly patients, who have had mastoid surgery may require the services of a home care nurse for a few days after returning home. However, most people find that assistance from a family member or a friend is sufficient. The caregiver and patient are cautioned that the patient may experience some vertigo and will therefore require help with ambulation to avoid falling. Any symptoms of complications are to be reported promptly to the surgeon. The importance of scheduling and keeping follow-up appointments is also stressed.

Evaluation

Expected Patient Outcomes

Expected patient outcomes may include:

1. Demonstrates reduced anxiety about surgical procedure
 - a. Verbalizes and exhibits less stress, tension, and irritability
 - b. Verbalizes acceptance of the results of surgery and adjustment to possible hearing impairment

CHART
59-6

PATIENT EDUCATION

Self-Care After Middle Ear or Mastoid Surgery

Postoperative instructions for patients who have had middle ear and mastoid surgery may vary among otolaryngologists. General teaching guidelines for the patient may include:

- Take antibiotics and other medications as prescribed.
 - Avoid nose blowing for 2 to 3 weeks after surgery.
 - Sneeze and cough with the mouth open for a few weeks after surgery.
 - Avoid heavy lifting (>10 lb), straining, and bending over for a few weeks after surgery.
 - Popping and crackling sensations in the operative ear are normal for approximately 3 to 5 weeks after surgery.
 - Temporary hearing loss is normal in the operative ear due to fluid, blood, or packing in the ear.
 - Report excessive or purulent ear drainage to the physician.
 - Avoid getting water in the operative ear for 2 weeks after surgery. You may shampoo the hair 2 to 3 days postoperatively if the ear is protected from water by saturating a cotton ball with petroleum jelly (or some other water-insoluble substance) and loosely placing it in the ear. If the postauricular suture line becomes wet, pat (not rub) the area and cover it with a thin layer of antibiotic ointment.
2. Remains free of discomfort or pain
 - a. Exhibits no facial grimacing, moaning, or crying, and reports absence of pain
 - b. Uses analgesic agents appropriately
 3. Demonstrates no signs or symptoms of infection
 - a. Has normal vital signs, including temperature
 - b. Demonstrates absence of purulent drainage from the external auditory canal
 - c. Describes method for preventing water from contaminating packing
 4. Exhibits signs that hearing has stabilized or improved
 - a. Describes surgical goal for hearing and judges whether the goal has been met
 - b. Verbalizes that hearing has improved
 5. Remains free of injury and trauma
 - a. Reports absence of vertigo or balance disturbance
 - b. Experiences no injury or fall
 - c. Avoids activities that can cause dislodgement of graft or prosthesis
 6. Adjusts to or remains free from altered sensory perception
 - a. Reports no taste disturbance, mouth dryness, or facial weakness
 7. Verbalizes the reasons for and methods of care and treatment
 - a. Discusses the discharge plan formulated with the nurse with regard to rest periods, medication, and activities permitted and restricted
 - b. Lists symptoms that should be reported to health care personnel
 - c. Keeps follow-up appointments

Otosclerosis

Otosclerosis involves the stapes and is thought to result from the formation of new, abnormal spongy bone, especially around the oval window, with resulting fixation of the stapes. The efficient transmission of sound is prevented because the stapes cannot vibrate and carry the sound as conducted from the malleus and incus to the inner ear. Otosclerosis is more common in women and frequently hereditary, and pregnancy may worsen it.

Clinical Manifestations

Otosclerosis may involve one or both ears and manifests as a progressive conductive or mixed hearing loss. The patient may or may not complain of tinnitus. Otoscopy examination usually reveals a normal tympanic membrane. Bone conduction is better than air conduction on Rinne testing. The audiogram confirms conductive hearing loss or mixed loss, especially in the low frequencies.

Medical Management

There is no known nonsurgical treatment for otosclerosis. However, some physicians believe the use of sodium fluoride can mature the abnormal spongy bone growth and prevent the breakdown of the bone tissue. Amplification with a hearing aid also may help (Porth & Matfin, 2009).

Surgical Management

One of two surgical procedures may be performed, the stapedectomy or the stapedotomy. A stapedectomy involves removing the stapes superstructure and part of the footplate and inserting a tissue graft and a suitable prosthesis (Fig. 59-6). The surgeon drills a small hole into the footplate to hold a prosthesis. The prosthesis bridges the gap between the incus and the inner ear, providing better sound conduction. Approximately 95% of patients experience resolution of conductive hearing loss following stapes surgery. Balance disturbance or true vertigo may occur during the postoperative period for several days. Long-term balance disorders are rare.

Middle Ear Masses

Other than cholesteatoma, masses in the middle ear are rare. Glomus tympanicum is a tumor that arises from Jacobson's nerve (in the temporal bone of the skull) and remains limited to the middle ear. On otoscopy, a red blemish on or behind the tympanic membrane is seen. Glomus jugulare tumors are rarely malignant; however, because of their location, treatment may be necessary to relieve symptoms. The treatment is surgical excision, except in poor surgical candidates, in whom radiation therapy is used.

A facial nerve neuroma is a tumor on cranial nerve VII. These types of tumors are usually not visible on otoscopic

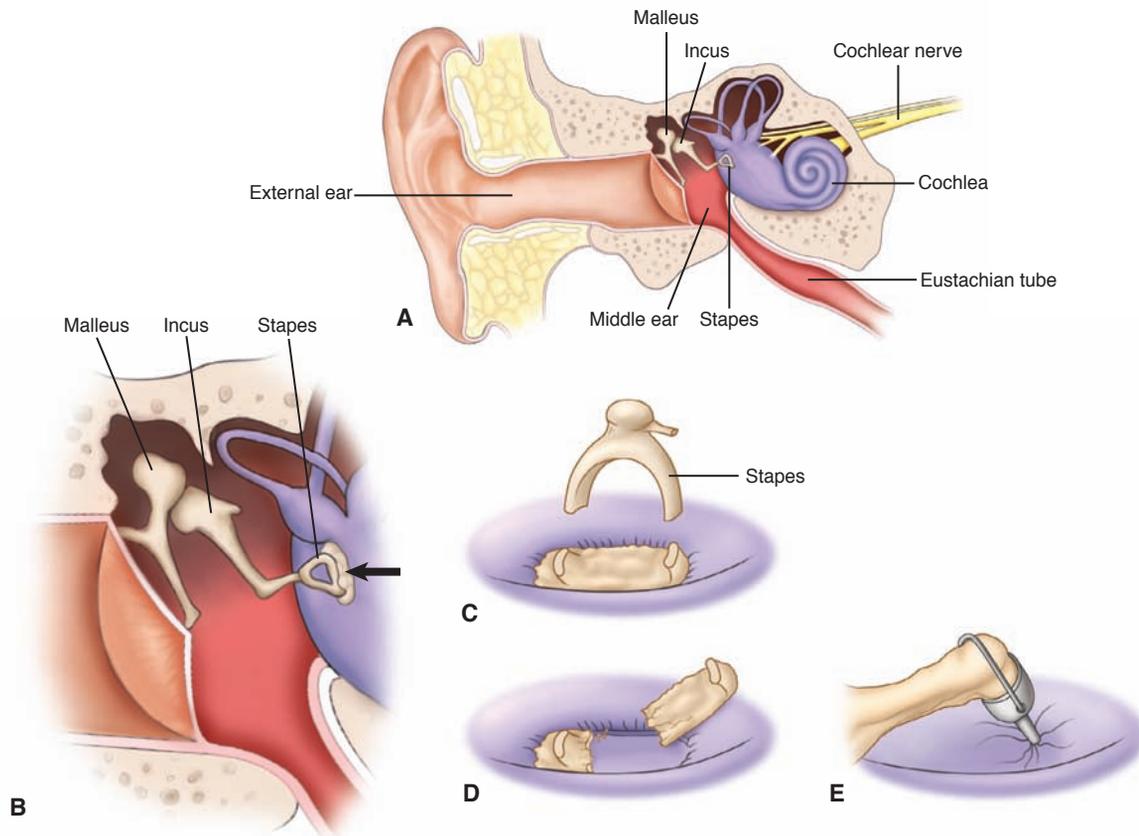

Figure 59-6 Stapedectomy for otosclerosis. **A**, Normal anatomy. **B**, Arrow points to sclerotic process at the foot of the stapes. **C**, Stapes broken away surgically from its diseased base. The hole in the footplate provides an area where an instrument can grasp the plate. **D**, The footplate is removed from its base. Some otosclerotic tissue may remain, and tissue is placed over it. **E**, Robinson stainless steel prosthesis in position.

examination but are suspected when a patient presents with a facial nerve paresis. X-ray evaluation is used to identify the site of the tumor along the facial nerve. The treatment is surgical removal.

CONDITIONS OF THE INNER EAR

Almost 8 million American adults are affected by a chronic problem with balance and an additional 2.4 million are affected by dizziness alone. Disorders of balance are a major cause of falls of elderly people (NIDCD, 2005).

The term **dizziness** is used frequently by patients and health care providers to describe any altered sensation of orientation in space. **Vertigo** is defined as the misperception or illusion of motion of the person or the surroundings. Most people with vertigo describe a spinning sensation or say they feel as though objects are moving around them. Ataxia is a failure of muscular coordination and may be present in patients with vestibular disease. Syncope, fainting, and loss of consciousness are not forms of vertigo and usually indicate disease in the cardiovascular system.

Nystagmus is an involuntary rhythmic movement of the eyes. Nystagmus occurs normally when a person watches a rapidly moving object (eg, through the side window of a moving car or train). However, pathologically it is an ocular disorder associated with vestibular dysfunction. Nystag-

mus can be horizontal, vertical, or rotary and can be caused by a disorder in the central or peripheral nervous system.

Motion Sickness

Motion sickness is a disturbance of equilibrium caused by constant motion. For example, it can occur aboard a ship, while riding on a merry-go-round or swing, or in a car.

Clinical Manifestations

The syndrome manifests itself in sweating, pallor, nausea, and vomiting caused by vestibular overstimulation. These manifestations may persist for several hours after the stimulation stops.

Management

Over-the-counter antihistamines such as dimenhydrinate (Dramamine) or meclizine hydrochloride (Antivert) may provide some relief of nausea and vomiting by blocking the conduction of the vestibular pathway of the inner ear. Anticholinergic medications, such as scopolamine patches, may also be effective because they antagonize the histamine response. These must be replaced every few days. Side effects such as dry mouth and drowsiness may occur. Potentially hazardous activities such as driving a car or operating heavy machinery should be avoided if drowsiness occurs.

Ménière's Disease

Ménière's disease is an abnormal inner ear fluid balance caused by a malabsorption in the endolymphatic sac or a blockage in the endolymphatic duct. **Endolymphatic hydrops**, a dilation in the endolymphatic space, develops, and either increased pressure in the system or rupture of the inner ear membrane occurs, producing symptoms of Ménière's disease.

Ménière's disease affects 15 to 50 people per 100,000 people in the United States (Kitahara, Kubo, Okumura, et al., 2008). More common in adults, it has an average age of onset in the 40s, with symptoms usually beginning between the ages of 20 and 60 years. Ménière's disease appears to be equally common in men and women, and it occurs bilaterally in about 20% of patients. About 50% of the patients who have Ménière's disease have a positive family history of the disease.

Clinical Manifestations

Symptoms of Ménière's disease include fluctuating, progressive sensorineural hearing loss; **tinnitus** or a roaring sound; a feeling of pressure or fullness in the ear; and episodic, incapacitating vertigo, often accompanied by nausea and vomiting. These symptoms range in severity from a minor nuisance to extreme disability, especially if the attacks of vertigo are severe. At the onset of the disease, perhaps only one or two of the symptoms are manifested.

Some clinicians believe that there are two subsets of the disease: cochlear and vestibular. Cochlear Ménière's disease is recognized as a fluctuating, progressive sensorineural hearing loss associated with tinnitus and aural pressure in the absence of vestibular symptoms or findings. Vestibular Ménière's disease is characterized as the occurrence of episodic vertigo associated with aural pressure but no cochlear symptoms. Patients may experience either cochlear or vestibular disease symptoms; however, eventually all of these symptoms develop.

Assessment and Diagnostic Findings

Vertigo is usually the most troublesome complaint related to Ménière's disease. A careful history is taken to determine the frequency, duration, severity, and character of the vertigo attacks. Vertigo may last minutes to hours, possibly accompanied by nausea or vomiting. Diaphoresis and a persistent feeling of imbalance or disequilibrium may awaken patients at night. Some patients report that these feelings last for days. However, they usually feel well between attacks. Hearing loss may fluctuate, with tinnitus and aural

pressure waxing and waning with changes in hearing. These feelings may occur during or before attacks, or they may be constant.

Physical examination findings are usually normal, with the exception of those of cranial nerve VIII. Sounds from a tuning fork (Weber test) may lateralize to the ear opposite the hearing loss, the one affected with Ménière's disease. An audiogram typically reveals a sensorineural hearing loss in the affected ear. This can be in the form of a "Pike's Peak" pattern, which looks like a hill or mountain. A sensorineural loss in the low frequencies occurs as the disease progresses. The electronystagmogram may be normal or may show reduced vestibular response.

Medical Management

Most patients with Ménière's disease can be successfully treated with diet and medication. Many patients can control their symptoms by adhering to a low-sodium (1000 to 1500 mg/day or less) diet. Chart 59-7 describes dietary guidelines that may be useful in Ménière's disease. The amount of sodium is one of many factors that regulate the balance of fluid within the body. Sodium and fluid retention disrupts the delicate balance between endolymph and perilymph in the inner ear. Psychological evaluation may be indicated if a patient is anxious, uncertain, fearful, or depressed.

Pharmacologic Therapy

Pharmacologic therapy for Ménière's disease consists of antihistamines, such as meclizine (Antivert), which suppress the vestibular system. Tranquilizers such as diazepam (Valium) may be used in acute instances to help control vertigo. Antiemetic agents such as promethazine (Phenergan) suppositories help control the nausea and vomiting and the vertigo because of their antihistamine effect. Diuretic therapy (eg, hydrochlorothiazide [Dyazide], triamterene [Dyrenium]) may relieve symptoms by lowering the pressure in the endolymphatic system. Intake of foods containing potassium (eg, bananas, tomatoes, oranges) is necessary if the patient takes a diuretic that causes potassium loss. There is no scientific basis for the use of vasodilators, such as papaverine hydrochloride (Pavabid) to alleviate the symptoms, but they are often used in conjunction with other therapies, such as methantheline bromide (Banthine).

In patients who may be noncompliant with the therapeutic regimen, intratympanic injection of gentamicin (Garamycin) is being used to cause ablation of the vestibular

CHART
59-7

PATIENT EDUCATION

Dietary Guidelines for Patients With Ménière's Disease

- Limit foods high in salt or sugar. Be aware of foods with hidden salts and sugars.
- Eat meals and snacks at regular intervals to stay hydrated. Missing meals or snacks may alter the fluid level in the inner ear.
- Eat fresh fruits, vegetables, and whole grains. Limit the amount of canned, frozen, or processed foods with high sodium content.
- Drink plenty of fluids daily. Water, milk, and low-sugar fruit juices are recommended. Limit intake of coffee, tea, and soft drinks. Avoid caffeine because of its diuretic effect.
- Limit alcohol intake. Alcohol may change the volume and concentration of the inner ear fluid and may worsen symptoms.
- Avoid monosodium glutamate (MSG), which may increase symptoms.
- Avoid aspirin and aspirin-containing medications. Aspirin may increase tinnitus and dizziness.

hair cells. However, the risk of significant hearing loss is high (Swartz & Longwell, 2005).

Surgical Management

Although most patients respond well to conservative therapy, some continue to have disabling attacks of vertigo. If these attacks reduce their quality of life, patients may elect to undergo surgery for relief. Surgical procedures include endolymphatic sac procedures and vestibular nerve section. However, hearing loss, tinnitus, and aural fullness may continue, because the surgical treatment of Ménière's disease is aimed at eliminating the attacks of vertigo (Mayo Clinic, 2008).

Endolymphatic Sac Decompression

Endolymphatic sac decompression, or shunting, theoretically equalizes the pressure in the endolymphatic space. A shunt or drain is inserted in the endolymphatic sac through a postauricular incision. This procedure is favored by many otolaryngologists as a first-line surgical approach to treat the vertigo of Ménière's disease because it is relatively simple and safe and can be performed on an outpatient basis.

Vestibular Nerve Sectioning

Vestibular nerve sectioning provides the greatest success rate (approximately 98%) in eliminating the attacks of vertigo. It can be performed by a translabyrinthine approach (ie, through the hearing mechanism) or in a manner that can conserve hearing (ie, suboccipital or middle cranial fossa), depending on the degree of hearing loss. Most patients with incapacitating Ménière's disease have little or no effective hearing. Cutting the nerve prevents the brain from receiving input from the semicircular canals. This procedure may require a brief hospital stay. A plan of nursing care for the patient with vertigo is presented in Chart 59-8.

Benign Paroxysmal Positional Vertigo

Benign paroxysmal positional vertigo is a brief period of incapacitating vertigo that occurs when the position of the patient's head is changed with respect to gravity, typically by placing the head back with the affected ear turned down. The onset is sudden and followed by a predisposition for positional vertigo, usually for hours to weeks but occasionally for months or years.

Benign paroxysmal positional vertigo is thought to be due to the disruption of debris within the semicircular canal. This debris is formed from small crystals of calcium carbonate from the inner ear structure, the utricle. This is frequently stimulated by head trauma, infection, or other events. In severe cases, vertigo may easily be induced by any head movement. The vertigo is usually accompanied by nausea and vomiting; however, hearing impairment does not generally occur (Labuguen, 2006).

Bed rest is recommended for patients with acute symptoms. There are repositioning techniques that can be used to treat vertigo. The canalith repositioning procedure is commonly used. This noninvasive procedure, which involves quick movements of the body, rearranges the debris in the canal. The procedure is performed by placing the patient in a sitting position, turning the head to a 45-degree angle on the affected

side, and then quickly moving the patient to the supine position. The procedure is safe, inexpensive, and easy to perform.

Patients with acute vertigo may be treated with meclizine for 1 to 2 weeks. After this time, the meclizine is stopped, and the patient is reassessed. Patients who continue to have severe positional vertigo may be premedicated with prochlorperazine (Compazine) 1 hour before the canalith repositioning procedure is performed.

Vestibular rehabilitation can be used in the management of vestibular disorders. This strategy promotes active use of the vestibular system through an interdisciplinary team approach, including medical and nursing care, stress management, biofeedback, vocational rehabilitation, and physical therapy. A physical therapist prescribes balance exercises that help the brain compensate for the impairment to the balance system (Swartz & Longwell, 2005).

Tinnitus

Tinnitus is a symptom of an underlying disorder of the ear that is associated with hearing loss. This condition affects approximately 37 million people in the United States, and it is most prevalent between 40 and 70 years of age (Porth & Matfin, 2009). The severity of tinnitus may range from mild to severe. Patients describe tinnitus as a roaring, buzzing, or hissing sound in one or both ears. Numerous factors may contribute to the development of tinnitus, including several ototoxic substances (Chart 59-9). Underlying disorders that contribute to tinnitus may include thyroid disease, hyperlipidemia, vitamin B₁₂ deficiency, psychological disorders (eg, depression, anxiety), fibromyalgia, otologic disorders (Ménière's disease, acoustic neuroma), and neurologic disorders (head injury, multiple sclerosis).

A physical examination should be performed to determine the cause of tinnitus. Diagnostic testing determines if hearing loss is present. An audiograph speech discrimination test or a tympanogram may be used to help determine the cause. Some forms of tinnitus are irreversible; therefore, patients may need teaching and counseling about ways of adjusting to their treatment and dealing with tinnitus in the future.

Labyrinthitis

Labyrinthitis, an inflammation of the inner ear, can be bacterial or viral in origin. Bacterial labyrinthitis is rare because of antibiotic therapy, but it sometimes occurs as a complication of otitis media. The infection can spread to the inner ear by penetrating the membranes of the oval or round windows. Viral labyrinthitis is a common diagnosis, but little is known about this disorder, which affects hearing and balance. The most common viral causes are mumps, rubella, rubeola, and influenza. Viral illnesses of the upper respiratory tract and herpetiform disorders of the facial and acoustic nerves (ie, Ramsay Hunt syndrome) also cause labyrinthitis.

Clinical Manifestations

Labyrinthitis is characterized by a sudden onset of incapacitating vertigo, usually with nausea and vomiting, various degrees of hearing loss, and possibly tinnitus. The first

PLAN OF NURSING CARE
Care of the Patient With Vertigo

NURSING DIAGNOSIS: Risk for injury related to altered mobility because of gait disturbance and vertigo
GOAL: Remains free of any injuries associated with imbalance and/or falls

Nursing Interventions	Rationale	Expected Outcomes
<ol style="list-style-type: none"> 1. Assess for vertigo, including history, onset, description of attacks, duration, frequency, and any associated ear symptoms (hearing loss, tinnitus, aural fullness). 2. Assess extent of disability in relation to activities of daily living. 3. Teach or reinforce vestibular/balance therapy as prescribed. 4. Administer, or teach administration of, antivertiginous medications and/or vestibular sedation medication; instruct patient about side effects. 5. Encourage patient to sit down when dizzy. 6. Place pillow on each side of head to restrict movement. 7. Assist patient in identifying aura that suggests an impending attack. 8. Recommend that the patient keep eyes open and stare straight ahead when lying down and experiencing vertigo. 	<ol style="list-style-type: none"> 1. History provides basis for interventions. 2. Extent of disability indicates risk of falling. 3. Exercises hasten labyrinthine compensation, which may decrease vertigo and gait disturbance. 4. Alleviates acute symptoms of vertigo 5. Decreases possibility of falling and injury 6. Movement aggravates vertigo. 7. Recognition of aura may trigger the need to take medication before an attack occurs, thereby minimizing the severity of effects. 8. Sensation of vertigo decreases and motion decelerates if eyes are kept in a fixed position. 	<ul style="list-style-type: none"> • Experiences no falls due to balance disturbance • Fear and anxiety are reduced. • Performs exercises as prescribed • Takes prescribed medications appropriately • Assumes safe position when vertigo is present • Keeps head still when vertigo is present • Identifies a characteristic fullness or sense of pressure in the ear as occurring before a full-blown attack • Reports measures that help reduce vertigo

NURSING DIAGNOSIS: Risk-prone health behavior related to disability requiring change in lifestyle due to unpredictability of vertigo
GOAL: Modifies lifestyle to decrease disability and exert maximum control and independence within limits posed by chronic vertigo

Nursing Interventions	Rationale	Expected Outcomes
<ol style="list-style-type: none"> 1. Encourage patient to identify personal strengths and roles that can still be fulfilled. 2. Provide information about vertigo and what to expect. 3. Include family and significant others in rehabilitative process. 4. Encourage patient to maintain sense of control by making decisions and assuming more responsibility for care. 	<ol style="list-style-type: none"> 1. Maximizes sense of regaining control and independence 2. Reduces fear and anxiety 3. Perceived beliefs of significant others are important for patient's adherence to medical regimen. 4. Reinforces positive psychological and social outcomes 	<ul style="list-style-type: none"> • Exerts maximum control of environment and independence within limits imposed by vertigo • Is informed about condition • Family and significant others are included in rehabilitation process. • Uses strengths and potentials to engage in the most independent and constructive lifestyle

NURSING DIAGNOSIS: Risk for deficient fluid volume related to increased fluid output, altered intake, and medications
GOAL: Maintains normal fluid and electrolyte balance

Nursing Interventions	Rationale	Expected Outcomes
<ol style="list-style-type: none"> 1. Assess, or have patient assess, intake and output (including emesis, liquid stools, urine, and diaphoresis). Monitor laboratory values. 	<ol style="list-style-type: none"> 1. Accurate records provide basis for fluid replacement. 	<ul style="list-style-type: none"> • Laboratory values within normal limits • Alert and oriented; vital signs within normal limits, skin turgor normal; electrolytes normal

PLAN OF NURSING CARE

Care of the Patient With Vertigo (Continued)

<p>Nursing Interventions</p> <ol style="list-style-type: none"> 2. Assess indicators of dehydration, including blood pressure (orthostasis), pulse, skin turgor, mucous membranes, and level of consciousness. 3. Encourage oral fluids as tolerated; discourage beverages containing caffeine (a vestibular stimulant). 4. Administer, or teach administration of, antiemetic and antidiarrheal medications as prescribed and needed. Instruct patient in side effects. 	<p>Rationale</p> <ol style="list-style-type: none"> 2. Prompt recognition of dehydration allows early intervention. 3. Oral replacement is begun as soon as possible to replace losses. Caffeine may increase diarrhea. 4. Antiemetics medications reduce nausea and vomiting, reducing fluid losses and improving oral intake. Antidiarrheal medication reduces intestinal motility and fluid losses. 	<p>Expected Outcomes</p> <ul style="list-style-type: none"> • Mucous membranes are moist. • Vomiting or diarrhea has stopped; usual oral intake resumed
<p>NURSING DIAGNOSIS: Anxiety related to threat of, or change in, health status and disability effects of vertigo GOAL: Experiences less or no anxiety</p>		
<p>Nursing Interventions</p> <ol style="list-style-type: none"> 1. Assess level of anxiety. Help patient identify coping skills used successfully in the past. 2. Provide information about vertigo and its treatment. 3. Encourage patient to discuss anxieties and explore concerns about vertigo attacks. 4. Teach patient stress management techniques or make appropriate referral. 5. Provide comfort measures and avoid stress-producing activities. 6. Instruct patient in aspects of treatment regimen. 	<p>Rationale</p> <ol style="list-style-type: none"> 1. Guides therapeutic interventions and participation in self-care. Past coping skills can relieve anxiety. 2. Increased knowledge helps to decrease anxiety. 3. Promotes awareness and understanding of relationship between anxiety level and behavior 4. Improved stress management can reduce the frequency and severity of some vertiginous attacks. 5. Stressful situations may exacerbate symptoms of the condition. 6. Patient knowledge helps to decrease anxiety. 	<p>Expected Outcomes</p> <ul style="list-style-type: none"> • Fear and anxiety about attacks of vertigo reduced or eliminated • Acquires knowledge and skills to deal with vertigo • Feels less tension, apprehension, and uncertainty • Uses stress management techniques when needed • Avoids upsetting encounters • Repeats instructions given and verbalizes understanding of treatments
<p>NURSING DIAGNOSIS: Risk for trauma related to impaired balance GOAL: Reduces the risk of trauma by adapting the home environment and by using assistive devices as necessary</p>		
<p>Nursing Interventions</p> <ol style="list-style-type: none"> 1. Assess for balance disturbance and/or vertigo by taking history and by examination for nystagmus, positive Romberg, and inability to perform tandem Romberg. 2. Assist with ambulation when indicated. 3. Assess for visual acuity and proprioceptive deficits. 4. Encourage increased activity level with or without use of assistive devices. 5. Help identify hazards in home environment. 	<p>Rationale</p> <ol style="list-style-type: none"> 1. Peripheral vestibular disorders cause these signs and symptoms. 2. Abnormal gait can predispose patient to unsteadiness and falls. 3. Balance depends on visual, vestibular, and proprioceptive systems. 4. Increased activity may help retrain balance system. 5. Adaptation of home environment can reduce risk of falls during rehabilitative process. 	<p>Expected Outcomes</p> <ul style="list-style-type: none"> • Has adapted home environment or uses rehabilitative devices to reduce risk of falling • Ambulates with needed assistance • Visual and proprioceptive risks identified • Activity level increased • Home environment free of hazards
<p>NURSING DIAGNOSIS: Self-care deficit: feeding, bathing/hygiene, dressing/grooming, toileting, related to labyrinth dysfunction and episodes of vertigo GOAL: Able to care for self</p>		
<p>Nursing Interventions</p> <ol style="list-style-type: none"> 1. Administer, or teach administration of, antiemetic and other prescribed medications to relieve nausea and vomiting associated with vertigo. 	<p>Rationale</p> <ol style="list-style-type: none"> 1. Antiemetic and sedative-type medications depress stimuli in the cerebellum. 	<p>Expected Outcomes</p> <ul style="list-style-type: none"> • Carries out necessary functions during symptom-free periods. Takes medications to relieve nausea, vomiting, or vertigo

CHART
59-8

PLAN OF NURSING CARE
Care of the Patient With Vertigo (Continued)

Nursing Interventions

2. Encourage patient to perform self-care when free of vertigo.
3. Review diet with patient and caregivers. Offer fluids as necessary.

Rationale

2. Spacing activities is important because episodes of vertigo vary in occurrence.
3. Sodium restriction helps improve an inner ear fluid imbalance in some patients, thereby decreasing vertigo. Fluids help prevent dehydration.

Expected Outcomes

- Carries out daily activities
- Accepts dietary plan and reports its effectiveness.
- Drinks fluids in sufficient amounts

NURSING DIAGNOSIS: Powerlessness related to illness regimen and being helpless in certain situations due to vertigo/balance disturbance

GOAL: Experiences increased sense of control over life and activities despite vertigo/balance disturbance

Nursing Interventions

1. Assess patient's needs, values, attitudes, and readiness to initiate activities.
2. Provide opportunities for patient to express feelings about self and illness.
3. Help patient identify previous coping behaviors that were successful.

Rationale

1. Involving patient in planning activities and care enhances potential for mastery.
2. Expressing feelings increases understanding of individual coping styles and defense mechanisms.
3. Awareness increases understanding of stressors that trigger feeling of powerlessness. Awareness of past successes enhances self-confidence.

Expected Outcomes

- Does not restrict activities unnecessarily due to vertigo
- Verbalizes positive feelings about own ability to achieve a sense of power and control
- Identifies previous successful coping behaviors

episode is usually the worst; subsequent attacks, which usually occur over a period of several weeks to months, are less severe.

Management

Treatment of bacterial labyrinthitis includes IV antibiotic therapy, fluid replacement, and administration of an antihistamine (eg, meclizine [Antivert]) and antiemetic medications. Treatment of viral labyrinthitis is based on the patient's symptoms.

Ototoxicity

A variety of medications may have adverse effects on the cochlea, vestibular apparatus, or cranial nerve VIII. All but a few, such as aspirin and quinine, cause irreversible hearing loss. At high doses, aspirin toxicity can produce bilateral tinnitus. IV medications, especially the aminoglycosides, are the most common cause of ototoxicity, and they destroy the hair cells in the organ of Corti (see Chart 59-9).

To prevent loss of hearing or balance, patients receiving potentially ototoxic medications should be counseled about the side effects of these medications. These medications should be used with caution in patients who are at high risk for complications, such as children, the elderly, pregnant patients, patients with kidney or liver problems, and patients with current hearing disorders. Blood levels of the medications should be monitored, and patients receiving long-term IV antibiotics should be monitored with an audiogram twice each week during therapy.

Acoustic Neuroma

Acoustic neuromas are slow-growing, benign tumors of cranial nerve VIII, usually arising from the Schwann cells of the vestibular portion of the nerve. Most acoustic tumors arise within the internal auditory canal and extend into the cerebellopontine angle to press on the brain stem, possibly destroying the vestibular nerve. Most acoustic neuromas are unilateral, except in von Recklinghausen's disease (neurofibromatosis type 2), in which bilateral tumors occur (Porth & Matfin, 2009).

Acoustic neuromas develop in 1 of every 10,000 people per year. These neuromas account for 5% to 10% of all intracranial tumors and seem to occur with equal frequency in men and women at any age, although most occur during middle age.

CHART
59-9

PHARMACOLOGY
Selected Ototoxic Substances

- **Diuretics:** ethacrynic acid, furosemide, acetazolamide
- **Chemotherapeutic agents:** cisplatin, nitrogen mustard
- **Antimalarial agents:** quinine, chloroquine
- **Anti-inflammatory agents:** salicylates (aspirin), indomethacin
- **Chemicals:** alcohol, arsenic
- **Aminoglycoside antibiotics:** amikacin, gentamicin, kanamycin, netilmicin, neomycin, streptomycin, tobramycin
- **Other antibiotics:** erythromycin, minocycline, polymyxin B, vancomycin
- **Metals:** gold, mercury, lead

Assessment and Diagnostic Findings

The most common assessment findings of patients with acoustic neuromas are unilateral tinnitus and hearing loss with or without vertigo or balance disturbance. It is important to identify asymmetry in audiovestibular test results so that further workup can be performed to rule out an acoustic neuroma. MRI with a contrast agent (ie, gadolinium or Magnevist) is the imaging study of choice. If the patient is claustrophobic or cannot undergo an MRI for other reasons or if the scan is unavailable, a CT scan with contrast dye is performed. However, MRI is more sensitive than CT in delineating a small tumor.

Management

Surgical removal of acoustic tumors is the treatment of choice because these tumors do not respond well to radiation or chemotherapy. Because treatment of acoustic tumors crosses several specialties, the interdisciplinary treatment approach involves a neurologist and a neurosurgeon. The objective of the surgery is to remove the tumor while preserving facial nerve function. Most acoustic tumors have damaged the cochlear portion of cranial nerve VIII, and hearing is impaired. In these patients, the surgery is performed using a translabyrinthine approach, and the hearing mechanism is destroyed. If hearing is still good before surgery, a suboccipital or middle cranial fossa approach to removing the tumor may be used. This procedure exposes the lateral third of the internal auditory canal and preserves hearing.

Complications of surgery include facial nerve paralysis, cerebrospinal fluid leakage, meningitis, and cerebral edema. Death from acoustic neuroma surgery is rare.

AURAL REHABILITATION

If hearing loss is permanent or cannot be treated by medical or surgical means or if the patient elects not to undergo surgery, aural rehabilitation may be beneficial. The purpose of aural rehabilitation is to maximize the communication skills of the person with hearing impairment. Aural rehabilitation includes auditory training, speech reading, speech training, and the use of hearing aids and hearing guide dogs.

Auditory training emphasizes listening skills, so the person who is hearing-impaired concentrates on the speaker. Speech reading (also known as lip reading) can help fill the gaps left by missed or misheard words. The goals of speech training are to conserve, develop, and prevent deterioration of current communication skills.

It is important to identify the type of hearing impairment a person has so that rehabilitative efforts can be directed at his or her particular need. Surgical correction may be all that is necessary to treat and improve a conductive hearing loss by eliminating the cause of the hearing loss. With advances in hearing aid technology, amplification for patients with sensorineural hearing loss is more helpful than ever.

Hearing Aids

A hearing aid is a device through which speech and environmental sounds are received by a microphone, converted to electrical signals, amplified, and reconverted to acoustic

Chart 59-10 • Hearing Aid Problems

Whistling Noise

- Loose ear mold
- Improperly made
- Improperly worn
- Worn out

Improper Aid Selection

- Too much power required in aid, with inadequate separation between microphone and receiver
- Open mold used inappropriately

Inadequate Amplification

- Dead batteries
- Cerumen in ear
- Cerumen or other material in mold
- Wires or tubing disconnected from aid
- Aid turned off or volume too low
- Improper mold
- Improper aid for degree of loss

Pain from Mold

- Improperly fitted mold
- Ear skin or cartilage infection
- Middle ear infection
- Ear tumor
- Unrelated conditions of the temporomandibular joint, throat, or larynx

signals. Many aids available for sensorineural hearing loss depress the low frequencies, or tones, and enhance hearing for the high frequencies. A general guideline for assessing the patient's need for a hearing aid is a hearing loss exceeding 30 dB in the range of 500 to 2000 Hz in the better-hearing ear.

A hearing aid makes sounds louder, but it does not improve a patient's ability to discriminate words or understand speech. People who have low discrimination scores (ie, 20%) on audiograms may derive little benefit from a hearing aid. Hearing aids amplify all sounds, including background noise, which may be disturbing to the wearer. Chart 59-10 identifies additional problems associated with hearing aid use. Computerized hearing aids are available to compensate for background noise or allow amplification at certain programmed frequencies rather than at all frequencies. Occasionally, depending on the type of hearing loss, binaural aids (ie, one for each ear) may be indicated. Chart 59-11 provides tips for hearing aid care.

A hearing aid should be fitted according to the patient's needs (eg, type of hearing loss, manual dexterity, and preferences), rather than the brand name, by a certified audiologist licensed to dispense hearing aids. Many states have consumer protection laws that allow the hearing aid to be returned after a trial use if the patient is not completely satisfied. In addition, to protect the health and safety of people with hearing impairments, the U.S. Food and Drug Administration (FDA) has established certain regulations. A medical evaluation of the impairment by a physician must be obtained within 6 months before the purchase of a hearing aid. However, the written statement from a physician may be waived if the patient (a fully informed adult 18 years

CHART
59-11

PATIENT EDUCATION
Tips for Hearing Aid Care

Cleaning

- The ear mold is the only part of the hearing aid that may be washed frequently.
- Wash ear mold daily with soap and water.
- Allow the ear mold to dry completely before it is snapped into the receiver.
- Clean the cannula with a small pipe cleaner–like device.
- Proper care of the ear device and keeping the ear canal clean and dry can prevent complications.

Malfunctioning

- Inadequate amplification, a whistling noise, or pain from the mold can occur when a hearing aid is not functioning properly.
- Check for malfunctions:
 - Is the switch on properly?
 - Are the batteries charged and positioned correctly?
- If the hearing aid is still not working properly, notify the hearing aid dealer.
- If the unit requires extended time for repair, the dealer may lend you a hearing aid until the repair can be accomplished.

Recognizing Complications

- Common medical complications include external otitis media and pressure ulcers in the external auditory canal. Signs and symptoms of these infections include painful ear, especially when the external ear is touched; canal swelling; redness; difficulty hearing; pain radiating to the jaw area; and fever.
- If any of these symptoms are present, notify your health care provider for evaluation. You may need medication to treat infection, pain, or both.

of age or older) signs a document to this effect. Health care professionals who dispense hearing aids are required to refer prospective users to a physician if any of the following otologic conditions are evident:

- Visible congenital or traumatic deformity of the ear
- Active drainage from the ear within the previous 90 days
- Sudden or rapidly progressive hearing loss within the previous 90 days
- Complaints of dizziness or tinnitus

- Unilateral hearing loss that occurred suddenly or within the previous 90 days
- Audiometric air–bone gap of 15 dB or more at 500, 1000, and 2000 Hz
- Significant accumulation of cerumen or a foreign body in the external auditory canal
- Pain or discomfort in the ear

A user instruction brochure is provided with every hearing aid device. In this brochure, the following information is presented:

- Notification that good health practice requires a medical evaluation before purchasing a hearing aid
- Notification that any of the eight otologic conditions previously listed should be investigated by a physician before purchase of a hearing aid
- Instructions for proper use, maintenance, and care of the hearing aid, as well as instructions for replacing or recharging the batteries
- Repair service information
- Description of avoidable conditions that could damage the hearing aid
- List of any known side effects that may warrant physician consultation (eg, skin irritation, accelerated cerumen accumulation)

The evolution in technology has led to the availability of many smaller and more effective hearing aids. It is estimated that 98% of all hearing aids sold today are behind-the-ear, in-the-ear, or in-the-canal types (Table 59-4). One of the newest in-the-ear models is the Lyric, and other new models are being developed. The Lyric is placed in the ear canal just 4 mm from the tympanic membrane. Its volume is controlled by a magnet, and when its batteries no longer function (1 to 4 months), a physician can remove it with the magnet and reinsert a new device. This device does not have many of the problems (eg, feedback noise, overamplification of background noise) associated with other hearing aids, and it does not involve the expense and uncertainty of surgical procedures. However, it is not an option for a person whose ear canal is too narrow to accommodate it.

Implanted Hearing Devices

Three types of implanted hearing devices are commercially available or in the investigational stage: the cochlear implant, the bone conduction device, and the semi-implantable

Table 59-4 HEARING AIDS

Site (and Range of Hearing Loss)	Advantages	Disadvantages
Body, usually on the trunk (mild–profound)	Separation of receiver and microphone prevents acoustic feedback, allowing high amplification. Generally used in a school setting	Bulky; requires long wire, which may be cosmetically displeasing; some loss of high-frequency response
Behind the ear (mild–profound)	Economical; powerful, with no long wires; easily used by children—adapts easily as the child grows, with only the ear mold needing replacement	Large size
In the ear (mild–moderately severe)	One-piece custom fit to contour of ear; no tubes or cords; miniature microphone is located in the ear, which is a more natural placement; more cosmetically appealing due to easy concealment	Smaller size limits output; patients who have arthritis or cannot perform tasks requiring good manual dexterity may have difficulty with the small size of aid and/or battery; can require more repair than the behind-the-ear aid
In the canal (mild–moderately severe)	Same as in-the-ear aids; less visible, so more cosmetically pleasing	Even smaller than in-the-ear aids; requires good manual dexterity

hearing device. Cochlear implants are for patients with little or no hearing. Bone conduction devices, which transmit sound through the skull to the inner ear, are used in patients with a conductive hearing loss if a hearing aid is contraindicated (eg, those with chronic infection). The device is implanted postauricularly under the skin into the skull, and an external device—worn above the ear, not in the canal—transmits the sound through the skin. There are two types of implantable hearing aids. The bone anchored hearing aid (BAHA) is implanted behind the ear in the mastoid area. The middle ear implantation (MEI) is implanted in the middle ear cavity. The BAHA is used for conductive or mixed hearing loss, while the MEI is used for sensorineural hearing loss.

A cochlear implant is an auditory prosthesis used for people with profound sensorineural hearing loss bilaterally who do not benefit from conventional hearing aids. The hearing loss may be congenital or acquired. An implant does not restore normal hearing; rather, it helps the person detect medium to loud environmental sounds and conversation. The implant provides stimulation directly to the auditory nerve, bypassing the nonfunctioning hair cells of the inner ear. The microphone and signal processor, worn outside the body, transmit electrical stimuli to the implanted electrodes. The electrical signals stimulate the auditory nerve fibers and then the brain, where they are interpreted.

Worldwide, more than 112,000 people have received a cochlear implant. In the United States, more than 23,000 adults and 15,500 children have cochlear implants (NIDCD, 2007).

Candidates for a cochlear implant, who are usually at least 1 year of age, are selected after careful screening by otologic history, physical examination, audiologic testing, x-rays, and psychological testing. Criteria for choosing adults who may benefit from a cochlear implant include the following:

- Profound sensorineural hearing loss in both ears
- Inability to hear and recognize speech well with hearing aids

- No medical contraindication to a cochlear implant or general anesthesia
- Indications that being able to hear would enhance the patient's life

The surgery involves implanting a small receiver in the temporal bone through a postauricular incision and placing electrodes into the inner ear (Fig. 59-7). The microphone and transmitter are worn on an external unit. The patient undergoes extensive cochlear rehabilitation with the multidisciplinary team, which includes an audiologist and speech pathologist. Several months may be needed to learn to interpret the sounds heard. Children and adults who lost their hearing before they learned to speak take much longer to acquire speech. There are wide variations of success with cochlear implants, and there is also controversy about their use, especially among the deaf community. Patients who have had a cochlear implant are cautioned that an MRI will inactivate the implant; MRI should be used only when there is no other diagnostic option.

Hearing Guide Dogs

Specially trained dogs (service dogs) are available to assist the person with a hearing loss. People who live alone are eligible to apply for a dog trained by International Hearing Dog, Inc. The dog reacts to the sound of a telephone, a doorbell, an alarm clock, a baby's cry, a knock at the door, a smoke alarm, or an intruder. The dog alerts its master by physical contact; the dog then runs to the source of the noise. In public, the dog positions itself between the person with hearing impairment and any potential hazard that the person cannot hear, such as an oncoming vehicle or a loud, hostile person. In many states, a certified hearing guide dog is legally permitted access to public transportation, public eating places, and stores, including food markets.

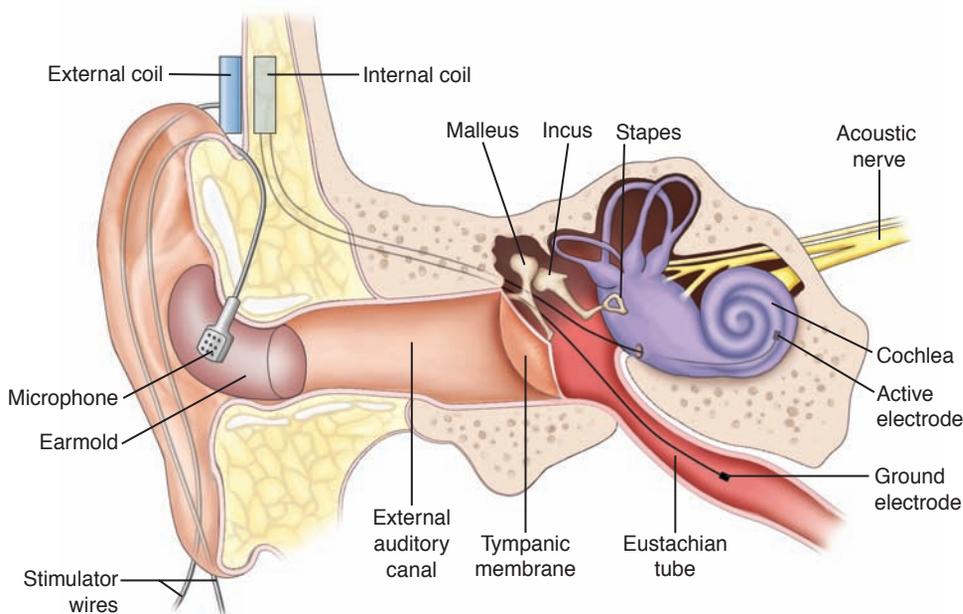

Figure 59-7 The cochlear implant. The internal coil has a stranded electrode lead. The electrode is inserted through the round window into the scala tympani of the cochlea. The external coil (the transmitter) is held in alignment with the internal coil (the receiver) by a magnet. The microphone receives the sound. The stimulator wire receives the signal after it has been filtered, adjusted, and modified so that the sound is at a comfortable level for the patient. Sound is passed by the external transmitter to the inner coil receiver by magnetic conduction and is then carried by the electrode to the cochlea.

CRITICAL THINKING EXERCISES

1 You are a new nurse in the outpatient clinic and you notice that many of the preoperative patients whom you interview have some type of hearing impairment. Discuss barriers for patients with hearing impairment and techniques you can use to assess hearing. List how you can improve your practice and communication techniques with patients who are hearing-impaired.

EBP 2 A 20-year-old man, a member of a college swim team, has recurrent external otitis—his third episode in the past 6 weeks. He is being treated at an ear-nose-throat clinic. Devise an evidence-based practice teaching plan for this patient.

3 A 44-year-old man has recently been diagnosed with Ménière's disease. Develop a teaching plan that focuses on control of the patient's symptoms. Provide rationale for each component of the teaching plan. Discuss the strength of the evidence that supports specific dietary strategies for controlling the symptoms of Ménière's disease.

4 A 50-year-old man is scheduled for coronary artery bypass graft surgery. He has been profoundly deaf since childhood. How should the preoperative and postoperative plans of nursing care be modified to meet this patient's communication needs? How would you modify discharge teaching for him?

unit 14

Neurologic Function

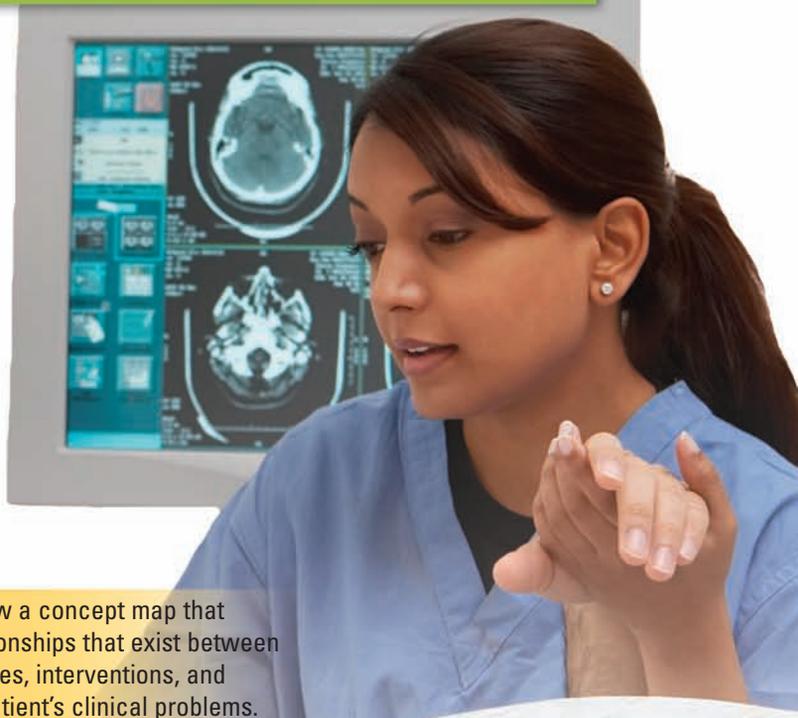

Case Study • Applying Concepts From NANDA, NIC, and NOC

A Patient With Brain Injury and a History of Alcohol Abuse

Mr. Williams is a 36-year-old man with a history of alcohol abuse. On the evening before his admission to the hospital, Mr. Williams fell down a flight of stairs while intoxicated, hitting the front and left side of his head. He was admitted to the neurologic intensive care unit (NICU) and diagnosed with a traumatic brain injury. After several days in the NICU, Mr. Williams developed increased intracranial pressure (ICP) and is being treated for alcohol withdrawal. When family members come to visit, they admit to a significant history of alcoholism in the family.

Visit thePoint to view a concept map that illustrates the relationships that exist between the nursing diagnoses, interventions, and outcomes for the patient's clinical problems.

Nursing Classifications and Languages

NANDA NURSING DIAGNOSES	NIC NURSING INTERVENTIONS	NOC NURSING OUTCOMES
		Return to functional baseline status, stabilization of, or improvement in:
DECREASED INTRACRANIAL ADAPTIVE CAPACITY —Intracranial fluid dynamic mechanisms that normally compensate for increases in intracranial volumes are compromised, resulting in repeated disproportionate increases in increased intracranial pressure (ICP) in response to a variety of noxious stimuli	NEUROLOGIC MONITORING —Collection and analysis of patient data to prevent or minimize neurologic complications	NEUROLOGICAL STATUS —Ability of the peripheral and central nervous system to receive, process, and respond to internal and external stimuli
RISK FOR INJURY —At risk of injury as a result of environmental conditions interacting with the individual’s adaptive and defensive resources	CEREBRAL EDEMA MANAGEMENT —Limitation of secondary cerebral injury resulting from swelling of brain tissue	SEIZURE CONTROL —Personal actions to reduce or minimize the occurrence of seizure episodes
DYSFUNCTIONAL FAMILY PROCESSES: ALCOHOLISM —Psychosocial, spiritual, and physiological functions of the family unit are chronically disorganized, which leads to conflict, denial of problems, resistance to change, ineffective problem solving, and a series of self-perpetuating crises	MEDICATION ADMINISTRATION —Preparing, giving, and evaluating the effectiveness of prescription and nonprescription drugs	PHYSICAL INJURY SEVERITY —Severity of injuries from trauma
	SURVEILLANCE: SAFETY —Purposeful and ongoing collection and analysis of information about the patient and the environment for use in promoting and maintaining patient safety	FAMILY COPING —Family actions to manage stressors that tax family resources
	FAMILY SUPPORT —Promotion of family values, interests and goals

Assessment of Neurologic Function

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

- 1 Describe the structures and functions of the central and peripheral nervous systems.
- 2 Differentiate between pathologic changes that affect motor control and those that affect sensory pathways.
- 3 Compare the functioning of the sympathetic and parasympathetic nervous systems.
- 4 Describe the significance of physical assessment to the diagnosis of neurologic dysfunction.
- 5 Describe changes in neurologic function associated with aging and their impact on neurologic assessment findings.
- 6 Describe diagnostic tests used for assessment of suspected neurologic disorders and the related nursing implications.

GLOSSARY

agnosia: loss of ability to recognize objects through a particular sensory system; may be visual, auditory, or tactile

ataxia: inability to coordinate muscle movements, resulting in difficulty in walking, talking, and performing self-care activities

autonomic nervous system: division of the nervous system that regulates the involuntary body functions

axon: portion of the neuron that conducts impulses away from the cell body

Babinski reflex (sign): a reflex action of the toes, indicative of abnormalities in the motor control pathways leading from the cerebral cortex

clonus: abnormal movement marked by alternating contraction and relaxation of a muscle occurring in rapid succession

delirium: transient loss of intellectual function, usually due to systemic problems

dendrite: portion of the neuron that conducts impulses toward the cell body

flaccidity: displaying lack of muscle tone; limp, floppy

parasympathetic nervous system: division of the autonomic nervous system active primarily during non-stressful conditions, controlling mostly visceral functions

photophobia: inability to tolerate light

position (postural) sense: awareness of position of parts of the body without looking at them; also referred to as proprioception

reflex: an automatic response to stimuli

rigidity: increase in muscle tone at rest characterized by increased resistance to passive stretch

Romberg test: test for cerebellar dysfunction requiring the patient to stand with feet together, eyes closed and arms extended; inability to maintain the position, with either significant stagger or sway, is a positive test

spasticity: sustained increase in tension of a muscle when it is passively lengthened or stretched

sympathetic nervous system: division of the autonomic nervous system with predominantly excitatory responses; the “fight-or-flight” system

vertigo: an illusion of movement, usually rotation

Nurses in many practice settings encounter patients with altered neurologic function. Disorders of the nervous system can occur at any time during the lifespan and can vary from mild, self-limiting symptoms to devastating, life-threatening disorders. Nurses must be skilled in the general assessment of neurologic function and be able to focus on specific areas as needed. Assessment requires knowledge of the anatomy and physiology of the nervous system and an understanding of the array of tests and procedures used to diagnose neurologic disorders. Knowledge about the nursing implications and interventions related to assessment and diagnostic testing is also essential.

Anatomic and Physiologic Overview

The nervous system consists of two major parts: the central nervous system (CNS), including the brain and spinal cord, and the peripheral nervous system, which includes the cranial nerves, spinal nerves, and autonomic nervous system. The function of the nervous system is to control motor, sensory, autonomic, cognitive, and behavioral activities. The brain itself contains more than 100 billion cells that link the motor and sensory pathways, monitor the body's processes, respond to the internal and external environment, maintain homeostasis, and direct all psychological, biologic, and physical activity through complex chemical and electrical messages (Klein & Stewart-Amidei, 2009).

Cells of the Nervous System

The basic functional unit of the brain is the neuron (Fig. 60-1). It is composed of dendrites, a cell body, and an axon. The **dendrites** are branch-type structures for receiving electrochemical messages. The **axon** is a long projection that carries electrical impulses away from the cell body. Some neurons have a myelinated sheath that increases speed of conduction. Nerve cell bodies occurring in clusters are called ganglia or nuclei. A cluster of cell bodies with the same function is called a center (eg, the respiratory center). Neuroglial cells, 50 times greater in number than neurons, serve to support, protect, and nourish neurons (Hickey, 2009).

Neurotransmitters

Neurotransmitters communicate messages from one neuron to another or from a neuron to a specific target tissue. Neurotransmitters are manufactured and stored in synaptic

vesicles. As an electrical action potential propagated along the axon reaches the nerve terminal, neurotransmitters are released into the synapse. The neurotransmitter diffuses or is transported across the synapse, binding to receptors in the postsynaptic cell membrane. A neurotransmitter potentiates, terminates, or modulates a specific action, and it can either excite or inhibit activity of the target cell. Usually, multiple neurotransmitters are at work in the neural synapse. The source and action of major neurotransmitters are described in Table 60-1. Once released, enzymes either destroy the neurotransmitter or reabsorb it into the cell for future use.

Many neurologic disorders are due, at least in part, to an imbalance in neurotransmitters. For example, Parkinson's disease develops from decreased availability of dopamine, while acetylcholine binding to muscle cells is impaired in myasthenia gravis (Porth & Matfin, 2009). All brain functions are modulated through neurotransmitter receptor site activity, including memory and other cognitive processes (Hickey, 2009).

Ongoing research is evaluating diagnostic tests that can detect abnormal levels of neurotransmitters in the brain. Positron emission tomography (PET), for example, can detect dopamine, serotonin, and acetylcholine. Single photon emission computed tomography (SPECT), similar to PET, can detect changes in some neurotransmitters such as dopamine in Parkinson's disease (Bremner, 2005). Both PET and SPECT are discussed in more detail later in this chapter.

The Central Nervous System

The Brain

The brain accounts for approximately 2% of the total body weight; in an average young adult, the brain weighs approximately 1400 g, whereas in an average elderly person, the brain weighs approximately 1200 g (Hickey, 2009). The brain is divided into three major areas: the cerebrum, the brain stem, and the cerebellum. The cerebrum is composed of two hemispheres, the thalamus, the hypothalamus, and the basal ganglia. The brain stem includes the midbrain, pons, and medulla. The cerebellum is located under the cerebrum and behind the brain stem (Fig. 60-2).

Cerebrum

The outside surface of the hemispheres has a wrinkled appearance that is the result of many folded layers or

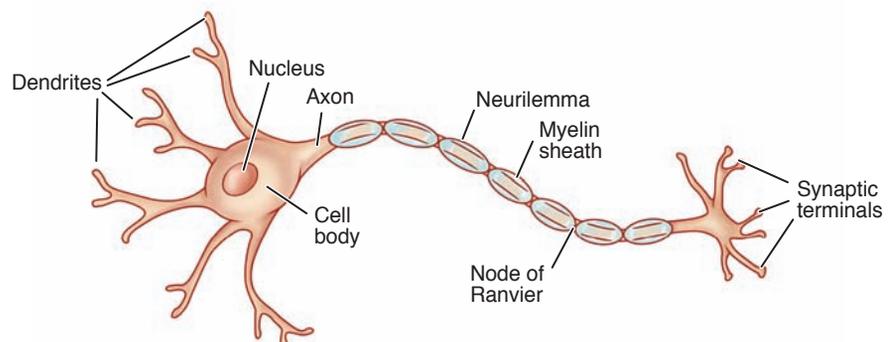

Figure 60-1 Neuron.

Table 60-1 MAJOR NEUROTRANSMITTERS

Neurotransmitter	Source	Action
Acetylcholine (major transmitter of the parasympathetic nervous system)	Many areas of the brain; autonomic nervous system	Usually excitatory; parasympathetic effects sometimes inhibitory (stimulation of heart by vagal nerve)
Serotonin	Brain stem, hypothalamus, dorsal horn of the spinal cord	Inhibitory, helps control mood and sleep, inhibits pain pathways
Dopamine	Substantia nigra and basal ganglia	Usually inhibits, affects behavior (attention, emotions) and fine movement
Norepinephrine (major transmitter of the sympathetic nervous system)	Brain stem, hypothalamus, postganglionic neurons of the sympathetic nervous system	Usually excitatory; affects mood and overall activity
Gamma-aminobutyric acid (GABA)	Spinal cord, cerebellum, basal ganglia, some cortical areas	Inhibitory
Enkephalin, endorphin	Nerve terminals in the spine, brain stem, thalamus and hypothalamus, pituitary gland	Excitatory; pleasurable sensation, inhibits pain transmission

convolutions called gyri, which increase the surface area of the brain, accounting for the high level of activity carried out by such a small-appearing organ. Between each gyrus is a sulcus or fissure that serves as an anatomic division. In between the cerebral hemispheres is the great longitudinal fissure that separates the cerebrum into the right and left hemispheres. The two hemispheres are joined at the lower portion of the fissure by the corpus callosum. The external or outer portion of the hemispheres (the cerebral cortex) is made up of gray matter approximately 2 to 5 mm in depth; it contains billions of neuron cell bodies, giving it a gray appearance. White matter makes up the innermost layer and is composed of myelinated nerve fibers and neuroglia cells that form tracts or pathways connecting various parts of the brain with one another. These pathways also connect the cortex with lower portions of the brain and spinal cord. The cerebral hemispheres are divided into pairs of lobes as follows (see Fig. 60-2):

- **Frontal**—the largest lobe, located in the front of the brain. The major functions of this lobe are concentration, abstract thought, information storage or memory, and motor function. It contains Broca's area, which is located in the left hemisphere and is critical for motor control of speech. The frontal lobe is also

responsible in large part for a person's affect, judgment, personality, and inhibitions (Hickey, 2009).

- **Parietal**—a predominantly sensory lobe posterior to the frontal lobe. This lobe analyzes sensory information and relays the interpretation of this information to other cortical areas and is essential to a person's awareness of body position in space, size and shape discrimination, and right–left orientation (Hickey, 2009).
- **Temporal**—located inferior to the frontal and parietal lobes, this lobe contains the auditory receptive areas and plays a role in memory of sound and understanding of language and music.
- **Occipital**—located posterior to the parietal lobe, this lobe is responsible for visual interpretation and memory.

The corpus callosum (Fig. 60-3), a thick collection of nerve fibers that connects the two hemispheres of the brain, is responsible for the transmission of information from one side of the brain to the other. Information transferred includes sensation, memory, and learned discrimination. Right-handed people and some left-handed people have cerebral dominance on the left side of the brain for verbal, linguistic, arithmetic, calculation, and analytic functions.

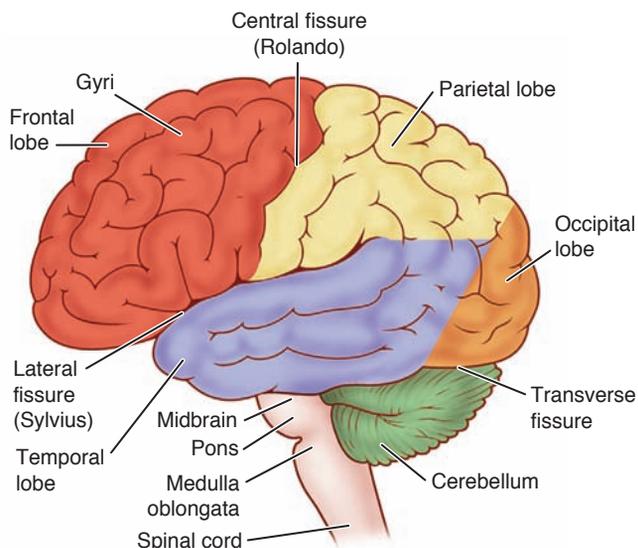

Figure 60-2 View of the external surface of the brain showing lobes, cerebellum, and brain stem.

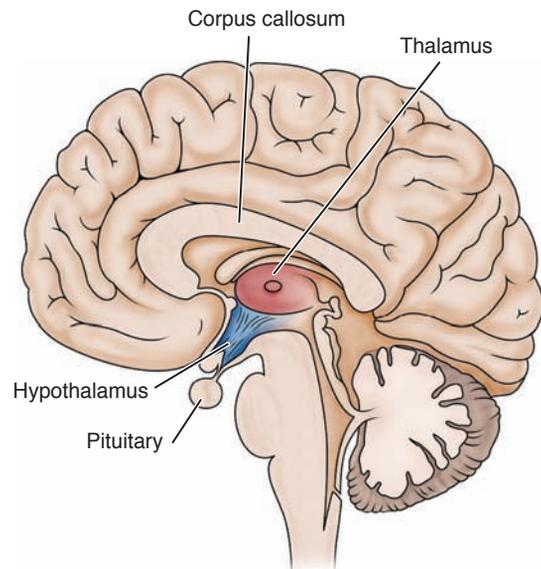

Figure 60-3 Medial view of the brain.

The nondominant hemisphere is responsible for geometric, spatial, visual, pattern, and musical functions. Nuclei for cranial nerves I and II are also located in the cerebrum.

The basal ganglia are masses of nuclei located deep in the cerebral hemispheres that are responsible for control of fine motor movements, including those of the hands and lower extremities.

The thalamus (see Fig. 60-3) lies on either side of the third ventricle and acts primarily as a relay station for all sensation except smell. All memory, sensation, and pain impulses pass through this section of the brain.

The hypothalamus (see Fig. 60-3) is located anterior and inferior to the thalamus, and beneath and lateral to the third ventricle. The infundibulum of the hypothalamus connects it to the posterior pituitary gland. The hypothalamus plays an important role in the endocrine system because it regulates the pituitary secretion of hormones that influence metabolism, reproduction, stress response, and urine production. It works with the pituitary to maintain fluid balance through hormonal release and maintains temperature regulation by promoting vasoconstriction or vasodilatation. In addition, the hypothalamus is the site of the hunger center and is involved in appetite control. It contains centers that regulate the sleep-wake cycle, blood pressure, aggressive and sexual behavior, and emotional responses (ie, blushing, rage, depression, panic, and fear). The hypothalamus also controls and regulates the autonomic nervous system. The optic chiasm (the point at which the two optic tracts cross) and the mamillary bodies (involved in olfactory reflexes and emotional response to odors) are also found in this area.

Brain Stem

The brain stem consists of the midbrain, pons, and medulla oblongata (see Fig. 60-2). The midbrain connects the pons and the cerebellum with the cerebral hemispheres; it contains sensory and motor pathways and serves as the center for auditory and visual reflexes. Cranial nerves III and IV originate in the midbrain. The pons is situated in front of the cerebellum between the midbrain and the medulla and is a bridge between the two halves of the cerebellum, and between the medulla and the midbrain. Cranial nerves V through VIII originate in the pons. The pons also contains motor and sensory pathways. Portions of the pons help regulate respiration.

Motor fibers from the brain to the spinal cord and sensory fibers from the spinal cord to the brain are located in the medulla. Most of these fibers cross, or decussate, at this level. Cranial nerves IX through XII originate in the medulla. Reflex centers for respiration, blood pressure, heart rate, coughing, vomiting, swallowing, and sneezing are located in the medulla as well. The reticular formation, responsible for arousal and the sleep-wake cycle, begins in the medulla and connects with numerous higher structures.

Cerebellum

The cerebellum is posterior to the midbrain and pons, and below the occipital lobe (see Fig. 60-2). The cerebellum integrates sensory information to provide smooth coordinated movement. It controls fine movement, balance, and **position (postural) sense** or proprioception (awareness of where each part of the body is).

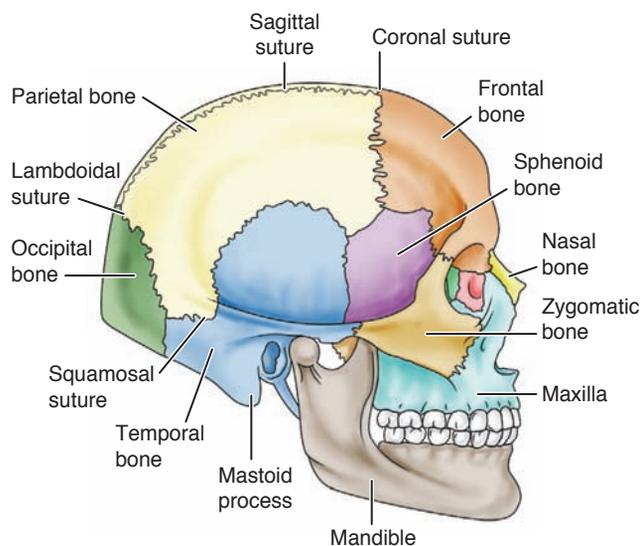

Figure 60-4 Bones and sutures of the skull.

Structures Protecting the Brain

The brain is contained in the rigid skull, which protects it from injury. The major bones of the skull are the frontal, temporal, parietal, occipital, and sphenoid bones. These bones join at the suture lines (Fig. 60-4) and form the base of the skull. Indentations in the skull base are known as fossae. The anterior fossa contains the frontal lobe, the middle fossa contains the temporal lobe, and the posterior fossa contains the cerebellum and brain stem.

The meninges, fibrous connective tissues that cover the brain and spinal cord, provide protection, support, and nourishment. The layers of the meninges are the dura mater, arachnoid, and pia mater (Fig. 60-5).

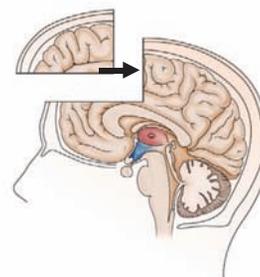

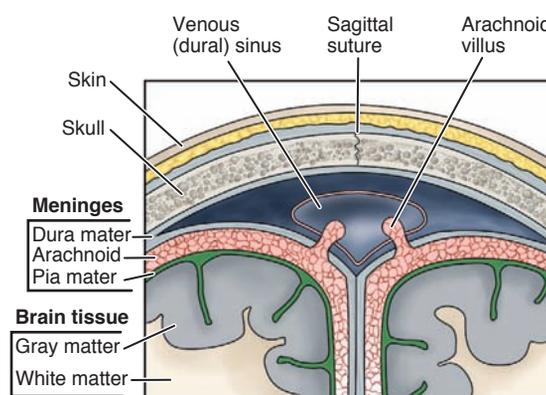

Figure 60-5 Meninges and related structures.

- Dura mater—the outermost layer; covers the brain and the spinal cord. It is tough, thick, inelastic, fibrous, and gray. There are three major extensions of the dura: the falx cerebri, which folds between the two hemispheres; the tentorium, which folds between the occipital lobe and cerebellum to form a tough, membranous shelf; and the falx cerebelli, which is located between the right and left side of the cerebellum. When excess pressure occurs in the cranial cavity, brain tissue may be compressed against these dural folds or displaced around them or downward, a process called herniation. A potential space exists between the dura and the skull, and between the periosteum and the dura in the vertebral column, known as the epidural space. Another potential space, the subdural space, also exists below the dura. Blood or an abscess can accumulate in these potential spaces.
- Arachnoid—the middle membrane; an extremely thin, delicate membrane that closely resembles a spider web (hence the name arachnoid). The arachnoid membrane has cerebrospinal fluid (CSF) in the space below it, called the subarachnoid space. This membrane has unique fingerlike projections, called arachnoid villi, that absorb CSF into the venous system. When blood or bacteria enter the subarachnoid space, the villi become obstructed and *communicating* hydrocephalus (increased size of ventricles) may result.
- Pia mater—the innermost, thin, transparent layer that hugs the brain closely and extends into every fold of the brain's surface.

Cerebrospinal Fluid

CSF is a clear and colorless fluid that is produced in the choroid plexus of the ventricles and circulates around the surface of the brain and the spinal cord. There are four ventricles: the right and left lateral and the third and fourth ventricles. The two lateral ventricles open into the third ventricle at the interventricular foramen or the foramen of Monro. The third and fourth ventricles connect via the aqueduct of Sylvius. The fourth ventricle drains CSF into the subarachnoid space on the surface of the brain and spinal cord, where it is absorbed by the arachnoid villi. Blockage of CSF flow anywhere in the ventricular system produces *obstructive* hydrocephalus.

CSF is important in immune and metabolic functions in the brain. It is produced at a rate of about 500 mL/day; the ventricles and subarachnoid space contain approximately 150 mL of fluid (Hickey, 2009). The composition of CSF is similar to other extracellular fluids (such as blood plasma), but the concentrations of the various constituents differ. A laboratory analysis of CSF indicates color (clear), specific gravity (normal 1.007), protein count, white blood cell count, glucose, and other electrolyte levels (see Appendix A, Table A-5). The CSF may also be tested for immunoglobulins or presence of bacteria. Normal CSF contains a minimal number of white blood cells and no red blood cells.

Cerebral Circulation

The brain does not store nutrients and requires a constant supply of oxygen. These needs are met through cerebral cir-

ulation; the brain receives approximately 15% of the cardiac output, or 750 mL per minute of blood flow. Brain circulation is unique in several aspects. First, arterial and venous circulation are not parallel as in other organs in the body; this is due in part to the role the venous system plays in CSF absorption. Second, the brain has collateral circulation through the circle of Willis, allowing blood flow to be redirected on demand. Third, blood vessels in the brain have two rather than three layers, which may make them more prone to rupture when weakened or under pressure.

Arteries

Arterial blood supply to the brain originates from the common carotid artery, the first bifurcation off the aorta. The internal carotid arteries arise at the bifurcation of the common carotid and supply much of the anterior circulation of the brain. Branches of the internal carotid arteries, anterior and middle cerebral arteries, along with their connections, anterior and posterior communicating arteries, form the circle of Willis (Fig. 60-6).

The vertebral arteries branch from the subclavian arteries to supply most of the posterior circulation of the brain. At the level of the brain stem, the vertebral arteries join to form the basilar artery. The basilar artery divides to form the two branches of the posterior cerebral arteries. Functionally, the posterior portion of the circulation and the anterior or carotid circulation usually remain separate. However, the circle of Willis can provide collateral circulation if one of the vessels supplying it becomes occluded or is ligated.

The bifurcations along the circle of Willis are frequent sites of aneurysm formation. Aneurysms are outpouchings of the blood vessel due to vessel wall weakness. Aneurysms can rupture and cause a hemorrhagic stroke. Aneurysms are discussed in more detail in Chapter 62.

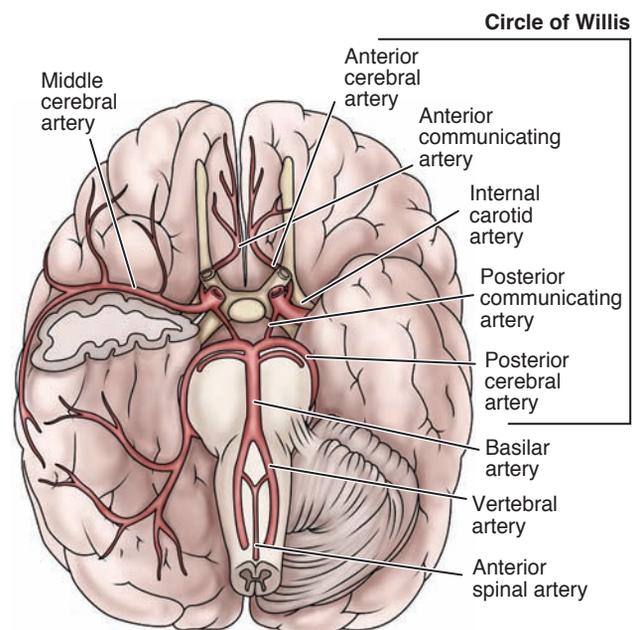

Figure 60-6 Arterial blood supply of the brain, including the circle of Willis, as viewed from the ventral surface.

Veins

Venous drainage for the brain does not follow the arterial circulation as in other body structures. The veins reach the brain's surface, join larger veins, then cross the subarachnoid space and empty into the dural sinuses, which are the vascular channels laying within the dura (see Fig. 60-5). The network of the sinuses carries venous outflow from the brain and empties into the internal jugular veins, returning the blood to the heart. Cerebral veins are unique because, unlike other veins in the body, they do not have valves to prevent blood from flowing backward and depend on both gravity and blood pressure for flow.

Blood-Brain Barrier

The CNS is inaccessible to many substances that circulate in the blood plasma (eg, dyes, medications, and antibiotics) because of the blood-brain barrier. This barrier is formed by the endothelial cells of the brain's capillaries, which form continuous tight junctions, creating a barrier to macromolecules and many compounds. All substances entering the CSF must filter through the capillary endothelial cells and astrocytes. The blood-brain barrier has a protective function but can be altered by trauma, cerebral edema, and cerebral hypoxemia; this has implications in the treatment and selection of medication for CNS disorders (Hickey, 2009).

The Spinal Cord

The spinal cord is continuous with the medulla, extending from the cerebral hemispheres and serving as the connection between the brain and the periphery. Approximately 45 cm (18 inches) long and about the thickness of a finger, it extends from the foramen magnum at the base of the skull to the lower border of the first lumbar vertebra, where it tapers to a fibrous band called the *conus medullaris*. Continuing below the second lumbar space are the nerve roots that extend beyond the conus, which are called the *cauda equina* because they resemble a horse's tail. Meninges surround the spinal cord.

In a cross-sectional view, the spinal cord has an H-shaped central core of nerve cell bodies (gray matter) surrounded by ascending and descending tracts (white matter) (Fig. 60-7). The lower portion of the H is broader than the upper portion and corresponds to the anterior horns. The anterior horns contain cells with fibers that form the anterior (motor) root and are essential for the voluntary and reflex activity of the muscles they innervate. The thinner posterior (upper horns) portion contains cells with fibers that enter over the posterior (sensory) root and thus serve as a relay station in the sensory/reflex pathway.

The thoracic region of the spinal cord has a projection from each side at the crossbar of the H-shaped structure of gray matter called the lateral horn. It contains the cells that give rise to the autonomic fibers of the sympathetic division. The fibers leave the spinal cord through the anterior roots in the thoracic and upper lumbar segments.

The Spinal Tracts

The white matter of the spinal cord is composed of myelinated and unmyelinated nerve fibers. The fast-conducting myelinated fibers form bundles that also contain glial cells. Fiber bundles with a common function are called tracts.

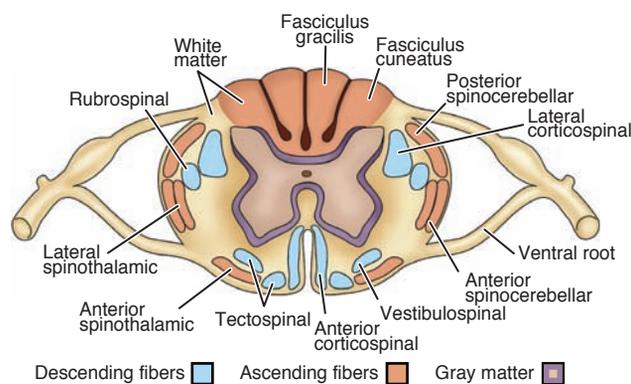

Figure 60-7 Cross-sectional diagram of the spinal cord showing major spinal tracts.

There are six ascending tracts. Two tracts, known as the fasciculus cuneatus and gracilis or the posterior columns, conduct sensations of deep touch, pressure, vibration, position, and passive motion from the same side of the body. Before reaching the cerebral cortex, these fibers cross to the opposite side in the medulla. The anterior and posterior spinocerebellar tracts conduct sensory impulses from muscle spindles, providing necessary input for coordinated muscle contraction. They ascend essentially uncrossed and terminate in the cerebellum. The anterior and lateral spinothalamic tracts are responsible for conduction of pain, temperature, proprioception, fine touch, and vibratory sense from the upper body to the brain. They cross to the opposite side of the cord, and then ascend to the brain, terminating in the thalamus (Klein & Stewart-Amidei, 2009).

There are eight descending tracts. The anterior and lateral corticospinal tracts conduct motor impulses to the anterior horn cells from the opposite side of the brain, cross in the medulla, and control voluntary muscle activity. The three vestibulospinal tracts descend uncrossed and are involved in some autonomic functions (sweating, pupil dilation, and circulation) and involuntary muscle control. The corticobulbar tract conducts impulses responsible for voluntary head and facial muscle movement and crosses at the level of the brain stem. The rubrospinal and reticulospinal tracts conduct impulses involved with involuntary muscle movement.

Vertebral Column

The bones of the vertebral column surround and protect the spinal cord and normally consist of 7 cervical, 12 thoracic, and 5 lumbar vertebrae, as well as the sacrum (a fused mass of 5 vertebrae), and terminate in the coccyx. Nerve roots exit from the vertebral column through the intervertebral foramina (openings). The vertebrae are separated by disks, except for the first and second cervical, the sacral, and the coccygeal vertebrae. Each vertebra has a ventral solid body and a dorsal segment or arch, which is posterior to the body. The arch is composed of two pedicles and two laminae supporting seven processes. The vertebral body, arch, pedicles, and laminae all encase and protect the spinal cord.

The Peripheral Nervous System

The peripheral nervous system includes the cranial nerves, the spinal nerves, and the autonomic nervous system.

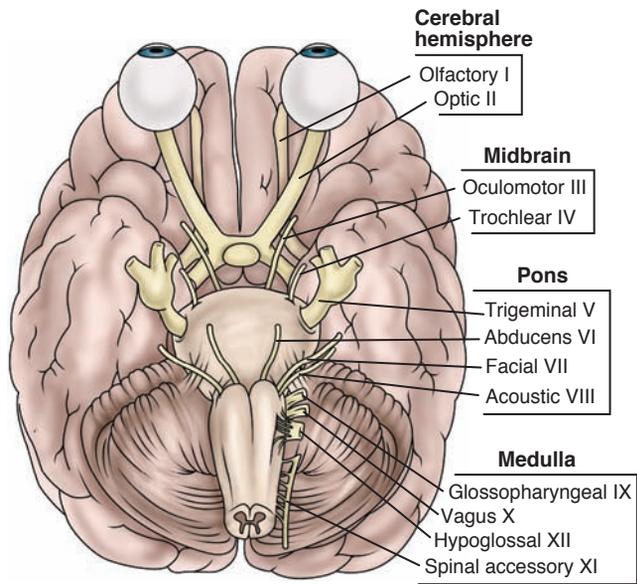

Figure 60-8 Diagram of the base of the brain showing entrance or exit of the cranial nerves. The right column shows the anatomic location of the connection of each cranial nerve to the central nervous system.

Cranial Nerves

Twelve pairs of cranial nerves emerge from the lower surface of the brain and pass through openings in the base of the skull. Three are entirely sensory (I, II, VIII), five are motor (III, IV, VI, XI, and XII), and four are mixed sensory and motor (V, VII, IX, and X). The cranial nerves are numbered in the order in which they arise from the brain (Fig. 60-8). The cranial nerves innervate the head, neck, and special sense structures. Table 60-2 identifies primary functions of the cranial nerves.

Spinal Nerves

The spinal cord is composed of 31 pairs of spinal nerves: 8 cervical, 12 thoracic, 5 lumbar, 5 sacral, and 1 coccygeal. Each spinal nerve has a ventral root and a dorsal root. The dorsal roots are sensory and transmit sensory impulses from specific areas of the body known as dermatomes (Fig. 60-9) to the dorsal horn ganglia. The sensory fiber may be somatic, carrying information about pain, temperature, touch, and position sense (proprioception) from the tendons, joints, and body surfaces; or visceral, carrying information from the internal organs.

The ventral roots are motor and transmit impulses from the spinal cord to the body, and these fibers are also either somatic or visceral. The visceral fibers include autonomic fibers that control the cardiac muscles and glandular secretions.

Autonomic Nervous System

The **autonomic nervous system** regulates the activities of internal organs such as the heart, lungs, blood vessels, digestive organs, and glands. Maintenance and restoration of internal homeostasis is largely the responsibility of the autonomic nervous system. There are two major divisions: the **sympathetic nervous system**, with predominantly excita-

Table 60-2 CRANIAL NERVES

Cranial Nerve	Type	Function
I (olfactory)	Sensory	Sense of smell
II (optic)	Sensory	Visual acuity and visual fields
III (oculomotor)	Motor	Muscles that move the eye and lid, pupillary constriction, lens accommodation
IV (trochlear)	Motor	Muscles that move the eye
V (trigeminal)	Mixed	Facial sensation, corneal reflex, mastication
VI (abducens)	Motor	Muscles that move the eye
VII (facial)	Mixed	Facial expression and muscle movement, salivation and tearing, taste, sensation in the ear
VIII (acoustic)	Sensory	Hearing and equilibrium
IX (glossopharyngeal)	Mixed	Taste, sensation in pharynx and tongue, pharyngeal muscles, swallowing
X (vagus)	Mixed	Muscles of pharynx, larynx, and soft palate; sensation in external ear, pharynx, larynx, thoracic and abdominal viscera; parasympathetic innervation of thoracic and abdominal organs
XI (spinal accessory)	Motor	Sternocleidomastoid and trapezius muscles
XII (hypoglossal)	Motor	Movement of the tongue

tory responses, most notably the “fight-or-flight” response, and the **parasympathetic nervous system**, which controls mostly visceral functions.

The autonomic nervous system innervates most body organs. Although usually considered part of the peripheral nervous system, this system is regulated by centers in the spinal cord, brain stem, and hypothalamus. The autonomic nervous system has two neurons in a series extending between the centers in the CNS and the organs innervated. The first neuron, the preganglionic neuron, is located in the brain or spinal cord, and its axon extends to the autonomic ganglia. There, it synapses with the second neuron, the postganglionic neuron, located in the autonomic ganglia, and its axon synapses with the target tissue and innervates the effector organ. Its regulatory effects are exerted not on individual cells but on large expanses of tissue and on entire organs. The responses elicited do not occur instantaneously but after a lag period. These responses are sustained far longer than other neurogenic responses to ensure maximal functional efficiency on the part of receptor organs, such as blood vessels.

The hypothalamus is the major subcortical center for the regulation of visceral and somatic activities, serving an inhibitory–excitatory role in the autonomic nervous system. The hypothalamus has connections that link the autonomic system with the thalamus, the cortex, the olfactory apparatus, and the pituitary gland. Located here are the mechanisms for the control of visceral and somatic reactions that were originally important for defense or attack and are associated with emotional states (eg, fear, anger, anxiety); for the control of metabolic processes, including fat, carbohydrate, and water metabolism; for the regulation

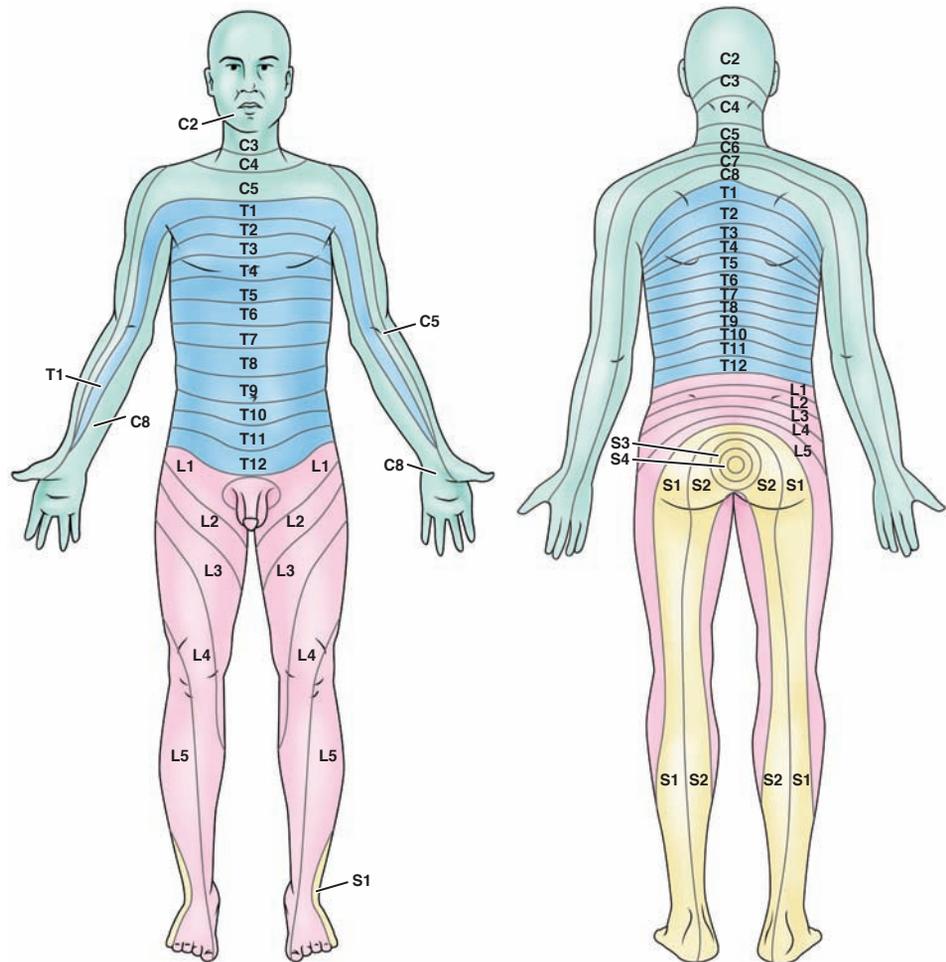

Figure 60-9 Dermatome distribution.

of body temperature, arterial pressure, and all muscular and glandular activities of the gastrointestinal tract; for control of genital functions; and for the sleep cycle.

The autonomic nervous system is separated into the anatomically and functionally distinct sympathetic and parasympathetic divisions. Most of the tissues and the organs under autonomic control are innervated by both systems. For example, the parasympathetic division causes contraction (stimulation) of the urinary bladder muscles and a decrease (inhibition) in heart rate, whereas the sympathetic division produces relaxation (inhibition) of the urinary bladder and an increase (stimulation) in the rate and force of the heartbeat. Table 60-3 compares the sympathetic and the parasympathetic effects on the different systems of the body.

Sympathetic Nervous System

The sympathetic division of the autonomic nervous system is best known for its role in the body's "fight-or-flight" response. Under stress from either physical or emotional causes, sympathetic impulses increase greatly. As a result, the bronchioles dilate for easier gas exchange; the heart's contractions are stronger and faster; the arteries to the heart and voluntary muscles dilate, carrying more blood to these organs; peripheral blood vessels constrict, making the skin

feel cool but shunting blood to essential organs; the pupils dilate; the liver releases glucose for quick energy; peristalsis slows; hair stands on end; and perspiration increases. The main sympathetic neurotransmitter is norepinephrine (noradrenaline). A sympathetic discharge is the same as if the body has been given an injection of adrenalin—hence, the term *adrenergic* is often used to refer to this division.

Sympathetic neurons are located primarily in the thoracic and the lumbar segments of the spinal cord, and their axons, or the preganglionic fibers, emerge by way of anterior nerve roots from the eighth cervical or first thoracic segment to the second or third lumbar segment. A short distance from the cord, these fibers diverge to join a chain, composed of 22 linked ganglia, that extends the entire length of the spinal column, adjacent to the vertebral bodies on both sides. Some form multiple synapses with nerve cells within the chain. Others traverse the chain without making connections or losing continuity to join large "prevertebral" ganglia in the thorax, the abdomen, or the pelvis or one of the "terminal" ganglia in the vicinity of an organ, such as the bladder or the rectum (Fig. 60-10). Postganglionic nerve fibers originating in the sympathetic chain rejoin the spinal nerves that supply the extremities and are distributed to blood vessels, sweat glands, and smooth muscle tissue in the skin. Postganglionic fibers from the prevertebral plexuses

Table 60-3 EFFECTS OF THE AUTONOMIC NERVOUS SYSTEM		
Structure or Activity	Parasympathetic Effects	Sympathetic Effects
Pupil of the Eye	Constricted	Dilated
Circulatory System		
Rate and force of heartbeat	Decreased	Increased
Blood vessels		
In heart muscle	Constricted	Dilated
In skeletal muscle	*	Dilated
In abdominal viscera and the skin	*	Constricted
Blood pressure	Decreased	Increased
Respiratory System		
Bronchioles	Constricted	Dilated
Rate of breathing	Decreased	Increased
Digestive System		
Peristaltic movements of digestive tube	Increased	Decreased
Muscular sphincters of digestive tube	Relaxed	Contracted
Secretion of salivary glands	Thin, watery saliva	Thick, viscid saliva
Secretions of stomach, intestine, and pancreas	Increased	*
Conversion of liver glycogen to glucose	*	Increased
Genitourinary System		
Urinary bladder		
Muscle walls	Contracted	Relaxed
Sphincters	Relaxed	Contracted
Muscles of the uterus	Relaxed; variable	Contracted under some conditions; varies with menstrual cycle and pregnancy
Blood vessels of external genitalia	Dilated	*
Integumentary System		
Secretion of sweat	*	Increased
Pilomotor muscles	*	Contracted (goose-flesh)
Adrenal Medulla	*	Secretion of epinephrine and norepinephrine

*No direct effect.

(eg, the cardiac, pulmonary, splanchnic, and pelvic plexuses) supply structures in the head and neck, thorax, abdomen, and pelvis, respectively, having been joined in these plexuses by fibers from the parasympathetic division.

The adrenal glands, kidneys, liver, spleen, stomach, and duodenum are under the control of the giant celiac plexus, commonly known as the solar plexus. This receives its sympathetic nerve components by way of the three splanchnic nerves, composed of preganglionic fibers from nine segments of the spinal cord (T4 to L1), and is joined by the vagus nerve, representing the parasympathetic division. From the celiac plexus, fibers of both divisions travel along the course of blood vessels to their target organs.

Sympathetic Syndromes. Certain syndromes are distinctive to diseases of the sympathetic nerve trunks. For example, sympathetic storm is a syndrome associated with changes in level of consciousness, altered vital signs, diaphoresis, and agitation that may result from hypothalamic stimulation of

the sympathetic nervous system following traumatic brain injury (Diepenbrock, 2007).

Parasympathetic Nervous System

The parasympathetic nervous system functions as the dominant controller for most visceral effectors; the primary neurotransmitter is acetylcholine. During quiet, nonstressful conditions, impulses from parasympathetic fibers (cholinergic) predominate. The fibers of the parasympathetic system are located in two sections, one in the brain stem and the other from spinal segments below L2. Because of the location of these fibers, the parasympathetic system is referred to as the craniosacral division, as distinct from the thoracolumbar (sympathetic) division of the autonomic nervous system.

The parasympathetic nerves arise from the midbrain and the medulla oblongata. Fibers from cells in the midbrain travel with the third oculomotor nerve to the ciliary ganglia, where postganglionic fibers of this division are joined by those of the sympathetic system, creating controlled opposition, with a delicate balance maintained between the two at all times.

Motor and Sensory Pathways of the Nervous System

Motor Pathways

The corticospinal tract begins in the motor cortex, a vertical band within each frontal lobe, and controls voluntary movements of the body. The exact locations within the brain at which the voluntary movements of the muscles of the face, thumb, hand, arm, trunk, and leg originate are known (Fig. 60-11). To initiate movement, these particular cells must send the stimulus along their fibers. Stimulation of these cells with an electric current also results in muscle contraction. En route to the pons, the motor fibers converge into a tight bundle known as the internal capsule. A comparatively small injury to the internal capsule results in a more severe paralysis than does a larger injury to the cortex itself.

At the medulla, the corticospinal tracts cross to the opposite side, continuing to the anterior horn of the spinal cord, in proximity to a motor nerve cell. Until this point, neurons are known as upper motor neurons. As they connect to motor fibers of the spinal nerves, they become lower motor neurons. The lower motor neurons receive the impulse in the posterior part of the cord and run to the myoneural junction located in the peripheral muscle.

Involuntary motor activity is also possible and is mediated through reflex arcs. Synaptic connections between anterior horn cells and sensory fibers that have entered adjacent or neighboring segments of the spinal cord serve as protective mechanisms. These connections are seen during deep tendon reflex testing.

Upper and Lower Motor Neurons

The voluntary motor system consists of two groups of neurons: upper motor neurons and lower motor neurons. Upper motor neurons originate in the cerebral cortex, the cerebellum, and the brain stem. Their fibers make up the descending motor pathways, are located entirely within the CNS,

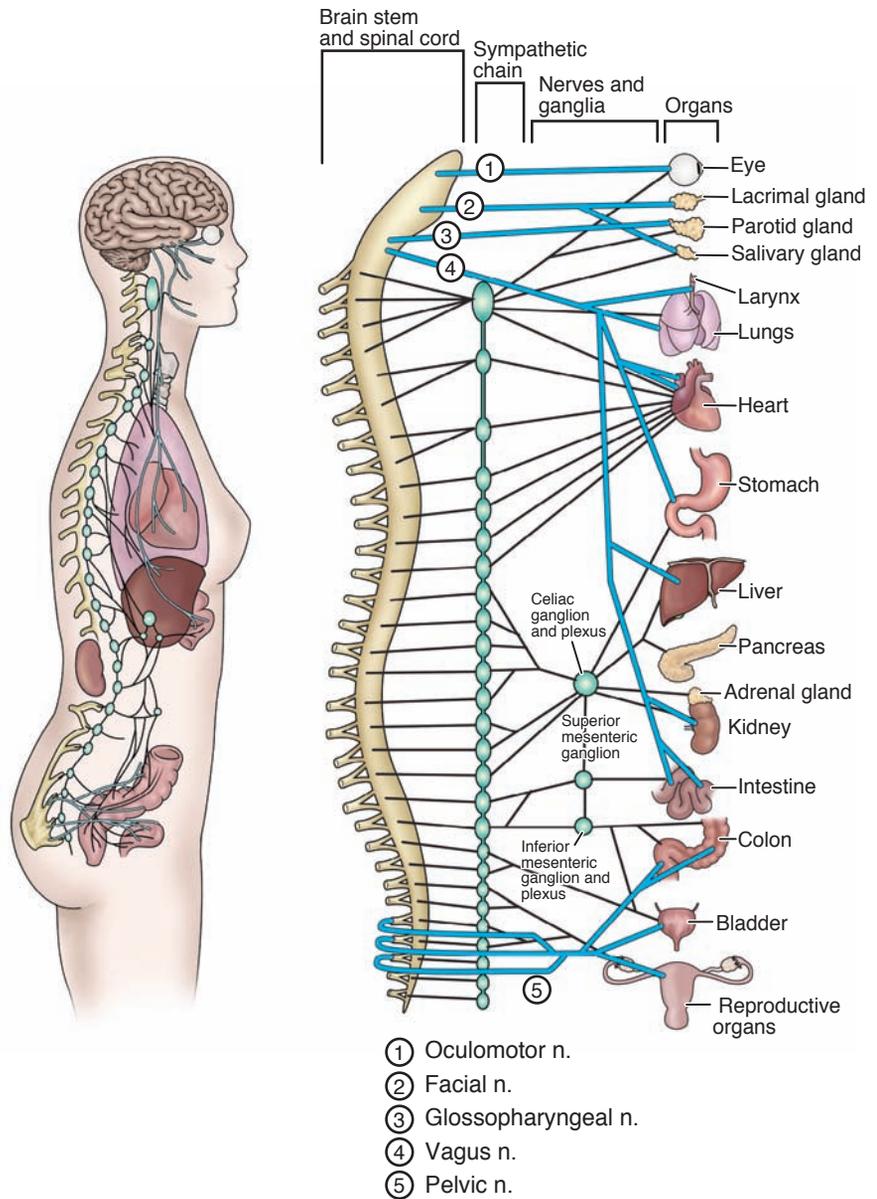

Figure 60-10 Anatomy of the autonomic nervous system.

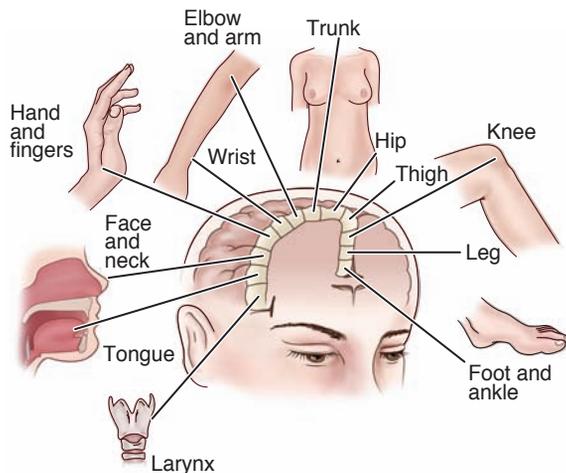

Figure 60-11 Diagrammatic representation of the cerebrum showing locations for control of motor movement of various parts of the body.

and modulate the activity of the lower motor neurons. Lower motor neurons are located either in the anterior horn of the spinal cord gray matter or within cranial nerve nuclei in the brain stem. Axons of lower motor neurons in both sites extend through peripheral nerves and terminate in skeletal muscle. Lower motor neurons are located in both the CNS and the peripheral nervous system.

The motor pathways from the brain to the spinal cord, as well as from the cerebrum to the brain stem, are formed by upper motor neurons. They begin in the cortex of one side of the brain, descend through the internal capsule, cross to the opposite side in the brain stem, descend through the corticospinal tract, and synapse with the lower motor neurons in the cord. The lower motor neurons receive the impulse in the posterior part of the cord and run to the myoneural junction located in the peripheral muscle. The clinical features of lesions of upper and lower motor neurons are discussed in the following sections and in Table 60-4.

Table 60-4 COMPARISON OF UPPER MOTOR NEURON AND LOWER MOTOR NEURON LESIONS

Upper Motor Neuron Lesions	Lower Motor Neuron Lesions
Loss of voluntary control	Loss of voluntary control
Increased muscle tone	Decreased muscle tone
Muscle spasticity	Flaccid muscle paralysis
No muscle atrophy	Muscle atrophy
Hyperactive and abnormal reflexes	Absent or decreased reflexes

Upper Motor Neuron Lesions. Upper motor neuron lesions can involve the motor cortex, the internal capsule, the spinal cord gray matter, and other structures of the brain through which the corticospinal tract descends. If the upper motor neurons are damaged or destroyed, as frequently occurs with stroke or spinal cord injury, paralysis (loss of voluntary movement) results. However, because the inhibitory influences of intact upper motor neurons are impaired, **reflex** (involuntary) movements are uninhibited, and hence hyperactive deep tendon reflexes, diminished or absent superficial reflexes, and pathologic reflexes such as a Babinski response occur. Severe leg spasms can occur as the result of an upper motor neuron lesion; the spasms result from the preserved reflex arc, which lacks inhibition along the spinal cord below the level of injury. There is little or no muscle atrophy, and muscles remain permanently tense, exhibiting spastic paralysis.

Paralysis associated with upper motor neuron lesions can affect a whole extremity, both extremities, or an entire half of the body. Hemiplegia (paralysis of an arm and leg on the same side of the body) can be the result of an upper motor neuron lesion. If hemorrhage, an embolus, or a thrombus destroys the fibers from the motor area in the internal capsule, the arm and the leg of the opposite side become stiff, weak, or paralyzed, and the reflexes are hyperactive (further discussion of hemiplegia is found in Chapter 62). If both legs are paralyzed, the condition is called paraplegia. If all four extremities are paralyzed, the condition is called tetraplegia. (Additional discussion of these disorders appears in Chapter 63.)

Lower Motor Neuron Lesions. A patient is considered to have lower motor neuron damage if a motor nerve is damaged between the spinal cord and muscle. The result of lower motor neuron damage is muscle paralysis. Reflexes are lost, and the muscle becomes flaccid (limp) and atrophied from disuse. If the patient has injured the spinal trunk and it can heal, use of the muscles connected to that section of the spinal cord may be regained. However, if the anterior horn motor cells are destroyed, the nerves cannot regenerate and the muscles are never useful again.

Flaccid paralysis and atrophy of the affected muscles are the principal signs of lower motor neuron disease. Lower motor neuron lesions can be the result of trauma, infection (poliomyelitis), toxins, vascular disorders, congenital malformations, degenerative processes, and neoplasms. Compression of nerve roots by herniated intervertebral disks is a common cause of lower motor neuron dysfunction. The clinical features of lesions of upper and lower motor neurons are discussed in the following sections and in Table 60-4.

Coordination of Movement

The motor system is complex, and motor function depends not only on the integrity of the corticospinal tracts but also on other pathways from the basal ganglia and cerebellum that control and coordinate voluntary motor function. The smoothness, accuracy, and strength that characterize the muscular movements of a normal person are attributable to the influence of the cerebellum and the basal ganglia.

Through the action of the cerebellum, the contractions of opposing muscle groups are adjusted in relation to each other to maximal mechanical advantage; muscle contractions can be sustained evenly at the desired tension and without significant fluctuation, and reciprocal movements can be reproduced at high and constant speed, in stereotyped fashion and with relatively little effort.

The basal ganglia play an important role in planning and coordinating motor movements and posture. Complex neural connections link the basal ganglia with the cerebral cortex. The major effect of these structures is to inhibit unwanted muscular activity.

Impaired cerebellar function, which may occur as a result of an intracranial injury or some type of an expanding mass (eg, a hemorrhage, an abscess, or a tumor), results in loss of muscle tone, weakness, and fatigue. Depending on the area of the brain affected, the patient has different motor symptoms or responses. The patient may demonstrate abnormal flexion, abnormal extension, or flaccid posturing. **Flaccidity** (lack of muscle tone) preceded by abnormal posturing in a patient with cerebral injury indicates severe neurologic impairment, which may herald brain death (Peiffer, 2007; Posner, Saper, Schiff, et al., 2007). For further explanation of this, see Figure 61-1 in Chapter 61.

Destruction or dysfunction of the basal ganglia leads not to paralysis but to muscle rigidity, disturbances of posture, and difficulty initiating or changing movement. The patient tends to have involuntary movements. These may take the form of coarse tremors, most often in the upper extremities, particularly in the distal portions; athetosis, movement of a slow, squirming, writhing, twisting type; or chorea, marked by spasmodic, purposeless, irregular, uncoordinated motions of the trunk and the extremities, and facial grimacing. Disorders affecting basal ganglia activity include Parkinson's and Huntington's diseases (see Chapter 65).

Sensory System Function

Receiving Sensory Impulses

Afferent impulses travel from their points of origin to their destinations in the cerebral cortex via the ascending pathways directly, or they may cross at the level of the spinal cord or in the medulla, depending on the type of sensation carried. Knowledge of these pathways is important for neurologic assessment and for understanding symptoms and their relationship to various lesions.

Sensory impulses convey sensations of heat, cold, pain, position and vibration sense. The axons enter the spinal cord by way of the posterior root, specifically in the posterior gray columns of the spinal cord, where they connect with the cells of secondary neurons. Pain and temperature fibers (located in the spinothalamic tract) cross immediately to the opposite side of the cord and course upward to

the thalamus. Fibers carrying sensations of touch, light pressure, and localization do not connect immediately with the second neuron but ascend the cord for a variable distance before entering the gray matter and completing this connection. The axon of the secondary neuron traverses the cord, crosses in the medulla, and proceeds upward to the thalamus.

Position and vibratory sensations are produced by stimuli arising from muscles, joints, and bones. These stimuli are conveyed, uncrossed, all the way to the brain stem by the axon of the primary neuron. In the medulla, synaptic connections are made with cells of the secondary neurons, whose axons cross to the opposite side and then proceed to the thalamus.

Integrating Sensory Impulses

The thalamus integrates all sensory impulses except olfaction. It plays a role in the conscious awareness of pain and the recognition of variation in temperature and touch. The thalamus is responsible for the sense of movement and position as well as the ability to recognize the size, shape, and quality of objects. Sensory information is relayed from the thalamus to the parietal lobe for interpretation.

Sensory Losses

Destruction of a sensory nerve results in total loss of sensation in its area of distribution (see Fig. 60-9). Lesions affecting the posterior spinal nerve roots may cause impairment of tactile sensation, including intermittent severe pain that is referred to their areas of distribution. Destruction of the spinal cord yields complete anesthesia below the level of injury. Selective destruction or degeneration of the posterior columns of the spinal cord is responsible for a loss of position and vibratory sense in segments distal to the lesion, without loss of touch, pain, or temperature perception. A cyst in the center of the spinal cord causes dissociation of sensation—loss of pain at the level of the lesion. This occurs because the fibers carrying pain and temperature cross within the cord immediately on entering; thus, any lesion that divides the cord longitudinally divides these fibers. Other sensory fibers ascend the cord for variable distances, some even to the medulla, before crossing, thereby bypassing the lesion and avoiding destruction. Lesions in the thalamus or parietal lobe result in impaired touch, pain, temperature, and proprioceptive sensations.

Assessment of the Nervous System

Health History

An important aspect of the neurologic assessment is the history of the present illness. The initial interview provides an excellent opportunity to systematically explore the patient's current condition and related events while simultaneously observing overall appearance, mental status, posture, movement, and affect. Depending on the patient's condition, the nurse may need to rely on yes-or-no answers to questions, a review of the medical record, input from witnesses or the family, or a combination of these.

Neurologic disease may be stable or progressive, characterized by symptom-free periods as well as fluctuations in

symptoms. The health history therefore includes details about the onset, character, severity, location, duration, and frequency of symptoms and signs; associated complaints; precipitating, aggravating, and relieving factors; progression, remission, and exacerbation; and the presence or absence of similar symptoms among family members.

Common Symptoms

The symptoms of neurologic disorders are as varied as the disease processes themselves. Symptoms may be subtle or intense, fluctuating or permanent, inconvenient or devastating. This chapter discusses the most common signs and symptoms associated with neurologic disease; the relationship of specific signs and symptoms to a particular disorder is presented in later chapters in this unit.

Pain

Pain is considered an unpleasant sensory perception and emotional experience associated with actual or potential tissue damage or described in terms of such damage. Pain is therefore considered multidimensional and entirely subjective. Pain can be acute or chronic. In general, acute pain lasts for a relatively short period of time and remits as the pathology resolves. In neurologic disease, acute pain may be associated with brain hemorrhage, spinal disk disease (Jarvis, 2007), or trigeminal neuralgia. In contrast, chronic or persistent pain extends for long periods of time and may represent a broader pathology. This type of pain can occur with many degenerative and chronic neurologic conditions (eg, multiple sclerosis). See Chapter 13 for a more detailed discussion of pain.

Seizures

Seizures are the result of abnormal paroxysmal discharges in the cerebral cortex, which then manifest as an alteration in sensation, behavior, movement, perception, or consciousness. The alteration may be short, such as in a blank stare that lasts only a second, or of longer duration, such as a tonic-clonic grand mal seizure that can last several minutes. The seizure activity reflects the area of the brain affected. Seizures can occur as isolated events, such as when induced by a high fever, alcohol or drug withdrawal, or hypoglycemia. A seizure may also be the first obvious sign of a brain lesion (Hickey, 2009).

Dizziness and Vertigo

Dizziness is an abnormal sensation of imbalance or movement. It is fairly common in the elderly and one of the most common complaints encountered by health professionals (Jarvis, 2007). Dizziness can have a variety of causes, including viral syndromes, hot weather, roller coaster rides, and middle ear infections, to name a few. One difficulty confronting health care providers when assessing dizziness is the vague and varied terms patients use to describe the sensation.

About 50% of all patients with dizziness have **vertigo**, which is defined as an illusion of movement, usually rotation (Jarvis, 2007). Vertigo is usually a manifestation of vestibular dysfunction. It can be so severe as to result in spatial disorientation, lightheadedness, loss of equilibrium (staggering), and nausea and vomiting.

Visual Disturbances

Visual defects that cause people to seek health care can range from the decreased visual acuity associated with aging to sudden blindness caused by glaucoma. Normal vision depends on functioning visual pathways through the retina and optic chiasm and the radiations into the visual cortex in the occipital lobes. Lesions of the eye itself (eg, cataract), lesions along the pathway (eg, tumor), or lesions in the visual cortex (eg, stroke) interfere with normal visual acuity. Abnormalities of eye movement (as in the nystagmus associated with multiple sclerosis) can also compromise vision by causing diplopia or double vision. See Chapter 58 for a more detailed discussion of disorders that affect vision.

Muscle Weakness

Muscle weakness is a common manifestation of neurologic disease. It frequently coexists with other symptoms of disease and can affect a variety of muscles, causing a wide range of disability. Weakness can be sudden and permanent, as in stroke, or progressive, as in neuromuscular diseases such as amyotrophic lateral sclerosis. Any muscle group can be affected.

Abnormal Sensation

Abnormal sensation is a neurologic manifestation of both central and peripheral nervous system disease. Altered sen-

sation can affect small or large areas of the body. It is frequently associated with weakness or pain and is potentially disabling. Lack of sensation places a person at risk for falls and injury.

Past Health, Family, and Social History

The nurse may inquire about any family history of genetic diseases (Chart 60-1). A review of the medical history, including a system-by-system evaluation, is part of the health history. The nurse should be aware of any history of trauma or falls that may have involved the head or spinal cord. Questions regarding the use of alcohol, medications, and illicit drugs are also relevant. The history-taking portion of the neurologic assessment is critical and, in many cases of neurologic disease, leads to an accurate diagnosis.

Physical Assessment

The neurologic examination is a systematic process that includes a variety of clinical tests, observations, and assessments designed to evaluate the neurologic status of a complex system. Many neurologic rating scales exist (Herndon, 2006), and some of the more common ones are discussed in this chapter.

The brain and spinal cord cannot be examined as directly as other systems of the body. Thus, much of the neurologic examination is an indirect evaluation that assesses

CHART
60-1

GENETICS IN NURSING PRACTICE

Neurologic Disorders

Diseases and Conditions Influenced by Genetic Factors

- Alzheimer's disease
- Amyotrophic lateral sclerosis (ALS)
- Duchenne muscular dystrophy
- Epilepsy
- Friedrich ataxia
- Huntington disease
- Myotonic dystrophy
- Neurofibromatosis type I
- Parkinson's disease
- Spina bifida
- Tourette syndrome

Nursing Assessments

Family History Assessment

- Assess for other similarly affected relatives with neurologic impairment.
- Inquire about age of onset (eg, present at birth—spina bifida; developed in childhood—Duchenne muscular dystrophy; developed in adulthood—Huntington disease, Alzheimer's disease, amyotrophic lateral sclerosis).
- Inquire about the presence of related conditions such as mental retardation and/or learning disabilities (neurofibromatosis type I).

Patient Assessment

- Assess for the presence of other physical features suggestive of an underlying genetic condition, such as skin lesions seen in neurofibromatosis type 1 (café-au-lait spots).
- Assess for other congenital abnormalities (eg, cardiac, ocular).

Management Specific to Genetics

- Inquire whether DNA mutation or other genetic testing has been performed on affected family members.
- If indicated, refer for further genetic counseling and evaluation so that family members can discuss inheritance, risk to other family members, availability of genetic testing, and gene-based interventions.
- Offer appropriate genetic information and resources.
- Assess patient's understanding of genetic information.
- Provide support to families with newly diagnosed genetic-related neurologic disorders.
- Participate in management and coordination of care of patients with genetic conditions and individuals predisposed to develop or pass on a genetic condition.

Genetics Resources for Nurses and Their Patients on the Web

Genetic Alliance—a directory of support groups for patients and families with genetic conditions, www.geneticalliance.org

Gene Clinics—a listing of common genetic disorders with up-to-date clinical summaries, genetic counseling, and testing information, www.geneclinics.org

National Organization of Rare Disorders—a directory of support groups and information for patients and families with rare genetic disorders, www.rarediseases.org

OMIM: Online Mendelian Inheritance in Man—a complete listing of inherited genetic conditions, www.ncbi.nlm.nih.gov/omim/stats/html

the function of the specific body part or parts controlled by the nervous system. A neurologic assessment is divided into five components: consciousness and cognition, cranial nerves, motor system, sensory system, and reflexes. One or more components may become the priority assessment, depending on the patient's condition. For example, motor, sensory, and reflex assessments are the priority in patients with spinal injury, while in a comatose patient, the cranial nerves and level of consciousness become the priority.

Assessing Consciousness and Cognition

Cerebral abnormalities may cause disturbances in mental status, intellectual functioning, thought content, and emotional status. There may also be alterations in language abilities, as well as lifestyle. The examiner must also be aware of the patient's overall level of consciousness and any changes over time (Posner, et al., 2007).

The examiner records and reports specific observations regarding mental status, intellectual function, thought content, and emotional status, all of which permit comparison by others over time. Alterations should be described in specific and nonjudgmental terms. Use of terms such as "inappropriate" or "demented" are avoided as they often mean different things to different people and are therefore not useful when describing behavior. Analysis and the conclusions that may be drawn from these findings usually depend on the examiner's knowledge of neuroanatomy, neurophysiology, and neuropathology.

Mental Status

An assessment of mental status begins by observing the patient's appearance and behavior, noting dress, grooming, and personal hygiene. Posture, gestures, movements, and facial expressions often provide important information about the patient. Does the patient appear to be aware of and interact with the surroundings?

Assessing orientation to time, place, and person assists in evaluating mental status. Does the patient know what day it is, what year it is, and the name of the president of the United States? Is the patient aware of where he or she is? Is the patient aware of who the examiner is and of his or her purpose for being in the room? Assessment of immediate and remote memory is also important. Is the capacity for immediate memory intact? (See Chapter 12.)

Intellectual Function

A person with an average IQ can repeat seven digits without faltering and can recite five digits backward. The examiner might ask the patient to count backward from 100 or to subtract 7 from 100, then 7 from that, and so forth (called serial 7s). The capacity to interpret well-known proverbs tests abstract reasoning, which is a higher intellectual function; for example, does the patient know what is meant by "a stitch in time saves nine"? The intellectual function of patients with damage to the frontal cortex appears intact until one or more tests of intellectual capacity are performed. Questions designed to assess this capacity might include the ability to recognize similarities: for example, how are a mouse and dog or pen and pencil alike? Can the patient make judgments about situations: for example, if the patient arrived home without a house key, what alternatives are there?

Thought Content

During the interview, it is important to assess the patient's thought content. Are the patient's thoughts spontaneous, natural, clear, relevant, and coherent? Does the patient have any fixed ideas, illusions, or preoccupations? What are his or her insights into these thoughts? Preoccupation with death or morbid events, hallucinations, and paranoid ideation are examples of unusual thoughts or perceptions that require further evaluation.

Emotional Status

An assessment of consciousness and cognition also includes the patient's emotional status. Is the patient's affect (external manifestation of mood) natural and even, or irritable and angry, anxious, apathetic or flat, or euphoric? Does his or her mood fluctuate normally, or does the patient unpredictably swing from joy to sadness during the interview? Is affect appropriate to words and thought content? Are verbal communications consistent with nonverbal cues?

Language Ability

The person with normal neurologic function can understand and communicate in spoken and written language. Does the patient answer questions appropriately? Can he or she read a sentence from a newspaper and explain its meaning? Can the patient write his or her name or copy a simple figure that the examiner has drawn? A deficiency in language function is called aphasia. Different types of aphasia result from injury to different parts of the brain (Table 60-5). Aphasia is discussed in detail in Chapter 62.

Impact on Lifestyle

The nurse assesses the impact any impairment has on the patient's lifestyle. Issues to consider include the limitations imposed on the patient by any cognitive deficit and the patient's role in society, including family and community roles. The plan of care that the nurse develops needs to address and support adaptation to the neurologic deficit and continued function to the extent possible within the patient's support system.

Level of Consciousness

Consciousness is the patient's wakefulness and ability to respond to the environment. Level of consciousness is the most sensitive indicator of neurologic function. To assess level of consciousness, the examiner observes for alertness and ability to follow commands.

If the patient is not alert or able to follow commands, the examiner observes for eye opening; verbal response and motor response to stimuli, if any; and the type of stimuli needed to obtain a response. Noxious stimuli should be used first, then painful stimuli if no response is observed. In the

Table 60-5 TYPES OF APHASIA AND REGION OF BRAIN INVOLVED

Type of Aphasia	Brain Area Involved
Auditory-receptive	Temporal lobe
Visual-receptive	Parietal-occipital area
Expressive speaking	Inferior posterior frontal areas

NURSING RESEARCH PROFILE

Early Identification of Vasospasm Following Subarachnoid Hemorrhage

Doerksen, K. & Naimark, B. (2006). Nonspecific behaviors as early indicators of cerebral vasospasm. *Journal of Neuroscience Nursing, 38*(6), 409–415.

Purpose

The significance of behavioral changes seen early after subarachnoid hemorrhage is not understood. The purpose of this study was to delineate nonspecific behaviors seen after subarachnoid hemorrhage and to determine the prevalence of those behaviors in patients with vasospasm (a complication of subarachnoid hemorrhage). If significant, such behaviors may be better early predictors of problems as compared to other assessment findings.

Design

This prospective study evaluated nursing documentation of nonspecific behaviors during the acute phase of care of 60 patients (39 female and 21 male) with subarachnoid hemorrhage. After record reviews, behavioral descriptors were

quantified. The prevalence of the behavioral descriptors was determined in the 31 patients who developed vasospasm and compared to those who did not develop vasospasm.

Findings

Twenty-four of the 31 patients who developed vasospasm demonstrated nonspecific behaviors prior to development of the traditional signs and symptoms of vasospasm (decreased level of consciousness, focal deficits, or aphasia). The three primary nonspecific behaviors were acting restless, impulsive, or strange.

Nursing Implications

More research is needed but this study illustrates that nursing assessment can reveal nonspecific behaviors that are useful in the early identification of vasospasm after subarachnoid hemorrhage. Use of earlier identification may result in earlier intervention and prevention of brain ischemia.

patient with decreased level of consciousness, motor and cranial nerve function become the priority assessments, as abnormalities can indicate the area of involvement in the absence of responsiveness. Further discussion of changes in level of consciousness is found in Chapter 61. See Chart 60-2.

Examining the Cranial Nerves

Cranial nerves are assessed when level of consciousness is decreased, with brain stem pathology, or in the presence of peripheral nervous system disease. Chart 60-3 describes assessment of the cranial nerves and significant findings. Right and left cranial nerve functions are compared throughout the examination.

Examining the Motor System**Motor Ability**

A thorough examination of the motor system includes an assessment of muscle size and tone as well as strength, coordination, and balance. The patient is instructed to walk across the room, if possible, while the examiner observes posture and gait. The muscles are inspected, and palpated if necessary, for their size and symmetry. Any evidence of atrophy or involuntary movements (tremors, tics) is noted. Muscle tone (the tension present in a muscle at rest) is evaluated by palpating various muscle groups at rest and during passive movement. Resistance to these movements is assessed and documented. Abnormalities in tone include **spasticity** (increased muscle tone), **rigidity** (resistance to passive stretch), and **flaccidity**.

Muscle Strength

Assessing the patient's ability to flex or extend the extremities against resistance tests muscle strength. The function of an individual muscle or group of muscles is evaluated by placing the muscle at a disadvantage. The quadriceps, for example, is a powerful muscle responsible for straightening the leg. Once the leg is straightened, it is exceedingly diffi-

cult for the examiner to flex the knee. If the knee is flexed and the patient is asked to straighten the leg against resistance, weakness can be elicited. The evaluation of muscle strength compares the sides of the body to each other. For example, the right upper extremity is compared to the left upper extremity. Subtle differences in strength may be evaluated by testing for drift. For example, both arms are out in front of the patient with palms up; drift is seen as pronation of the palm, indicating a subtle weakness that may not have been detected on the resistance examination.

Clinicians use a 5-point scale to rate muscle strength. A 5 indicates full power of contraction against gravity and resistance or normal muscle strength; 4 indicates fair but not full strength against gravity and a moderate amount of resistance or slight weakness; 3 indicates just sufficient strength to overcome the force of gravity or moderate weakness; 2 indicates the ability to move but not to overcome the force of gravity or severe weakness; 1 indicates minimal contractile power (weak muscle contraction can be palpated but no movement is noted) or very severe weakness; and 0 indicates no movement (Jarvis, 2007). A stick figure may be used to record muscle strength and is a precise form of documenting findings. Distal and proximal strength in both upper and lower extremities is recorded using the 5-point scale (Fig. 60-12).

Assessment of muscle strength may be as detailed as necessary. One may quickly test the strength of the proximal muscles of the upper and lower extremities, always comparing both sides. The strength of the finer muscles that control the function of the hand (hand grasp) and the foot (dorsiflexion and plantar flexion) can then be assessed.

Balance and Coordination

Cerebellar and basal ganglia influence on the motor system is reflected in balance control and coordination. Coordination in the hands and upper extremities is tested by having the patient perform rapid, alternating movements and

Guidelines for Assessing Cranial Nerve Function

Equipment

- Tongue depressor
- Flashlight
- Sugar and salt samples
- Watch
- Cotton-tipped swab
- Snellen chart
- Ophthalmoscope
- Samples of familiar odors
- Tuning fork

Implementation

Step

1. Assess cranial nerve (CN) I (olfactory). With eyes closed, patient is asked to identify familiar odors (coffee, tobacco). Each nostril is tested separately.
2. Assess CN II (optic). Assess vision using a Snellen eye chart. Assess visual fields. Perform ophthalmoscopic examination.
3. Assess CN III (oculomotor). Test for eye movement toward the nose; inspect for conjugate movements and nystagmus. Evaluate papillary size and test for pupillary reactivity to light; inspect ability to open eyelids.
4. Assess CN IV (trochlear). Test for upward eye movement; inspect for conjugate movements and nystagmus.
5. Assess CN V (trigeminal). Have patient close the eyes. Touch cotton to forehead, cheeks, and jaw. Sensitivity to superficial pain is tested in these same three areas by using the sharp and dull ends of a broken tongue blade. Alternate between the sharp point and the dull end. Patient reports "sharp" or "dull" with each movement. If responses are incorrect, test for temperature sensation. Test tubes of cold and hot water are used alternately.

While patient looks up, *lightly* touch a wisp of cotton against the temporal surface of each cornea. A blink and tearing are normal responses.

Have patient clench and move the jaw from side to side. Palpate the masseter and temporal muscles, noting strength and equality.
6. Assess CN VI (abducens). Test for lateral eye movement; inspect for conjugate movement.
7. Assess CN VII (facial). Observe for symmetry while patient performs facial movements: smiles, whistles, elevates eyebrows, frowns, tightly closes eyelids against resistance (examiner attempts to open them). Observe face for flaccid paralysis (shallow nasolabial folds). Have patient extend tongue. Test ability to discriminate between sugar and salt.
8. Assess CN VIII (acoustic). Perform whisper or watch-tick test. Test for lateralization (Weber test). Test for air and bone conduction (Rinne test). Assess standing balance with eyes closed (Romberg test).
9. Assess CN IX (glossopharyngeal). Assess patient's ability to swallow and discriminate between sugar and salt on posterior third of the tongue.
10. Assess CN X (vagus). Depress a tongue blade on posterior tongue, or stimulate posterior pharynx to elicit gag reflex. Note any hoarseness in voice. Check ability to swallow. Have patient say "ah." Observe for symmetric rise of uvula and soft palate.

Rationale

The significant finding is loss of sense of smell (anosmia).

Significant findings include visual field defects (hemianopias) and decreased visual acuity or blindness.

Significant findings include dysconjugate gaze; gaze weakness or paralysis; double vision; dilated pupil, with or without impaired pupillary reaction to light; and inability to open the affected eyelid.

Significant findings include dysconjugate gaze, gaze weakness or paralysis, and double vision.

Significant findings include impaired or absent corneal reflex, facial numbness, and jaw weakness.

Significant findings include dysconjugate gaze, gaze weakness or paralysis, and double vision.

Significant findings include facial weakness, inability to completely close the eyelid, and impaired taste.

Significant findings include decreased hearing or deafness and impaired balance.

Significant findings include difficulty swallowing (dysphagia) and impaired taste.

Significant findings include weak or absent gag reflex, difficulty swallowing, aspiration, hoarseness, and slurred speech (dysarthria).

CHART
60-3
Guidelines for Assessing Cranial Nerve Function (Continued)

11. Assess CN XI (spinal accessory). While patient shrugs shoulders against resistance, palpate and note strength of trapezius muscles. As patient turns head against opposing pressure of the examiner's hand, palpate and note strength of each sternocleidomastoid muscle.
12. Assess CN XII (hypoglossal). While patient protrudes the tongue, note any deviation or tremors. Test the strength of the tongue by having patient move the protruded tongue from side to side against a tongue depressor.

Significant findings include weak or absent shoulder shrug and inability to turn the head to the side.

Significant findings include difficulty swallowing and slurred speech.

point-to-point testing. First, the patient is instructed to pat his or her thigh as fast as possible with each hand separately. Then the patient is instructed to alternately pronate and supinate the hand as rapidly as possible. Last, the patient is asked to touch each of the fingers with the thumb in a consecutive motion. Speed, symmetry, and degree of difficulty are noted. Point-to-point testing is accomplished by having the patient touch the examiner's extended finger and then his or her own nose. This is repeated several times.

Coordination in the lower extremities is tested by having the patient run the heel down the anterior surface of the tibia of the other leg. Each leg is tested in turn. **Ataxia** is defined as incoordination of voluntary muscle action, particularly of the muscle groups used in activities such as walking or reaching for objects. Tremors (rhythmic, involuntary movements) noted at rest or during movement suggest a problem in the anatomic areas responsible for balance and coordination.

The **Romberg test** is a screening test for balance. The patient stands with feet together and arms at the side, first with eyes open and then with both eyes closed for 20 to 30 seconds. The examiner stands close to support the patient if

he or she begins to fall. Slight swaying is normal, but a loss of balance is abnormal and is considered a positive Romberg test. Additional cerebellar tests for balance in the ambulatory patient include hopping in place, alternating knee bends, and heel-to-toe walking (both forward and backward).

Examining the Sensory System

The sensory system is even more complex than the motor system, because sensory modalities are more widespread throughout the central and peripheral nervous systems. The sensory examination is largely subjective and requires the cooperation of the patient. The examiner should be familiar with dermatomes that represent the distribution of the peripheral nerves that arise from the spinal cord (see Fig. 60-9) (Bickley, 2009; Jarvis, 2007).

Assessment of the sensory system involves tests for tactile sensation, superficial pain, temperature, vibration, and position sense (proprioception). During the sensory assessment, the patient's eyes are closed. Simple directions and reassurance that the examiner will not hurt or startle the patient encourage the cooperation of the patient.

Tactile sensation is assessed by lightly touching a cotton wisp or fingertip to corresponding areas on each side of the body. The sensitivity of proximal parts of the extremities is compared with that of distal parts, and the right and left sides are compared.

Pain and temperature sensations are transmitted together in the lateral part of the spinal cord, so it is unnecessary to test for temperature sense in most circumstances. Determining the patient's sensitivity to a sharp object can assess superficial pain perception. However, pain sensation is usually reserved for patients who do not respond to or cannot discriminate touch stimulation. The patient is asked to differentiate between the sharp and dull ends of a broken wooden cotton swab or tongue blade; using a safety pin is inadvisable because it breaks the integrity of the skin. Both the sharp and dull sides of the object are applied with equal intensity at all times, and the two sides are compared.

Vibration and proprioception are transmitted together in the posterior part of the cord. Vibration may be evaluated through the use of a low-frequency (128- or 256-Hz) tuning fork. The handle of the vibrating fork is placed against a bony prominence, and the patient is asked if he or she feels a sensation and is instructed to signal the examiner when the sensation ceases. Common locations used to test for vibratory sense include the distal joint of the great toe and the

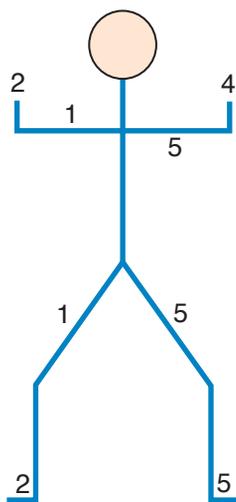

Figure 60-12 A stick figure may be used to record muscle strength as follows: 5, full range of motion against gravity and resistance; 4, full range of motion against gravity and a moderate amount of resistance; 3, full range of motion against gravity only; 2, full range of motion when gravity is eliminated; 1, a weak muscle contraction when muscle is palpated, but no movement; and 0, complete paralysis.

proximal thumb joint. If the patient does not perceive the vibrations at the distal bony prominences, the examiner progresses upward with the tuning fork until the patient perceives the vibrations. As with all measurements of sensation, a side-to-side comparison is made.

Position sense or proprioception may be determined by asking the patient to close both eyes and indicate, as the great toe or index finger is alternately moved up and down, in which direction movement has taken place. Vibration and position sense are often lost together, frequently in circumstances in which all other sensation remains intact.

Integration of sensation in the brain is evaluated by testing two-point discrimination. When the patient is touched with two sharp objects simultaneously, are they perceived as two or as one? If touched simultaneously on opposite sides of the body, the patient should normally report being touched in two places. If only one site is reported, the one not being recognized is said to demonstrate extinction. Another test of higher cortical sensory ability is tactile identification. The patient is instructed to close both eyes and identify an object (eg, key, coin) that is placed in one hand by the examiner; inability to identify an object by touch is known as tactile agnosia or astereognosis. **Agnosia** is the general loss of ability to recognize objects through a particular sensory system. The patient can also be shown a familiar object and asked to identify it by name; inability to identify a visualized object is known as visual agnosia. Each of these dysfunctions implicates a different part of the brain (Table 60-6).

Decreased or absent sensations occur with problems anywhere along the sensory pathway. Sensory deficits resulting from peripheral neuropathy or spinal cord injury follow anatomic dermatomes. Destructive lesions of the brain may affect sensation on an entire side of the body. Stroke affecting a portion of the sensory cortex will produce altered sensory discrimination.

Examining the Reflexes

Reflexes are involuntary contractions of muscles or muscle groups in response to a stimulus. Reflexes are classified as deep tendon, superficial, or pathologic. Testing reflexes enables the examiner to assess involuntary reflex arcs that depend on the presence of afferent stretch receptors, spinal or brain stem synapses, efferent motor fibers, and a variety of modifying influences from higher levels.

Deep Tendon Reflexes

A reflex hammer is used to elicit a deep tendon reflex. The handle of the hammer is held loosely between the thumb and index finger, allowing a full swinging motion. The wrist

motion is similar to that used during percussion. The extremity is positioned so that the tendon is slightly stretched. This requires a sound knowledge of the location of muscles and their tendon attachments. The tendon is then struck briskly (Fig. 60-13), and the response is compared with that on the opposite side of the body. A wide variation in reflex response may be considered normal; however, it is more important that the reflexes be symmetrically equivalent. When the comparison is made, both sides should be equivalently relaxed and each tendon struck with equal force.

Valid findings depend on several factors: proper use of the reflex hammer, proper positioning of the extremity, and a relaxed patient (Bickley, 2007; Jarvis, 2007). If the reflexes are symmetrically diminished or absent, the examiner may use isometric contraction of other muscle groups to increase reflex activity. For example, if lower extremity reflexes are diminished or absent, the patient is instructed to lock the fingers together and pull in opposite directions. Having the patient clench the jaw or press the heels against the floor or examining table may similarly elicit more reliable biceps, triceps, and brachioradialis reflexes.

The absence of reflexes is significant, although ankle jerks (Achilles reflex) may be normally absent in older people. Deep tendon reflex responses are often graded on a scale of 0 to 4+ (Chart 60-4). As stated previously, scale ratings are highly subjective. Findings can be recorded as a fraction, indicating the scale range (eg, 2/4). Some examiners prefer to use the terms *present*, *absent*, and *diminished* when describing reflexes. As with muscle strength recording, a stick figure may be used to record numerical findings.

Biceps Reflex. The biceps reflex is elicited by striking the biceps tendon over a slightly flexed elbow (see Fig. 60-13A). The examiner supports the forearm with one arm while placing the thumb against the tendon and striking the thumb with the reflex hammer. The normal response is flexion at the elbow and contraction of the biceps.

Triceps Reflex. To elicit a triceps reflex, the patient's arm is flexed at the elbow and positioned in front of the chest. The examiner supports the patient's arm and identifies the triceps tendon by palpating 2.5 to 5 cm (1 to 2 inches) above the elbow. A direct blow on the tendon (see Fig. 60-13B) normally produces contraction of the triceps muscle and extension of the elbow.

Brachioradialis Reflex. With the patient's forearm resting on the lap or across the abdomen, the brachioradialis reflex is assessed. A gentle strike of the hammer 2.5 to 5 cm (1 to 2 inches) above the wrist results in flexion and supination of the forearm (Weber & Kelley, 2007).

Patellar Reflex. The patellar reflex is elicited by striking the patellar tendon just below the patella. The patient may be in a sitting or a lying position. If the patient is supine, the examiner supports the legs to facilitate relaxation of the muscles (see Fig. 60-13C). Contractions of the quadriceps and knee extension are normal responses.

Achilles Reflex. To elicit an Achilles reflex, the foot is dorsiflexed at the ankle and the hammer strikes the stretched Achilles tendon (see Fig. 60-13D). This reflex normally produces plantar flexion. If the examiner cannot

Table 60-6 TYPES OF AGNOSIA AND CORRESPONDING SITES OF LESIONS

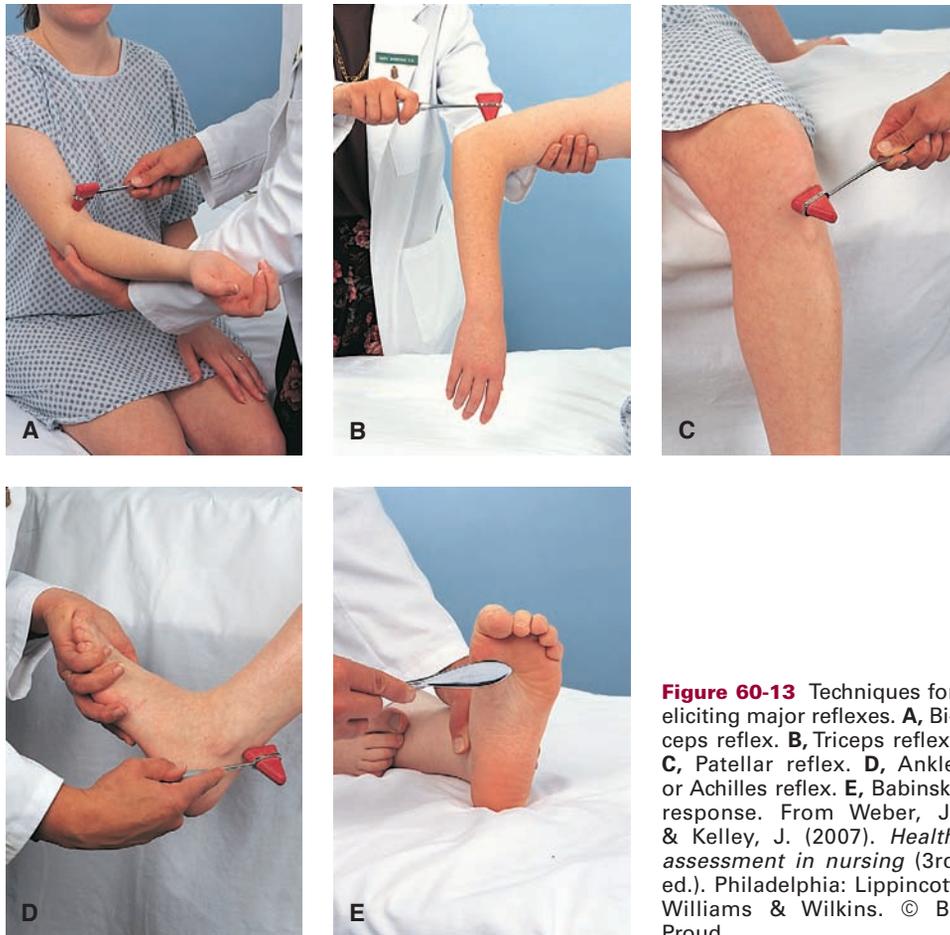

Figure 60-13 Techniques for eliciting major reflexes. **A**, Biceps reflex. **B**, Triceps reflex. **C**, Patellar reflex. **D**, Ankle or Achilles reflex. **E**, Babinski response. From Weber, J. & Kelley, J. (2007). *Health assessment in nursing* (3rd ed.). Philadelphia: Lippincott Williams & Wilkins. © B. Proud.

elicit the ankle reflex and suspects that the patient cannot relax, the patient is instructed to kneel on a chair or similar elevated, flat surface. This position places the ankles in dorsiflexion and reduces any muscle tension in the gastrocnemius. The Achilles tendons are struck in turn, and plantar flexion is usually demonstrated (Weber & Kelley, 2007).

Clonus. When reflexes are very hyperactive, a phenomenon called **clonus** may be elicited. If the foot is abruptly

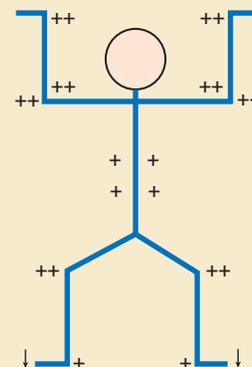

dorsiflexed, it may continue to “beat” two or three times before it settles into a position of rest. Occasionally with central nervous system disease this activity persists, and the foot does not come to rest while the tendon is being stretched but persists in repetitive activity. The unsustained clonus associated with normal but hyperactive reflexes is not considered pathologic. Sustained clonus always indicates the presence of central nervous system disease and requires further evaluation.

Chart 60-4 • Documenting Reflexes

Deep tendon reflexes are graded on a scale of 0 to 4:

- 0 No response
- 1+ Diminished (hypoactive)
- 2+ Normal
- 3+ Increased (may be interpreted as normal)
- 4+ Hyperactive (hyperreflexia)

The deep tendon responses and plantar reflexes are commonly recorded on stick figures. The arrow points downward if the plantar response is normal and upward if the response is abnormal.

Superficial Reflexes

The major superficial reflexes include corneal, palpebral, gag, upper/lower abdominal, cremasteric (men only), plantar, and perianal. These reflexes are graded differently than the motor reflexes and are noted to be present (+) or absent (−). Of these, only the corneal, gag, and plantar reflexes are tested commonly.

The corneal reflex is tested carefully using a clean wisp of cotton and lightly touching the outer corner of each eye on the sclera. The reflex is present if the action elicits a blink. A stroke or brain injury might result in loss of this reflex, either unilaterally or bilaterally. Loss of this reflex indicates the need for eye protection and possible lubrication to prevent corneal damage.

The gag reflex is elicited by gently touching the back of the pharynx with a cotton-tipped applicator, first on one side of the uvula and then the other. Positive response is an equal elevation of the uvula and “gag” with stimulation. Absent response on one or both sides can be seen following a stroke and requires careful evaluation and treatment of the resultant swallowing dysfunction to prevent aspiration of food and fluids.

The plantar reflex is elicited by stroking the sole of the foot with a tongue blade or the handle of a reflex hammer. Stimulation normally causes toe flexion.

Pathologic Reflexes

Pathologic reflexes are seen in the presence of neurologic disease; they often represent emergence of earlier reflexes that disappeared with maturity of the nervous system. A well-known pathologic reflex indicative of central nervous system disease affecting the corticospinal tract is the **Babinski reflex**. In a person with an intact central nervous system, if the lateral aspect of the sole of the foot is stroked, the toes contract and draw together (see Fig. 60-13E). However, in a person who has central nervous system disease of the motor system, the toes fan out and draw back (Jarvis, 2007; Weber & Kelley, 2007). This is normal in newborns but represents a serious abnormality in adults. Several other pathologic reflexes convey similar information. Although many of them are interesting, they are not particularly informative.

Gerontologic Considerations

During the normal aging process, the nervous system undergoes many changes, and is more vulnerable to illness. Changes throughout the nervous system that occur with age vary in degree. Nervous system changes due to aging must be distinguished from those due to disease; it is important for clinicians not to attribute abnormality or dysfunction to aging without appropriate investigation (Neal-Boylan, 2007). For example, while diminished strength and agility are a normal part of aging, localized weakness can only be attributed to disease.

Structural and Physiologic Changes

A number of alterations occur with increasing age. A loss of neurons occurs, leading to a decrease in the number of synapses and neurotransmitters. This results in slowed nerve conduction and response time. Brain weight is decreased and the ventricle size increases to maintain cranial volume. Cere-

bral blood flow and metabolism are reduced, leading to slower mental functions. Temperature regulation becomes less efficient. In the peripheral nervous system, myelin is lost, resulting in a decrease in conduction velocity in some nerves. Visual and auditory nerves degenerate, leading to loss of visual acuity and hearing. Taste buds atrophy and nerve cell fibers in the olfactory bulb degenerate (Jarvis, 2007). Nerve cells in the vestibular system of the inner ear, cerebellum, and proprioceptive pathways also degenerate, leading to balance difficulties. Deep tendon reflexes can be decreased or in some cases absent. Hypothalamic function is modified such that stage IV sleep is reduced. There is an overall slowing of autonomic nervous system responses. Pupillary responses are reduced or may not appear at all in the presence of cataracts.

Motor Alterations

Reduced nerve input into muscle contributes to an overall reduction in muscle bulk, with atrophy most easily noted in the hands. Changes in motor function often result in decreased strength and agility, with increased reaction time. Gait is often slowed and wide based. These changes can create difficulties in maintaining balance, predisposing the older person to falls.

Sensory Alterations

Tactile sensation is dulled in the elderly person due to a decrease in the number of sensory receptors. There may be difficulty in identifying objects by touch, because fewer tactile cues are received from the bottom of the feet and the person may become confused about body position and location (Wickremaratchi & Llewelyn, 2006).

Sensitivity to glare, decreased peripheral vision, and a constricted visual field occur due to degeneration of visual pathways, resulting in disorientation, especially at night when there is little or no light in the room. Because the elderly person takes longer to recover visual sensitivity when moving from a light to dark area, nightlights and a safe and familiar arrangement of furniture are essential.

Loss of hearing can contribute to confusion, anxiety, disorientation, misinterpretation of the environment, feelings of inadequacy, and social isolation. A decreased sense of taste and smell may contribute to weight loss and disinterest in food. A decreased sense of smell may present a safety hazard, because elderly people living alone may be unable to detect household gas leaks or fires. Smoke and carbon monoxide detectors, important for all, are critical for the elderly.

Temperature Regulation and Pain Perception

The elderly patient may feel cold more readily than heat and may require extra covering when in bed; a room temperature somewhat higher than usual may be desirable. Reaction to painful stimuli may be decreased with age. Because pain is an important warning signal, caution must be used when hot or cold packs are used. The older patient may be burned or suffer frostbite before being aware of any discomfort. Complaints of pain, such as abdominal discomfort or chest pain, may be more serious than the patient's perception might indicate and thus require careful evaluation (Neal-Boylan, 2007). Two pain syndromes that are common in the neurologic system in older adults are diabetic neuropathies and postherpetic neuropathies (Bickley, 2007).

Mental Status

Although mental processing time decreases with age, memory, language, and judgment capacities remain intact. Change in mental status should never be assumed to be a normal part of aging. **Delirium** (mental confusion, usually with delusions and hallucinations) is seen in elderly patients who have underlying central nervous system damage or are experiencing an acute condition such as infection, adverse medication reaction, or dehydration. Drug toxicity and depression may produce impairment of attention and memory, and should be evaluated as a possible cause of mental status change. Delirium must be differentiated from dementia, which is a chronic and irreversible deterioration of cognitive status. Chapter 12 contains further discussion of delirium and dementia.

Nursing Implications

Nursing care for patients with age-related changes to the nervous system and for patients with long-term neurologic disability who are aging should include the previously described modifications. In addition, the consequences of any neurologic deficit and its impact on overall function such as activities of daily living, use of assistive devices, and individual coping should be assessed and considered in planning patient care. Fall risk must be evaluated, and fall prevention measures instituted for the hospitalized patient as well as in the home.

The nurse must understand the altered responses and the changing needs of the elderly patient before providing education. Visual and hearing deficits require adaptations in activities such as preoperative teaching, diet therapy, and instruction about new medications. When using visual materials for teaching or menu selection, adequate lighting without glare, contrasting colors, and large print are used to offset visual difficulties caused by rigidity and opacity of the lens in the eye and slower pupillary reaction. Procedures and preparations needed for diagnostic tests are explained, taking into account the possibility of impaired hearing and slowed responses in the elderly. Even with hearing loss, the elderly patient often hears adequately if the speaker uses a low-pitched, clear voice; shouting only makes it harder for the patient to understand the speaker. Providing auditory and visual cues aids understanding; if the patient has a significant hearing or visual loss, assistive devices, a signer, an interpreter, or a translator may be needed.

Teaching at an unrushed pace and using reinforcement enhance learning and retention. Material should be short, concise, and concrete. Vocabulary is matched to the patient's ability, and terms are clearly defined. The elderly patient requires adequate time to receive and respond to stimuli, learn, and react. These measures allow comprehension, memory, and formation of association and concepts.

Diagnostic Evaluation

Computed Tomography Scanning

Computed tomography (CT) scanning uses a narrow x-ray beam to scan body parts in successive layers. The images provide cross-sectional views of the brain, distinguishing differences in tissue densities of the skull, cortex, subcortical structures, and ventricles. An intravenous (IV) contrast

agent may be used to highlight differences further. The brightness of each slice of the brain in the final image is proportional to the degree to which it absorbs x-rays. The image is displayed on an oscilloscope or TV monitor and is photographed and stored digitally (Bremner, 2005). CT scanning is usually performed first without contrast material and then with IV contrast, if needed. The patient lies on an adjustable table with the head in a head rest while the scanning system rotates around the head and produces cross-sectional images. The patient must lie with the head held perfectly still without talking or moving the face, because head motion distorts the image. CT scanning is quick and painless and uses a small amount of radiation to produce images; it has a high degree of sensitivity for detecting lesions.

Brain lesions have a different tissue density from the surrounding normal brain tissue. Abnormalities detected on brain CT include tumor or other masses, infarction, hemorrhage, displacement of the ventricles, and cortical atrophy (Bremner, 2005). CT angiography allows visualization of blood vessels; in some situations this eliminates the need for formal angiography. Whole-body CT scanners allow cross-sections of the spinal cord to be visualized. The injection of a water-soluble iodinated contrast agent into the subarachnoid space through lumbar puncture improves the visualization of the spinal and intracranial contents on these images. The CT scan, along with magnetic resonance imaging (MRI), has largely replaced myelography as a diagnostic procedure for the diagnosis of herniated lumbar disks.

Nursing Interventions

Essential nursing interventions include preparation for the procedure and patient monitoring. Preparation includes teaching the patient about the need to lie quietly throughout the procedure. A review of relaxation techniques may be helpful for patients with claustrophobia. Sedation can be used if agitation, restlessness, or confusion interferes with a successful study. Ongoing patient monitoring during sedation is necessary. If a contrast agent is used, the patient must be assessed before the CT scan for an iodine/shellfish allergy, because the contrast agent used may be iodine based. Renal function must also be evaluated, as the contrast material is cleared through the kidneys. A suitable IV line for contrast injection and a period of fasting (usually 4 hours) are required prior to the study. Patients who receive an IV contrast agent are monitored during and after the procedure for allergic reactions and changes in kidney function (Karpoff & Labus, 2008).

Magnetic Resonance Imaging

MRI uses a powerful magnetic field to obtain images of different areas of the body. The magnetic field causes the hydrogen nuclei (protons) within the body to align like small magnets in a magnetic field. In combination with radiofrequency pulses, the protons emit signals, which are converted to images. An MRI scan can be performed with or without a contrast agent and can identify a cerebral abnormality earlier and more clearly than other diagnostic tests (Bremner, 2005). It can provide information about the chemical changes within cells, allowing the clinician to monitor a tumor's response to treatment. It is particularly useful in the diagnosis of brain tumor, stroke, and multiple

sclerosis, and does not involve ionizing radiation. A complete MRI scan may take an hour or longer to complete, so use in emergency situations is limited.

Newer MRI applications allow imaging of brain blood flow and metabolism via special imaging techniques added to the MRI. Such techniques include diffusion-weighted imaging (DWI), perfusion-weighted imaging (PWI), magnetic resonance spectroscopy, and fluid attenuation inversion recovery (FLAIR) (Bremner, 2005). Magnetic resonance angiography (MRA) allows separate visualization of the cerebral vasculature without the administration of an arterial contrast agent. Both MRI and CT images are used as tools to plan and direct surgical intervention.

Nursing Interventions

Patient preparation includes teaching and obtaining an adequate history. Ferromagnetic substances in the body may become dislodged by the magnet, so history of working with metal fragments must be reviewed. The patient is questioned about any implants of any metal objects (eg, aneurysm clips, orthopedic hardware, pacemakers, artificial heart valves, intrauterine devices). These objects could malfunction, be dislodged, or heat up as they absorb energy. Cochlear implants will be inactivated by MRI; therefore, other imaging procedures are considered. A complete list of metal compatibility may be found on MRI manufacturers' Web sites contained in the resource section at the end of the chapter.

Before the patient enters the room where the MRI is to be performed, all metal objects and credit cards (the magnetic field can erase them) must be removed. This includes medication patches that have a metal backing and metallic lead wires; these can cause burns if not removed (Bremner, 2005). No metal objects may be brought into the room where the MRI is located; this includes oxygen tanks, IV poles, ventilators, or even stethoscopes. The magnetic field generated by the unit is so strong that any metal-containing items will be strongly attracted and literally can be pulled away with such force that they fly like projectiles toward the magnet. There is a risk of severe injury and death. Further, damage to expensive equipment may occur.

NURSING ALERT

For patient safety, the nurse must make sure that no patient care equipment (eg, portable oxygen tanks) that contains metal or metal parts enters the room where the MRI is located. The patient must be assessed for the presence of medication patches with foil backing (such as nicotine) that may cause a burn.

For the MRI, the patient lies with the head in a frame on a flat platform that is moved into a tube housing the magnet (Fig. 60-14). The tube is narrow; persons with a wide girth may not fit into the scanner. Patients who are unable to lie flat will not be able to tolerate an MRI. The scanning process is painless, but the patient hears loud thumping of the magnetic coils as the magnetic field is being pulsed. Patients may experience claustrophobia while inside the narrow tube; sedation may be prescribed in these circumstances. Newer versions of MRI machines (open MRI) are

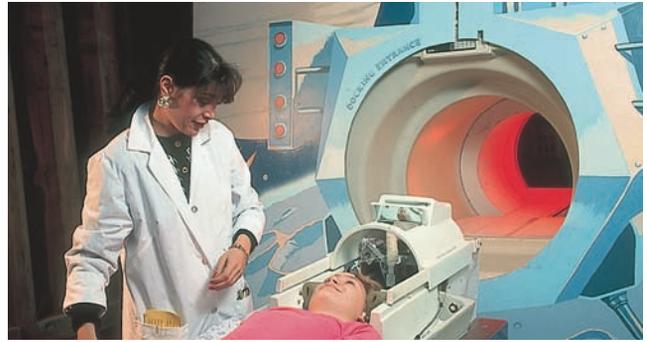

Figure 60-14 Technician explains what to expect during a magnetic resonance imaging procedure.

less claustrophobic than the earlier devices and are available in some locations. However, the images produced on these machines are often not as detailed, and traditional devices are preferable for accurate diagnosis. The patient may be taught to use relaxation techniques while in the scanner. The patient is informed that he or she will be able to talk to the staff during the scan through a microphone inside the scanner (Karpoff & Labus, 2008).

Positron Emission Tomography

PET is a computer-based nuclear imaging technique that produces images of actual organ functioning. The patient either inhales a radioactive gas or is injected with a radioactive substance that emits positively charged particles. When these positrons combine with negatively charged electrons (normally found in the body's cells), the resultant gamma rays can be detected by a scanning device that produces a series of two-dimensional views at various levels of the brain. This information is integrated by a computer and gives a composite picture of the brain at work.

PET permits the measurement of blood flow, tissue composition, and brain metabolism and thus indirectly evaluates brain function. The brain is one of the most metabolically active organs, consuming 80% of the glucose the body uses. PET measures this activity in specific areas of the brain and can detect changes in glucose use.

PET is useful in showing metabolic changes in the brain (Alzheimer's disease), locating lesions (brain tumor, epileptogenic lesions), identifying blood flow and oxygen metabolism in patients with strokes, distinguishing tumor from areas of necrosis, and revealing biochemical abnormalities associated with mental illness. The isotopes used have a very short half-life and are expensive to produce, requiring specialized equipment for production. PET scanning has been useful in research settings for the last 20 years and is becoming more available in clinical settings. Improvement in the scanning procedure and production of isotopes, as well as the advent of reimbursement by third-party payers, has increased the availability of PET studies.

Nursing Interventions

Key nursing interventions include patient preparation, which involves explaining the test and teaching the patient about inhalation techniques and the sensations (eg, dizziness, lightheadedness, and headache) that may occur. The IV injection

of the radioactive substance produces similar side effects. Relaxation exercises may reduce anxiety during the test.

Single Photon Emission Computed Tomography

SPECT is a three-dimensional imaging technique that uses radionuclides and instruments to detect single photons. It is a perfusion study that captures a moment of cerebral blood flow at the time of injection of a radionuclide. Gamma photons are emitted from a radiopharmaceutical agent administered to the patient and are detected by a rotating gamma camera or cameras; the image is sent to a minicomputer. This approach allows areas behind overlying structures or background to be viewed, greatly increasing the contrast between normal and abnormal tissue. It is relatively inexpensive, and the duration is similar to that of a CT scan.

SPECT is useful in detecting the extent and location of abnormally perfused areas of the brain, thus allowing detection, localization, and sizing of stroke (before it is visible by CT scan); localization of seizure foci in epilepsy; detection of tumor progression (Bremner, 2005); and evaluation of perfusion before and after neurosurgical procedures. Pregnancy and breast-feeding are contraindications to SPECT.

Nursing Interventions

The nursing interventions for SPECT primarily include patient preparation and patient monitoring. Teaching about what to expect before the test can allay anxiety and ensure patient cooperation during the test. Premenopausal women are advised to practice effective contraception before and for several days after testing, and the woman who is breast-feeding is instructed to stop nursing for the time period recommended by the nuclear medicine department (Pagana & Pagana, 2006).

The nurse may need to accompany and monitor the patient during transport to the nuclear medicine department for the scan. Patients are monitored during and after the procedure for allergic reactions to the radiopharmaceutical agent.

Cerebral Angiography

Cerebral angiography is an x-ray study of the cerebral circulation with a contrast agent injected into a selected artery. A valuable tool in investigating vascular disease or anomalies, it is used to determine vessel patency, identify presence of collateral circulation, and provide detail on vascular anomalies that can be used in planning interventions. With the advent of additional imaging techniques, formal cerebral angiography is less frequently performed.

Cerebral angiograms are performed by threading a catheter through the femoral artery in the groin and up to the desired vessel. Alternatively, direct puncture of the carotid artery or retrograde injection of a contrast agent into the brachial artery may be performed. X-ray images are obtained as the contrast agent flows through the vessels; the carotid and vertebral arterial systems are visualized, as well as venous drainage. Arterial access may also be used for interventional procedures, such as placing coils in an aneurysm or arteriovenous malformation.

Nursing Interventions

Prior to the angiography, the patient's blood urea nitrogen and creatinine should be checked to ensure the kidneys will be able to clear the contrast agent. The patient should be well hydrated, and clear liquids are usually permitted up to the time of the test. The patient is instructed to void immediately before the test, and locations of the appropriate peripheral pulses are marked with a felt-tip pen. The patient is instructed to remain immobile during the angiogram process and is told to expect a brief feeling of warmth in the face, behind the eyes, or in the jaw, teeth, tongue, and lips, and a metallic taste when the contrast agent is injected.

After the groin is shaved and prepared, a local anesthetic agent is administered to minimize pain at the insertion site and to reduce arterial spasm. A catheter is introduced into the femoral artery, flushed with heparinized saline, and filled with contrast agent. Fluoroscopy is used to guide the catheter to the appropriate vessels. Neurologic assessment is conducted during and immediately following cerebral angiography to observe for embolism or arterial dissection that may occur during the test. Signs of these complications include new onset of alterations in the level of consciousness, weakness on one side of the body, motor or sensory deficits, and speech disturbances.

Nursing care after cerebral angiography includes observation of the injection site for bleeding or hematoma formation (a localized collection of blood). Because a hematoma at the puncture site or embolization to a distal artery affects the peripheral pulses, peripheral pulses that were marked prior to the test are monitored frequently. The color and temperature of the involved extremity are assessed to detect possible embolism (Karpoff & Labus, 2008).

Myelography

A myelogram is an x-ray of the spinal subarachnoid space taken after the injection of a contrast agent into the spinal subarachnoid space through a lumbar puncture. The water-based contrast agent disperses upward through the CSF to outline the spinal subarachnoid space and show any distortion of the spinal cord or spinal dural sac caused by tumors, cysts, herniated vertebral disks, or other lesions. Myelography is performed infrequently today because of the sensitivity of CT and MRI scanning (Bremner, 2005).

Nursing Interventions

Because many patients have misconceptions about myelography, the nurse clarifies the explanation given by the physician and answers questions. The patient is informed about what to expect during the procedure and made aware that changes in position may be made during the procedure. After myelography, the patient lies in bed with the head of the bed elevated 30 to 45 degrees. The patient is advised to remain in bed in the recommended position for 3 hours or as prescribed. Drinking liberal amounts of fluid for rehydration and replacement of CSF may decrease the incidence of post-lumbar puncture headache. The blood pressure, pulse, respiratory rate, and temperature are monitored, as well as the patient's ability to void. Untoward signs include headache, fever, stiff neck, **photophobia** (sensitivity to

light), seizures, and signs of chemical or bacterial meningitis (Hickey, 2009).

Noninvasive Carotid Flow Studies

Noninvasive carotid flow studies use ultrasound imagery and Doppler measurements of arterial blood flow to evaluate carotid and deep orbital circulation. The graph produced indicates blood velocity. Increased blood velocity can indicate stenosis or partial obstruction. These tests are often obtained before more invasive tests such as arteriography, or used as screening tools. Carotid Doppler, carotid ultrasonography, oculoplethysmography, and ophthalmodynamometry are four common noninvasive vascular techniques that permit evaluation of arterial blood flow and detection of arterial stenosis, occlusion, and plaques. These vascular studies allow noninvasive imaging of extracranial and intracranial circulation (Diepenbrock, 2007).

Transcranial Doppler

Transcranial Doppler uses the same noninvasive techniques as carotid flow studies except that it records the blood flow velocities of the intracranial vessels. Arterial flow velocities can be measured through thin areas of the temporal and occipital bones of the skull. A handheld Doppler probe emits a pulsed beam; the signal is reflected by the moving red blood cells within the blood vessels. Transcranial Doppler is a noninvasive technique that is helpful in assessing vasospasm (a complication following subarachnoid hemorrhage), altered cerebral blood flow found in occlusive vascular disease, other cerebral pathology, and brain death.

Nursing Interventions

When a carotid flow study or transcranial Doppler is scheduled, the procedure is described to the patient. The patient is informed that this is a noninvasive test, that a handheld transducer will be placed over the neck and the orbits of the eyes, and that a water-soluble jelly is used on the transducer. Either one of these low-risk tests can be performed at the patient's bedside (Littlejohns & Bader, 2009).

Electroencephalography

An electroencephalogram (EEG) represents a record of the electrical activity generated in the brain (Hickey, 2009). It is obtained through electrodes applied on the scalp or through microelectrodes placed within the brain tissue. It provides an assessment of cerebral electrical activity. It is useful for diagnosing and evaluating seizure disorders, coma, or organic brain syndrome. Tumors, brain abscesses, blood clots, and infection may cause abnormal patterns in electrical activity. The EEG is also used in making a determination of brain death.

Electrodes are applied to the scalp to record the electrical activity in various regions of the brain. The amplified activity of the neurons between any two of these electrodes is recorded on continuously moving paper; this record is called the encephalogram.

For a baseline recording, the patient lies quietly with both eyes closed. The patient may be asked to hyperventilate for 3 to 4 minutes or to look at a bright, flashing light for photic stimulation. These activation procedures are performed to evoke abnormal electrical discharges, such as seizure potentials. A sleep EEG may be recorded after seda-

tion because some abnormal brain waves are seen only when the patient is asleep. If the epileptogenic area is inaccessible to conventional scalp electrodes, nasopharyngeal electrodes may be used.

Depth recording of EEG is performed by introducing electrodes stereotactically (radiologically placed using instrumentation) into a target area of the brain, as indicated by the patient's seizure pattern and scalp EEG. It is used to identify patients who may benefit from surgical excision of epileptogenic foci. Special transsphenoidal, mandibular, and nasopharyngeal electrodes can be used, and video recording combined with EEG monitoring and telemetry is used in hospital settings to capture epileptiform abnormalities and their sequelae. Some epilepsy centers provide long-term ambulatory EEG monitoring with portable recording devices.

Nursing Interventions

To increase the chances of recording seizure activity, it is sometimes recommended that the patient be deprived of sleep on the night before the EEG. Antiseizure agents, tranquilizers, stimulants, and depressants should be withheld 24 to 48 hours before an EEG because these medications can alter the EEG wave patterns or mask the abnormal wave patterns of seizure disorders (Pagana & Pagana, 2006). Coffee, tea, chocolate, and cola drinks are omitted in the meal before the test because of their stimulating effect. However, the meal is not omitted, because an altered blood glucose level can cause changes in brain wave patterns.

The patient is informed that the standard EEG takes 45 to 60 minutes; a sleep EEG requires 12 hours. The patient is assured that the procedure does not cause an electric shock and that the EEG is a diagnostic test, not a form of treatment. An EEG requires the patient to lie quietly during the test. Sedation is not advisable, because it may lower the seizure threshold in patients with a seizure disorder and it alters brain wave activity in all patients. The nurse needs to check the physician's prescription regarding the administration of antiseizure medication prior to testing.

Routine EEGs use a water-soluble lubricant for electrode contact, which can be wiped off and removed by shampooing later. Sleep EEGs involve the use of collodion glue for electrode contact, which requires acetone for removal.

Electromyography

An electromyogram (EMG) is obtained by inserting needle electrodes into the skeletal muscles to measure changes in the electrical potential of the muscles (Pagana & Pagana, 2006). The electrical potentials are shown on an oscilloscope and amplified so that both the sound and appearance of the waves can be analyzed and compared simultaneously.

An EMG is useful in determining the presence of neuromuscular disorders and myopathies. It helps distinguish weakness due to neuropathy (functional or pathologic changes in the peripheral nervous system) from weakness resulting from other causes.

Nursing Interventions

The procedure is explained, and the patient is warned to expect a sensation similar to that of an intramuscular injection as the needle is inserted into the muscle. The muscles examined may ache for a short time after the procedure.

Nerve Conduction Studies

Nerve conduction studies are performed by stimulating a peripheral nerve at several points along its course and recording the muscle action potential or the sensory action potential that results. Surface or needle electrodes are placed on the skin over the nerve to stimulate the nerve fibers. This test is useful in the study of peripheral neuropathies and is often included as part of the EMG.

Evoked Potential Studies

Evoked potential studies involve application of an external stimulus to specific peripheral sensory receptors with subsequent measurement of the electrical potential generated. Electrical changes are detected with the aid of computerized devices that extract the signal, display it on an oscilloscope, and store the data on magnetic tape or disk. In neurologic diagnosis, they reflect nerve conduction times in the peripheral nervous system. In clinical practice, the visual, auditory, and somatosensory systems are most often tested.

In visual evoked responses, the patient looks at a visual stimulus (flashing lights, a checkerboard pattern on a screen). The average of several hundred stimuli is recorded by EEG leads placed over the occipital lobe. The transit time from the retina to the occipital area is measured using computer-averaging methods.

Brain stem auditory evoked responses (BAERs) are measured by applying an auditory stimulus (repetitive auditory click) and measuring the transit time via the brain stem into the cortex. Specific lesions in the auditory pathway modify or delay the response. BAERs may be used in the diagnosis of brain stem abnormalities and in determination of brain death.

In somatosensory evoked responses (SERs), the peripheral nerves are stimulated (electrical stimulation through skin electrodes) and the transit time along the spinal cord to the cortex is measured and recorded from scalp electrodes. SERs are used to detect deficits in spinal cord or peripheral nerve conduction and to monitor spinal cord function during surgical procedures. It is also useful in the diagnosis of demyelinating diseases, such as multiple sclerosis and polyneuropathies, where nerve conduction is slowed.

Nursing Interventions

The nurse explains the procedure and reassures the patient and encourages him or her to relax. The patient is advised to remain perfectly still throughout the recording to prevent artifacts (signals not generated by the brain) that interfere with the recording and interpretation of the test.

Lumbar Puncture and Examination of Cerebrospinal Fluid

A lumbar puncture (spinal tap) is carried out by inserting a needle into the lumbar subarachnoid space to withdraw CSF. The test may be performed to obtain CSF for examination, to measure and reduce CSF pressure, to determine the presence or absence of blood in the CSF, and to administer medications intrathecally (into the spinal canal).

The needle is usually inserted into the subarachnoid space between the third and fourth or fourth and fifth lumbar vertebrae. Because the spinal cord ends at the first

lumbar vertebra, insertion of the needle below the level of the third lumbar vertebra prevents puncture of the spinal cord.

A successful lumbar puncture requires that the patient be relaxed; an anxious patient is tense, and this may increase the pressure reading. CSF pressure with the patient in a lateral recumbent position is normally 50 to 1800 mm H₂O (Karpoff & Labus, 2008).

A lumbar puncture may be risky in the presence of an intracranial mass lesion because intraspinal pressure is decreased by removal of CSF, and the brain may herniate downward through the foramen magnum. See Chart 60-5 for instructions for assisting with a lumbar puncture.

Cerebrospinal Fluid Analysis

The CSF should be clear and colorless. Pink, blood-tinged, or grossly bloody CSF may indicate a subarachnoid hemorrhage. The CSF may be bloody initially because of local trauma but becomes clearer as more fluid is drained. Specimens are obtained for cell count, culture, glucose, protein, and other tests as indicated. The specimens should be sent to the laboratory immediately because changes will take place and alter the result if the specimens are allowed to stand. (See Table A-5 in Appendix A for the normal values of CSF.)

Post-Lumbar Puncture Headache

A post-lumbar puncture headache, ranging from mild to severe, may occur a few hours to several days after the procedure. This complication occurs in 15% to 30% of patients. It is a throbbing bifrontal or occipital headache, dull and deep in character. It is particularly severe on sitting or standing but lessens or disappears when the patient lies down.

The headache is caused by CSF leakage at the puncture site. The fluid continues to escape into the tissues by way of the needle track from the spinal canal. As a result of a leak, the supply of CSF in the cranium is depleted to a point at which it is insufficient to maintain proper mechanical stabilization of the brain. When the patient assumes an upright position, tension and stretching of the venous sinuses and pain-sensitive structures occur.

Post-lumbar puncture headache may be avoided if a small-gauge needle is used and if the patient remains prone after the procedure. When more than 20 mL of CSF is removed, the patient is positioned supine for several hours. Keeping the patient flat overnight may reduce the incidence of headaches.

A postpuncture headache is usually managed by bed rest, analgesic agents, and hydration. Occasionally, if the headache persists, the epidural blood patch technique may be used. Blood is withdrawn from the antecubital vein and injected into the epidural space, usually at the site of the previous spinal puncture. The rationale is that the blood acts as a gelatinous plug to seal the hole in the dura, preventing further loss of CSF.

Other Complications of Lumbar Puncture

Herniation of the intracranial contents, spinal epidural abscess, spinal epidural hematoma, and meningitis are rare but serious complications of lumbar puncture. Other

Chart 60-5 • Assisting With a Lumbar Puncture

A needle is inserted into the subarachnoid space through the third and fourth or fourth and fifth lumbar interface to withdraw spinal fluid.

Preprocedure

1. Determine whether written consent for the procedure has been obtained.
2. Explain the procedure to the patient and describe sensations that are likely during the procedure (ie, a sensation of cold as the site is cleansed with solution, a needle prick when local anesthetic agent is injected).
3. Determine whether the patient has any questions or misconceptions about the procedure; reassure the patient that the needle will not enter the spinal cord or cause paralysis.
4. Instruct the patient to void before the procedure.

Procedure

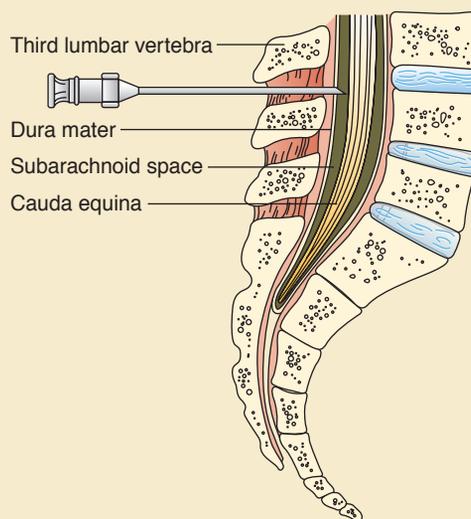

1. The patient is positioned on one side at the edge of the bed or examining table with back toward the physician; the thighs and legs are flexed as much as possible to increase the space between the spinous processes of the vertebrae, for easier entry into the subarachnoid space.

© B. Proud.

2. A small pillow may be placed under the patient's head to maintain the spine in a horizontal position; a pillow may be placed between the legs to prevent the upper leg from rolling forward.
3. The nurse assists the patient to maintain the position to avoid sudden movement, which can produce a traumatic (bloody) tap.
4. The patient is encouraged to relax and is instructed to breathe normally, because hyperventilation may lower an elevated pressure.

5. The nurse describes the procedure step by step to the patient as it proceeds.
6. The physician cleanses the puncture site with an antiseptic agent solution and drapes the site.
7. The physician injects local anesthetic agent to numb the puncture site, and then inserts a spinal needle into the subarachnoid space through the third and fourth or fourth and fifth lumbar interspace. A pressure reading may be obtained.
8. A specimen of CSF is removed and usually collected in three test tubes, labeled in order of collection. The needle is withdrawn.
9. The physician applies a small dressing to the puncture site.
10. The tubes of CSF are sent to the laboratory immediately.

Postprocedure

1. Instruct the patient to lie prone for 2 to 3 hours to separate the alignment of the dural and arachnoid needle punctures in the meninges, to reduce leakage of CSF.
2. Monitor the patient for complications of lumbar puncture; notify physician if complications occur.
3. Encourage increased fluid intake to reduce the risk of postprocedure headache.

complications include temporary voiding problems, slight elevation of temperature, backache or spasms, and stiffness of the neck.

Promoting Home and Community-Based Care

Teaching Patients Self-Care

Many diagnostic tests that were once performed as part of a hospital stay are now carried out in short-procedure units or

outpatient testing settings or units. As a result, family members often provide the postprocedure care. Therefore, the patient and family must receive clear verbal and written instructions about precautions to take after the procedure, complications to watch for, and steps to take if complications occur. Because many patients undergoing neurologic diagnostic studies are elderly or have neurologic deficits, provisions must be made to ensure that transportation, post-procedure care, and appropriate monitoring are available.

Continuing Care

Contacting the patient and family after diagnostic testing enables the nurse to determine whether they have any questions about the procedure or whether the patient had any untoward results. Teaching is reinforced and the patient and family are reminded to make and keep follow-up appointments. Patients, family members, and health care providers are focused on the immediate needs, issues, or deficits that necessitated the diagnostic testing.

CRITICAL THINKING EXERCISES

1 A patient is admitted to your unit with lower extremity paralysis. What findings in your examination help distinguish between upper motor neuron and lower motor neuron causes for the paralysis? How do those findings affect your care?

2 A 78-year-old patient is scheduled for an MRI. Explain why the MRI is indicated and what, if any, precautions must be taken. What nursing observations and assessments are indicated? What safety precautions are essential in the MRI suite, and why?

EBP 3 Your patient complains of a headache following a lumbar puncture. What resources would you use to identify the current guidelines for treatment of headache following lumbar puncture? What is the evidence base for these practices? Identify the criteria used to evaluate the strength of the evidence for these practices.

chapter 61

Management of Patients With Neurologic Dysfunction

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

- 1 Describe the nursing needs of patients with various neurologic dysfunctions.
- 2 Describe the multiple needs of the patient with altered level of consciousness.
- 3 Use the nursing process as a framework for care of the patient with altered level of consciousness.
- 4 Identify the early and late clinical manifestations of increased intracranial pressure.
- 5 Use the nursing process as a framework for care of the patient with increased intracranial pressure.
- 6 Describe the needs of the patient undergoing intracranial or transsphenoidal surgery.
- 7 Use the nursing process as a framework for care of the patient undergoing intracranial or transsphenoidal surgery.
- 8 Identify the various types and causes of seizures.
- 9 Use the nursing process to develop a plan of care for the patient experiencing seizures.
- 10 Identify the needs of the patient experiencing headaches.

GLOSSARY

akinetic mutism: unresponsiveness to the environment; the patient makes no movement or sound but sometimes opens the eyes

altered level of consciousness: condition of being less responsive to and aware of environmental stimuli

autoregulation: ability of cerebral blood vessels to dilate or constrict to maintain stable cerebral blood flow despite changes in systemic arterial blood pressure

brain death: irreversible loss of all functions of the entire brain, including the brain stem

coma: prolonged state of unconsciousness

craniectomy: a surgical procedure that involves removal of a portion of the skull

craniotomy: a surgical procedure that involves entry into the cranial vault

Cushing's response: the brain's attempt to restore blood flow by increasing arterial pressure to overcome the increased intracranial pressure

Cushing's triad: three classic signs—bradycardia, hypertension, and bradypnea—seen with pressure on the medulla as a result of brain stem herniation

GLOSSARY (Continued)

decerebration: an abnormal body posture associated with a severe brain injury, characterized by extreme extension of the upper and lower extremities

decortication: an abnormal posture associated with severe brain injury, characterized by abnormal flexion of the upper extremities and extension of the lower extremities

epidural monitor: a sensor placed between the skull and the dura to monitor intracranial pressure

epilepsy: a group of syndromes characterized by paroxysmal transient disturbances of brain function

fiberoptic monitor: a system that uses light refraction to determine intracranial pressure

herniation: abnormal protrusion of tissue through a defect or natural opening

intracranial pressure: pressure exerted by the volume of the intracranial contents within the cranial vault

locked-in syndrome: condition resulting from a lesion in the pons in which the patient lacks all distal motor activity (paralysis) but cognition is intact

microdialysis: procedure in which an intracranial catheter is inserted near an injured area of brain to measure lactate, pyruvate, glutamate, and glucose levels

migraine headache: a severe, unrelenting headache often accompanied by symptoms such as nausea, vomiting, and visual disturbances

Monro-Kellie hypothesis: theory that states that due to limited space for expansion within the skull, an increase in any one of the cranial contents—brain tissue, blood, or cerebrospinal fluid—causes a change in the volume of the others

persistent vegetative state: condition in which the patient is wakeful but devoid of conscious content, without cognitive or affective mental function

primary headache: a headache for which no specific organic cause can be found

secondary headache: headache identified as a symptom of another organic disorder (eg, brain tumor, hypertension)

seizures: paroxysmal transient disturbance of the brain resulting from a discharge of abnormal electrical activity

status epilepticus: episode in which the patient experiences multiple seizure bursts with no recovery time in between

subarachnoid screw or bolt: device placed into the subarachnoid space to measure intracranial pressure

transsphenoidal: surgical approach to the pituitary via the sphenoid sinuses

ventriculostomy: a catheter placed in one of the lateral ventricles of the brain to measure intracranial pressure and allow for drainage of fluid

This chapter presents an overview of care of the patient with an altered level of consciousness, the patient with increased **intracranial pressure (ICP)**, and the patient who is undergoing neurosurgical procedures, experiencing seizures, or experiencing headaches. Some of the disorders in this chapter, such as headaches and seizures, may be symptoms of dysfunction in another body system. Alternatively, headaches and seizures can be symptoms of a disruption of the neurologic system. These disorders can also be diagnosed at times as “idiopathic,” or without an identifiable cause. The commonalities of these disorders are often the behaviors and needs of the patient and the approaches nurses use to support the patient.

The central nervous system (CNS) contains a vast network of neurons that control the body’s vital functions. Yet this system is vulnerable, and its optimal function depends on several key factors. First, the neurologic system relies on its structural integrity for support and homeostasis, but this integrity may be disrupted. Examples of structural disruption include head injury, brain tumor, intracranial hemorrhage, infection, and stroke. As brain tissue expands in the inflexible cranium, ICP rises, and cerebral perfusion is impaired. Further expansion places pressure on vital centers, which can cause permanent neurologic deficits or lead to brain death.

Second, the neurologic system relies on the body’s ability to maintain a homeostatic environment. It requires the delivery of the essential elements of oxygen and glucose, as well as filtration of substrates that are toxic to the neurons. The functions of the neurologic system may be decreased or absent because of the effect of toxic substrates or the body’s inability to provide essential substrates. Sepsis, hypovolemia, myocardial infarction, respiratory arrest, hypoglycemia, electrolyte imbalance, drug and/or alcohol overdose, encephalopathy, and ketoacidosis are all examples of such circumstances. Some conditions can be treated and reversed; others result in permanent neurologic deficits and disabilities.

Although the specialty of neuroscience nursing requires an understanding of neuroanatomy, neurophysiology, neurodiagnostic testing, critical care nursing, and rehabilitation nursing, nurses in all settings care for patients with neurologic disorders. Ongoing assessment of the patient’s neurologic function and health needs, identification of problems, mutual goal setting, development and implementation of care plans (including teaching, counseling, and coordinating activities), and evaluation of the outcomes of care are nursing actions integral to the recovery of the patient. The nurse also collaborates with other members of the health care team to provide essential care, offer a variety of solutions to problems, help the patient and family gain control of their lives, and explore the educational and supportive resources available in the community. The goals are to achieve as high a level of function as possible and to enhance the quality of life for the patient with neurologic impairment and his or her family.

ALTERED LEVEL OF CONSCIOUSNESS

An **altered level of consciousness (LOC)** is apparent in the patient who is not oriented, does not follow commands, or needs persistent stimuli to achieve a state of alertness. LOC is gauged on a continuum, with a normal state of alertness

and full cognition (consciousness) on one end and coma on the other end. **Coma** is a clinical state of unarousable unresponsiveness in which there are no purposeful responses to internal or external stimuli, although nonpurposeful responses to painful stimuli and brain stem reflexes may be present (Gusa, Miers, Pfrimmer, et al., 2007). The usual duration of coma is 2 to 4 weeks. **Akinetic mutism** is a state of unresponsiveness to the environment in which the patient makes no voluntary movement. **Persistent vegetative state** is a condition in which the unresponsive patient resumes sleep–wake cycles after coma but is devoid of cognitive or affective mental function. **Locked-in syndrome** results from a lesion affecting the pons and results in paralysis and the inability to speak, but vertical eye movements and lid elevation remain intact and are used to indicate responsiveness (Maurer, 2008). The level of responsiveness and consciousness is the most important indicator of the patient’s condition.

Pathophysiology

Altered LOC is not a disorder itself; rather, it is a result of multiple pathophysiologic phenomena. The cause may be neurologic (head injury, stroke), toxicologic (drug overdose, alcohol intoxication), or metabolic (hepatic or renal failure, diabetic ketoacidosis).

The underlying cause of neurologic dysfunction is disruption in the cells of the nervous system, neurotransmitters, or brain anatomy (see Chapter 60). Disruptions result from cellular edema or other mechanisms, such as disruption of chemical transmission at receptor sites by antibodies.

Intact anatomic structures of the brain are needed for normal function. The two hemispheres of the cerebrum must communicate, via an intact corpus callosum, and the lobes of the brain (frontal, parietal, temporal, and occipital) must communicate and coordinate their specific functions (see Chapter 60). Other anatomic structures of importance are the cerebellum and the brain stem. The cerebellum has both excitatory and inhibitory actions and is largely responsible for coordination of movement. The brain stem contains areas that control the heart, respiration, and blood pressure. Disruptions in the anatomic structures result from trauma, edema, pressure from tumors, or other mechanisms, such as an increase or decrease in the circulation of blood or cerebrospinal fluid (CSF).

Clinical Manifestations

Alterations in LOC occur along a continuum, and the clinical manifestations depend on where the patient is on this continuum. As the patient’s state of alertness and consciousness decreases, changes occur in the pupillary response, eye opening response, verbal response, and motor response. However, initial alterations in LOC may be reflected by subtle behavioral changes, such as restlessness or increased anxiety. The pupils, normally round and quickly reactive to light, become sluggish (response is slower); as the patient becomes comatose, the pupils become fixed (no response to light). The patient in a coma does not open the eyes, respond verbally, or move the extremities in response to a request to do so.

Assessment and Diagnostic Findings

The patient with an altered LOC is at risk for alterations in every body system. A complete assessment is performed, with particular attention to the neurologic system. The

neurologic examination should be as complete as the LOC allows (American Association of Neuroscience Nurses [AANN], 2005). It includes an evaluation of mental status, cranial nerve function, cerebellar function (balance and coordination), reflexes, and motor and sensory function. LOC, a sensitive indicator of neurologic function, is assessed based on the criteria in the Glasgow Coma Scale: eye opening, verbal response, and motor response (Gusa, et al., 2007). The patient's responses are rated on a scale from 3 to 15. A score of 3 indicates severe impairment of neurologic function, brain death, or pharmacologic inhibition of the neurologic response. A score of 15 indicates that the patient is fully responsive (see Chapter 63).

If the patient is comatose and has localized signs such as abnormal pupillary and motor responses, it is assumed that neurologic disease is present until proven otherwise. If the patient is comatose but pupillary light reflexes are preserved, a toxic or metabolic disorder is suspected. Common diagnostic procedures used to identify the cause of unconsciousness include computed tomography (CT) scanning, magnetic resonance imaging (MRI), and electroencephalography (EEG). Less common procedures include positron emission tomography (PET) and single photon emission computed tomography (SPECT; see Chapter 60). Laboratory tests include analysis of blood glucose, electrolytes, serum ammonia, and liver function tests; blood urea nitrogen (BUN) levels; serum osmolality; calcium level; and partial thromboplastin and prothrombin times. Other studies may be used to evaluate serum ketones, alcohol and drug concentrations, and arterial blood gases.

Medical Management

The first priority of treatment for the patient with altered LOC is to obtain and maintain a patent airway. The patient may be orally or nasally intubated, or a tracheostomy may be performed. Until the ability of the patient to breathe is determined, a mechanical ventilator is used to maintain adequate oxygenation and ventilation. The circulatory status (blood pressure, heart rate) is monitored to ensure adequate perfusion to the body and brain. An intravenous (IV) catheter is inserted to provide access for IV fluids and medications. Neurologic care focuses on the specific neurologic pathology, if known. Nutritional support, via a feeding tube or a gastrostomy tube, is initiated as soon as possible. In addition to measures designed to determine and treat the underlying causes of altered LOC, other medical interventions are aimed at pharmacologic management and prevention of complications.

NURSING PROCESS

THE PATIENT WITH AN ALTERED LEVEL OF CONSCIOUSNESS

Assessment

Assessment of the patient with an altered LOC often starts with assessing the verbal response through determining the patient's orientation to time, person, and place. Patients are asked to identify the day, date, or season of the year and to identify where they are or to identify the clinicians, family members, or visitors present. Other

questions such as, "Who is the president?" or "What is the next holiday?" may be helpful in determining the patient's processing of information. (Verbal response cannot be evaluated if the patient is intubated or has a tracheostomy, and this should be clearly documented.)

Alertness is measured by the patient's ability to open the eyes spontaneously or in response to a vocal or noxious stimulus (pressure or pain). Patients with severe neurologic dysfunction cannot do this. The nurse assesses for periorbital edema (swelling around the eyes) or trauma, which may prevent the patient from opening the eyes, and documents any such condition that interferes with eye opening.

Motor response includes spontaneous, purposeful movement (eg, the awake patient can move all four extremities with equal strength on command), movement only in response to painful stimuli, or abnormal posturing (Olsen & Graffagnino, 2005). If the patient is not responding to commands, the motor response is tested by applying a painful stimulus (firm but gentle pressure) to the nail bed or by squeezing a muscle. If the patient attempts to push away or withdraw, the response is recorded as purposeful or appropriate ("patient withdraws from painful stimulus"). This response is considered purposeful if the patient can cross the midline from one side of the body to the other in response to a painful stimulus. An inappropriate or nonpurposeful response is random and aimless. Posturing may be decorticate or decerebrate (Fig. 61-1; see also Chapter 60). The most severe neurologic impairment results in flaccidity. The motor response cannot be elicited or assessed when the patient has been administered pharmacologic paralyzing agents.

In addition to LOC, the nurse monitors parameters such as respiratory status, eye signs, and reflexes on an ongoing basis. Table 61-1 summarizes the assessment and the clinical significance of the findings. Body functions (circulation, respiration, elimination, fluid and electrolyte balance) are examined in a systematic and ongoing manner.

Diagnosis

Nursing Diagnoses

Based on the assessment data, the major nursing diagnoses may include the following:

- Ineffective airway clearance related to altered LOC
- Risk of injury related to decreased LOC
- Deficient fluid volume related to inability to take fluids by mouth
- Impaired oral mucous membrane related to mouth breathing, absence of pharyngeal reflex, and altered fluid intake
- Risk for impaired skin integrity related to prolonged immobility
- Impaired tissue integrity of cornea related to diminished or absent corneal reflex
- Ineffective thermoregulation related to damage to hypothalamic center
- Impaired urinary elimination (incontinence or retention) related to impairment in neurologic sensing and control
- Bowel incontinence related to impairment in neurologic sensing and control and also related to changes in nutritional delivery methods

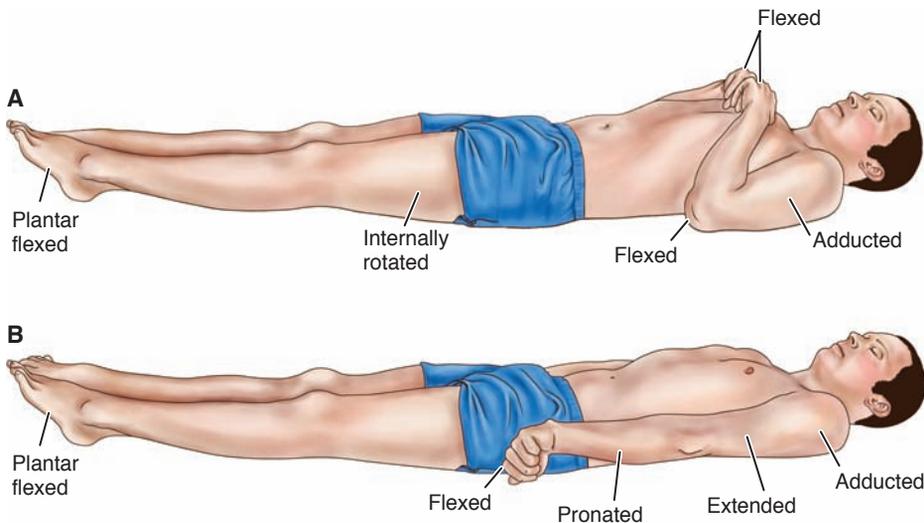

Figure 61-1 Abnormal posture response to stimuli. **A**, Decorticate posturing and flexion of the upper extremities, internal rotation of the lower extremities, and plantar flexion of the feet. **B**, Decerebrate posturing, involving extension and outward rotation of upper extremities and plantar flexion of the feet.

- Disturbed sensory perception related to neurologic impairment
- Interrupted family processes related to health crisis

Collaborative Problems/Potential Complications

Based on the assessment data, potential complications may include:

- Respiratory distress or failure
- Pneumonia
- Aspiration
- Pressure ulcer
- Deep vein thrombosis (DVT)
- Contractures

Planning and Goals

The patient with altered LOC is subject to all the complications associated with immobility. Therefore, the goals of care for the patient with altered LOC include maintenance of a clear airway, protection from injury, attainment of fluid volume balance, achievement of intact oral mucous membranes, maintenance of normal skin integrity, absence of corneal irritation, attainment of effective thermoregulation, and effective urinary elimination. Additional goals include bowel continence, accurate perception of environmental stimuli, maintenance of intact family or support system, and absence of complications.

Because the unconscious patient's protective reflexes are impaired, the quality of nursing care provided may mean the difference between life and death. The nurse must assume responsibility for the patient until the basic reflexes (coughing, blinking, and swallowing) return and the patient becomes conscious and oriented. Therefore, the major nursing goal is to compensate for the absence of these protective reflexes.

Nursing Interventions

Maintaining the Airway

The most important consideration in managing the patient with altered LOC is to establish an adequate airway and ensure ventilation. Obstruction of the airway is a risk because the epiglottis and tongue may relax, occluding the orophar-

ynx, or the patient may aspirate vomitus or nasopharyngeal secretions.

The accumulation of secretions in the pharynx presents a serious problem. Because the patient cannot swallow and lacks pharyngeal reflexes, these secretions must be removed to eliminate the danger of aspiration. Elevating the head of the bed to 30 degrees helps prevent aspiration. Positioning the patient in a lateral or semiprone position also helps, because it allows the jaw and tongue to fall forward, thus promoting drainage of secretions.

Positioning alone is not always adequate, however. Suctioning and oral hygiene may be required. Suctioning is performed to remove secretions from the posterior pharynx and upper trachea. Before and after suctioning, the patient is adequately ventilated to prevent hypoxia (Hickey, 2009). Chest physiotherapy and postural drainage may be initiated to promote pulmonary hygiene, unless contraindicated by the patient's underlying condition. The chest should be auscultated at least every 8 hours to detect adventitious breath sounds or absence of breath sounds.

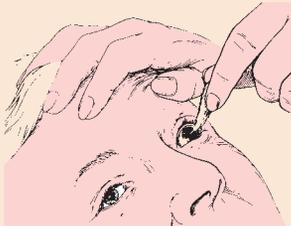

Despite these measures, or because of the severity of impairment, the patient with altered LOC often requires intubation and mechanical ventilation. Nursing actions for the mechanically ventilated patient include maintaining the patency of the endotracheal tube or tracheostomy, providing frequent oral care, monitoring arterial blood gas measurements, and maintaining ventilator settings (see Chapter 25).

Protecting the Patient

For the protection of the patient, side rails are padded. Two rails are kept in the raised position during the day and three at night; however, raising all four side rails is considered a restraint by the Joint Commission if the intent is to limit the patient's mobility. Care should be taken to prevent injury from invasive lines and equipment, and other potential sources of injury should be identified, such as restraints, tight dressings, environmental irritants, damp bedding or dressings, and tubes and drains.

Protection also includes ensuring the patient's dignity during altered LOC. Simple measures such as providing privacy and speaking to the patient during nursing care

Table 61-1 NURSING ASSESSMENT OF THE UNCONSCIOUS PATIENT

Examination	Clinical Assessment	Clinical Significance
Level of responsiveness or consciousness	Eye opening; verbal and motor responses; pupils (size, equality, reaction to light)	Obedying commands is a favorable response and demonstrates a return to consciousness.
Pattern of respiration	Respiratory pattern Cheyne-Stokes respiration Hyperventilation Ataxic respiration with irregularity in depth/rate	Disturbances of respiratory center of brain may result in various respiratory patterns. Suggests lesions deep in both hemispheres; area of basal ganglia and upper brain stem Suggests onset of metabolic problem or brain stem damage Ominous sign of damage to medullary center
Eyes Pupils (size, equality, reaction to light)	Equal, normally reactive pupils Equal or unequal diameter Progressive dilation Fixed dilated pupils	Suggests that coma is toxic or metabolic in origin Helps determine location of lesion Indicates increasing intracranial pressure Indicates injury at level of midbrain
 Eye movements	Normally, eyes should move from side to side.	Functional and structural integrity of brain stem is assessed by inspection of extraocular movements; usually absent in deep coma.
Corneal reflex 	When cornea is touched with a wisp of clean cotton, blink response is normal.	Tests cranial nerves V and VII; helps determine location of lesion if unilateral; absent in deep coma
Facial symmetry Swallowing reflex	Asymmetry (sagging, decrease in wrinkles) Drooling versus spontaneous swallowing	Sign of paralysis Absent in coma Paralysis of cranial nerves X and XII Subarachnoid hemorrhage, meningitis Fracture or dislocation of cervical spine Asymmetric response in paralysis
Neck	Stiff neck Absence of spontaneous neck movement	Subarachnoid hemorrhage, meningitis
Response of extremity to noxious stimuli	Firm pressure on a joint of the upper and lower extremity Observe spontaneous movements.	Fracture or dislocation of cervical spine Asymmetric response in paralysis
Deep tendon reflexes	Tap patellar and biceps tendons.	Absent in deep coma Brisk response may have localizing value Asymmetric response in paralysis
Pathologic reflexes 	Firm pressure with blunt object on sole of foot, moving along lateral margin and crossing to the ball of foot	Absent in deep coma Flexion of the toes, especially the great toe, is normal except in newborn. Dorsiflexion of toes (especially great toe) indicates contralateral pathology of corticospinal tract (Babinski reflex). Helps determine location of lesion in brain
Abnormal posture	Observation for posturing (spontaneous or in response to noxious stimuli) Flaccidity with absence of motor response Decorticate posture (flexion and internal rotation of forearms and hands) Decerebrate posture (extension and external rotation)	Deep extensive brain lesion Seen with cerebral hemisphere pathology and in metabolic depression of brain function Decerebrate posturing indicates deeper and more severe dysfunction than does decorticate posturing; implies brain pathology; poor prognostic sign.

activities preserve the patient's dignity. Not speaking negatively about the patient's condition or prognosis is also important, because patients in a light coma may be able to hear. The comatose patient has an increased need for advocacy, and the nurse is responsible for seeing that these advocacy needs are met.

NURSING ALERT

If the patient begins to emerge from unconsciousness, every measure that is available and appropriate for calming and quieting the patient should be used. Any form of restraint is likely to be countered with resistance, leading to self-injury or to a dangerous increase in ICP. Therefore, physical restraints should be avoided if possible; a written prescription must be obtained if their use is essential for the patient's well-being.

Maintaining Fluid Balance and Managing Nutritional Needs

Hydration status is assessed by examining tissue turgor and mucous membranes, assessing intake and output trends, and analyzing laboratory data. Fluid needs are met initially by administering the required IV fluids. However, IV solutions (and blood component therapy) for patients with intracranial conditions must be administered slowly. If they are administered too rapidly, they can increase ICP. The quantity of fluids administered may be restricted to minimize the possibility of cerebral edema.

If the patient does not recover quickly and sufficiently enough to take adequate fluids and calories by mouth, a feeding or gastrostomy tube will be inserted for the administration of fluids and enteral feedings (Dudek, 2006).

Providing Mouth Care

The mouth is inspected for dryness, inflammation, and crusting. The unconscious patient requires careful oral care, because there is a risk of parotitis if the mouth is not kept scrupulously clean. The mouth is cleansed and rinsed carefully to remove secretions and crusts and to keep the mucous membranes moist. A thin coating of petrolatum on the lips prevents drying, cracking, and encrustations. If the patient has an endotracheal tube, the tube should be moved to the opposite side of the mouth daily to prevent ulceration of the mouth and lips. If the patient is intubated and mechanically ventilated, good oral care is also necessary. Recent evidence shows that a routine of toothbrushing every 8 hours significantly decreases ventilator-associated pneumonia (Fields, 2008).

Maintaining Skin and Joint Integrity

Preventing skin breakdown requires continuing nursing assessment and intervention. Special attention is given to unconscious patients, because they cannot respond to external stimuli. Assessment includes a regular schedule of turning to avoid pressure, which can cause breakdown and necrosis of the skin. Turning also provides kinesthetic (sensation of movement), proprioceptive (awareness of position), and vestibular (equilibrium) stimulation. After turning, the patient is carefully repositioned to prevent ischemic necrosis

over pressure areas. Dragging or pulling the patient up in bed must be avoided, because this creates a shearing force and friction on the skin surface (see Chapter 11).

Maintaining correct body position is important; equally important is passive exercise of the extremities to prevent contractures. The use of splints or foam boots aids in the prevention of foot drop and eliminates the pressure of bedding on the toes. The use of trochanter rolls to support the hip joints keeps the legs in proper alignment. The arms are in abduction, the fingers lightly flexed, and the hands in slight supination. The heels of the feet are assessed for pressure areas. Specialty beds, such as fluidized or low-air-loss beds, may be used to decrease pressure on bony prominences (Hickey, 2009).

Preserving Corneal Integrity

Some unconscious patients have their eyes open and have inadequate or absent corneal reflexes. The cornea may become irritated, dried out, or scratched, leading to ulceration. The eyes may be cleansed with cotton balls moistened with sterile normal saline to remove debris and discharge. If artificial tears are prescribed, they may be instilled every 2 hours. Periorbital edema (swelling around the eyes) often occurs after cranial surgery. If cold compresses are prescribed, care must be exerted to avoid contact with the cornea. Eye patches should be used cautiously because of the potential for corneal abrasion from contact with the patch.

Maintaining Body Temperature

High fever in the unconscious patient may be caused by infection of the respiratory or urinary tract, drug reactions, or damage to the hypothalamic temperature-regulating center. A slight elevation of temperature may be caused by dehydration. The environment can be adjusted, depending on the patient's condition, to promote a normal body temperature. If body temperature is elevated, a minimum amount of bedding is used. The room may be cooled to 18.3°C (65°F). However, if the patient is elderly and does not have an elevated temperature, a warmer environment is needed.

Because of damage to the temperature-regulating center in the brain or severe intracranial infection, unconscious patients often develop very high temperatures. Such temperature elevations must be controlled, because the increased metabolic demands of the brain can exceed cerebral circulation and oxygen delivery, potentially resulting in cerebral deterioration (Hickey, 2009). Studies suggest that hyperthermia may contribute to poor outcome after brain injury but not through a decreased brain oxygen level (Spitotta, Stiefel, Heuer, et al., 2008). Persistent hyperthermia with no identified clinical source of infection indicates brain stem damage and a poor prognosis.

NURSING ALERT

The body temperature of an unconscious patient is never taken by mouth. Rectal or tympanic (if not contraindicated) temperature measurement is preferred to the less accurate axillary temperature.

Strategies for reducing fever include:

- Removing all bedding over the patient (with the possible exception of a light sheet, towel, or small drape)

- Administering acetaminophen as prescribed
- Giving cool sponge baths and allowing an electric fan to blow over the patient to increase surface cooling
- Using a hypothermia blanket
- Frequent temperature monitoring to assess the patient's response to the therapy and to prevent an excessive decrease in temperature and shivering

Preventing Urinary Retention

The patient with an altered LOC is often incontinent or has urinary retention. The bladder is palpated or scanned at intervals to determine whether urinary retention is present, because a full bladder may be an overlooked cause of overflow incontinence. A portable bladder ultrasound instrument is a useful tool in bladder management and retraining programs (Wu & Baguley, 2005).

If the patient is not voiding, an indwelling urinary catheter is inserted and connected to a closed drainage system. A catheter may also be inserted during the acute phase of illness to monitor urinary output. Because catheters are a major cause of urinary tract infection, the patient is observed for fever and cloudy urine. The area around the urethral orifice is inspected for drainage. The urinary catheter is usually removed if the patient has a stable cardiovascular system and if no diuresis, sepsis, or voiding dysfunction existed before the onset of coma. Although many unconscious patients urinate spontaneously after catheter removal, the bladder should be palpated or scanned with a portable ultrasound device periodically for urinary retention (Wu & Baguley, 2005). An intermittent catheterization program may be initiated to ensure complete emptying of the bladder at intervals, if indicated.

An external catheter (condom catheter) for the male patient and absorbent pads for the female patient can be used for unconscious patients who can urinate spontaneously, although involuntarily. As soon as consciousness is regained, a bladder-training program is initiated (Hickey, 2009). The incontinent patient is monitored frequently for skin irritation and skin breakdown. Appropriate skin care is implemented to prevent these complications.

Promoting Bowel Function

The abdomen is assessed for distention by listening for bowel sounds and measuring the girth of the abdomen with a tape measure. There is a risk of diarrhea from infection, antibiotics, and hyperosmolar fluids. Frequent loose stools may also occur with fecal impaction. Commercial fecal collection bags are available for patients with fecal incontinence.

Immobility and lack of dietary fiber can cause constipation. The nurse monitors the number and consistency of bowel movements and performs a rectal examination for signs of fecal impaction. Stool softeners may be prescribed and can be administered with tube feedings. To facilitate bowel emptying, a glycerin suppository may be indicated. The patient may require an enema every other day to empty the lower colon.

Providing Sensory Stimulation

Once increased ICP is not a problem, sensory stimulation can help overcome the profound sensory deprivation of the

unconscious patient. This involves using auditory, visual, olfactory, gustatory, tactile, and kinesthetic activities to stimulate the patient emerging from coma (Gerber, 2005). Efforts are made to restore the sense of daily rhythm by maintaining usual day and night patterns for activity and sleep. The nurse touches and talks to the patient and encourages family members and friends to do so. Communication is extremely important and includes touching the patient and spending enough time with the patient to become sensitive to his or her needs. It is also important to avoid making any negative comments about the patient's status or prognosis in the patient's presence.

The nurse orients the patient to time and place at least once every 8 hours. Sounds from the patient's usual environment may be introduced using a tape recorder. Family members can read to the patient from a favorite book and may suggest radio and television programs that the patient previously enjoyed as a means of enriching the environment and providing familiar input.

When arousing from coma, many patients experience a period of agitation, indicating that they are becoming more aware of their surroundings but still cannot react or communicate in an appropriate fashion. Although this is disturbing for many family members, it is actually a positive clinical sign. At this time, it is necessary to minimize stimulation by limiting background noises, having only one person speak to the patient at a time, giving the patient a longer period of time to respond, and allowing for frequent rest or quiet times. After the patient has regained consciousness, videotaped family or social events may assist the patient in recognizing family and friends and allow him or her to experience missed events.

Various programs of structured sensory stimulation for patients with brain injury have been developed to improve outcomes. Although these are controversial programs with inconsistent results, some research supports the concept of providing structured stimulation (Gerber, 2005).

Meeting the Family's Needs

The family of the patient with altered LOC may be thrown into a sudden state of crisis and go through the process of severe anxiety, denial, anger, remorse, grief, and reconciliation. Depending on the disorder that caused the altered LOC and the extent of the patient's recovery, the family may be unprepared for the changes in the cognitive and physical status of their loved one. If the patient has significant residual deficits, the family may require considerable time, assistance, and support to come to terms with these changes. To help family members mobilize resources and coping skills, the nurse reinforces and clarifies information about the patient's condition, permits the family to be involved in care, and listens to and encourages ventilation of feelings and concerns while supporting decision making about management and placement after hospitalization. Families may benefit from participation in support groups offered through the hospital, rehabilitation facility, or community organizations.

In some circumstances, the family may need to face the death of their loved one. The patient with a neurologic disorder is often pronounced brain dead before the heart stops beating. The term **brain death** describes irreversible loss of

all functions of the entire brain, including the brain stem (Burck, Anderson-Shaw, Sheldon, et al., 2006). The term may be misleading to the family because, although brain function has ceased, the patient appears to be alive, with the heart rate and blood pressure sustained by vasoactive medications and breathing continued by mechanical ventilation. When discussing a patient who is brain dead with family members, it is important to provide accurate, timely, understandable, and consistent information (Peiffer, 2007). End-of-life care is discussed in Chapter 17.

Monitoring and Managing Potential Complications

Pneumonia, aspiration, and respiratory failure are potential complications in any patient who has a depressed LOC and who cannot protect the airway or turn, cough, and take deep breaths. The longer the period of unconsciousness, the greater the risk is of pulmonary complications.

Vital signs and respiratory function are monitored closely to detect any signs of respiratory failure or distress. Total blood count and arterial blood gas measurements are assessed to determine whether there are adequate red blood cells to carry oxygen and whether ventilation is effective. Chest physiotherapy and suctioning are initiated to prevent respiratory complications such as pneumonia. Oral care interventions are performed for patients receiving mechanical ventilation to decrease the incidence of pneumonia (Fields, 2008). If pneumonia develops, cultures are obtained to identify the organism so that appropriate antibiotics can be administered.

The patient with altered LOC is monitored closely for evidence of impaired skin integrity, and strategies to prevent skin breakdown and pressure ulcers are continued through all phases of care, including hospitalization, rehabilitation, and home care. Factors that contribute to impaired skin integrity (eg, incontinence, inadequate dietary intake, pressure on bony prominences, edema) are addressed. If pressure ulcers develop, strategies to promote healing are undertaken. Care is taken to prevent bacterial contamination of pressure ulcers, which may lead to sepsis and septic shock. Assessment and management of pressure ulcers are discussed in Chapter 11.

The patient should also be monitored for signs and symptoms of deep vein thrombosis (DVT). Patients who develop DVT are at risk for pulmonary embolism. Prophylaxis such as subcutaneous heparin or low-molecular-weight heparin (Fragmin, Orgaran) should be prescribed if not contraindicated (Vergouwen, Roos & Kamphuisen, 2008). Anti-embolism stockings or pneumatic compression devices should also be prescribed to reduce the risk of clot formation. The nurse observes for signs and symptoms of DVT.

Evaluation

Expected Patient Outcomes

Expected patient outcomes may include the following:

1. Maintains clear airway and demonstrates appropriate breath sounds
2. Experiences no injuries
3. Attains or maintains adequate fluid balance
 - a. Has no clinical signs or symptoms of dehydration
 - b. Demonstrates normal range of serum electrolytes
 - c. Has no clinical signs or symptoms of overhydration
4. Achieves healthy oral mucous membranes
5. Maintains normal skin integrity
6. Has no corneal irritation
7. Attains or maintains thermoregulation
8. Has no urinary retention
9. Has no diarrhea or fecal impaction
10. Receives appropriate sensory stimulation
11. Has family members who cope with crisis
 - a. Verbalize fears and concerns
 - b. Participate in patient's care and provide sensory stimulation by talking and touching
12. Is free of complications
 - a. Has arterial blood gas values or O₂ saturation levels within normal range
 - b. Displays no signs or symptoms of pneumonia
 - c. Exhibits intact skin over pressure areas
 - d. Does not develop DVT or pulmonary embolism (PE)

INCREASED INTRACRANIAL PRESSURE

The rigid cranial vault contains brain tissue (1400 g), blood (75 mL), and CSF (75 mL). The volume and pressure of these three components are usually in a state of equilibrium and produce the ICP. ICP is usually measured in the lateral ventricles, with the normal pressure being 0 to 10 mm Hg, and 15 mm Hg being the upper limit of normal (Hickey, 2009).

The **Monro-Kellie hypothesis** states that, because of the limited space for expansion within the skull, an increase in any one of the components causes a change in the volume of the others. Because brain tissue has limited space to expand, compensation typically is accomplished by displacing or shifting CSF, increasing the absorption or diminishing the production of CSF, or decreasing cerebral blood volume. Without such changes, ICP begins to rise. Under normal circumstances, minor changes in blood volume and CSF volume occur constantly as a result of alterations in intrathoracic pressure (coughing, sneezing, straining), posture, blood pressure, and systemic oxygen and carbon dioxide levels (Hickey, 2009).

Pathophysiology

Increased ICP affects many patients with acute neurologic conditions because pathologic conditions alter the relationship between intracranial volume and ICP. Although elevated ICP is most commonly associated with head injury, it also may be seen as a secondary effect in other conditions, such as brain tumors, subarachnoid hemorrhage, and toxic and viral encephalopathies. Increased ICP from any cause decreases cerebral perfusion, stimulates further swelling (edema), and may shift brain tissue, resulting in **herniation**, a dire and frequently fatal event.

Decreased Cerebral Blood Flow

Increased ICP may reduce cerebral blood flow, resulting in ischemia and cell death. In the early stages of cerebral

ischemia, the vasomotor centers are stimulated and the systemic pressure rises to maintain cerebral blood flow. Usually, this is accompanied by a slow bounding pulse and respiratory irregularities. These changes in blood pressure, pulse, and respiration are important clinically because they suggest increased ICP.

The concentration of carbon dioxide in the blood and in the brain tissue also plays a role in the regulation of cerebral blood flow. An increase in the arterial partial pressure of carbon dioxide (PaCO_2) causes cerebral vasodilation, leading to increased cerebral blood flow and increased ICP. A decrease in PaCO_2 has a vasoconstrictive effect, limiting blood flow to the brain. Decreased venous outflow may also increase cerebral blood volume, thus raising ICP.

Cerebral Edema

Cerebral edema or swelling is defined as an abnormal accumulation of water or fluid in the intracellular space, extracellular space, or both, associated with an increase in the volume of brain tissue. Edema can occur in the gray, white, or interstitial matter. As brain tissue swells within the rigid skull, several mechanisms attempt to compensate for the increasing ICP. These compensatory mechanisms include autoregulation as well as decreased production and flow of CSF. **Autoregulation** refers to the brain's ability to change the diameter of its blood vessels to maintain a constant cerebral blood flow during alterations in systemic blood pressure. This mechanism can be impaired in patients who are experiencing a pathologic and sustained increase in ICP.

Cerebral Response to Increased Intracranial Pressure

As ICP rises, compensatory mechanisms in the brain work to maintain blood flow and prevent tissue damage. The brain can maintain a steady perfusion pressure if the arterial systolic blood pressure is 50 to 150 mm Hg and the ICP is less than 40 mm Hg. Changes in ICP are closely linked with cerebral perfusion pressure (CPP). The CPP is calculated by subtracting the ICP from the mean arterial pressure (MAP). For example, if the MAP is 100 mm Hg and the ICP is 15 mm Hg, then the CPP is 85 mm Hg. The normal CPP is 70 to 100 mm Hg (Hickey, 2009). As ICP rises and the autoregulatory mechanism of the brain is overwhelmed, the CPP can increase to greater than 100 mm Hg or decrease to less than 50 mm Hg. Patients with a CPP of less than 50 mm Hg experience irreversible neurologic damage. Therefore, the CPP must be maintained at 70 to 80 mm Hg to ensure adequate blood flow to the brain. If ICP is equal to MAP, cerebral circulation ceases.

A clinical phenomenon known as the **Cushing's response** (or Cushing's reflex) is seen when cerebral blood flow decreases significantly. When ischemic, the vasomotor center triggers an increase in arterial pressure in an effort to overcome the increased ICP. A sympathetically mediated response causes an increase in the systolic blood pressure with a widening of the pulse pressure and cardiac slowing. This response is seen clinically as an increase in systolic blood pressure, widening of the pulse pressure, and reflex slowing of the heart rate. It is a late sign requiring immediate intervention; however, perfusion may be recoverable if the Cushing's response is treated rapidly.

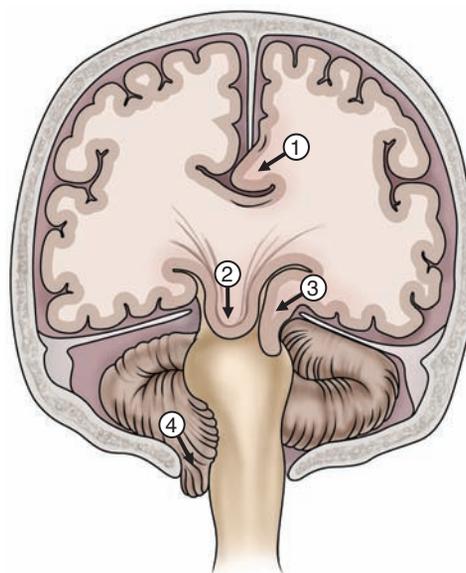

Figure 61-2 Brain with intracranial shifts from supratentorial lesions. 1, Herniation of the cingulate gyrus under the falx cerebri. 2, Central transtentorial herniation. 3, Uncal herniation of the temporal lobe into the tentorial notch. 4, Infratentorial herniation of the cerebral tonsils. Adapted from Porth, C. M. & Matfin, G. (2009). *Pathophysiology: Concepts of altered health states* (8th ed.). Philadelphia: Lippincott Williams & Wilkins.

At a certain point, the brain's ability to autoregulate becomes ineffective and decompensation (ischemia and infarction) begins. When this occurs, the patient exhibits significant changes in mental status and vital signs. The bradycardia, hypertension, and bradypnea associated with this deterioration are known as **Cushing's triad**, a grave sign. At this point, herniation of the brain stem and occlusion of the cerebral blood flow occur if therapeutic intervention is not initiated. Herniation refers to the shifting of brain tissue from an area of high pressure to an area of lower pressure (Fig. 61-2). The herniated tissue exerts pressure on the brain area into which it has shifted, which interferes with the blood supply in that area. Cessation of cerebral blood flow results in cerebral ischemia, infarction, and brain death.

Clinical Manifestations

If ICP increases to the point at which the brain's ability to adjust has reached its limits, neural function is impaired; this may be manifested at first by clinical changes in LOC and later by abnormal respiratory and vasomotor responses.

NURSING ALERT

The earliest sign of increasing ICP is a change in LOC. Slowing of speech and delay in response to verbal suggestions are other early indicators.

Any sudden change in the patient's condition, such as restlessness (without apparent cause), confusion, or increasing drowsiness, has neurologic significance. These signs may result from compression of the brain due to swelling from

hemorrhage or edema, an expanding intracranial lesion (hematoma or tumor), or a combination of both.

As ICP increases, the patient becomes stuporous, reacting only to loud or painful stimuli. At this stage, serious impairment of brain circulation is probably taking place, and immediate intervention is required. As neurologic function deteriorates further, the patient becomes comatose and exhibits abnormal motor responses in the form of **decortication** (abnormal flexion of the upper extremities and extension of the lower extremities), **decerebration** (extreme extension of the upper and lower extremities), or flaccidity (see Fig. 61-1). If the coma is profound, with the pupils dilated and fixed and respirations impaired or absent, death is usually inevitable (Posner, Saper, Schiff, et al., 2007).

Assessment and Diagnostic Findings

The diagnostic studies used to determine the underlying cause of increased ICP are discussed in detail in Chapter 60. The most common diagnostic tests are CT scanning and MRI. The patient may also undergo cerebral angiography, PET, or SPECT. Transcranial Doppler studies provide information about cerebral blood flow. The patient with increased ICP may also undergo electrophysiologic monitoring to observe cerebral blood flow indirectly. Evoked potential monitoring measures the electrical potentials produced by nerve tissue in response to external stimulation (auditory, visual, or sensory). Lumbar puncture is avoided in patients with increased ICP, because the sudden release of pressure in the lumbar area can cause the brain to herniate (Mazzoni, Pearson & Rowland, 2006). (See Chapter 60 for further discussion of lumbar puncture and other diagnostic tests.)

Complications

Complications of increased ICP include brain stem herniation, diabetes insipidus, and syndrome of inappropriate antidiuretic hormone (SIADH).

Brain stem herniation results from an excessive increase in ICP in which the pressure builds in the cranial vault and the brain tissue presses down on the brain stem. This increasing pressure on the brain stem results in cessation of blood flow to the brain, leading to irreversible brain anoxia and brain death.

Diabetes insipidus is the result of decreased secretion of antidiuretic hormone (ADH). The patient has excessive urine output, decreased urine osmolality, and serum hyperosmolality (Porth & Matfin, 2009). Therapy consists of administration of fluids, electrolyte replacement, and vasopressin (desmopressin, [DDAVP]) therapy. Diabetes insipidus is discussed in Chapters 14 and 42.

SIADH is the result of increased secretion of ADH. The patient becomes volume overloaded, urine output diminishes, and serum sodium concentration becomes dilute. Treatment of SIADH includes fluid restriction (less than 800 mL/day with no free water), which is usually sufficient to correct the hyponatremia. In severe cases, careful administration of a 3% hypertonic saline solution may be therapeutic (Mortimer & Jancik, 2006). The change in serum sodium concentration should not exceed a correction rate of approximately 1.3 mEq/L/h. Further discussion of SIADH is presented in Chapters 14 and 42.

Medical Management

Increased ICP is a true emergency and must be treated promptly. Invasive monitoring of ICP is an important component of management. Immediate management to relieve increased ICP requires decreasing cerebral edema, lowering the volume of CSF, or decreasing cerebral blood volume while maintaining cerebral perfusion. These goals are accomplished by administering osmotic diuretics, restricting fluids, draining CSF, controlling fever, maintaining systemic blood pressure and oxygenation, and reducing cellular metabolic demands. Management of increased ICP is discussed in Chapter 63.

Monitoring Intracranial Pressure and Cerebral Oxygenation

The purposes of ICP monitoring are to identify increased pressure early in its course (before cerebral damage occurs), to quantify the degree of elevation, to initiate appropriate treatment, to provide access to CSF for sampling and drainage, and to evaluate the effectiveness of treatment. ICP can be monitored with the use of an intraventricular catheter (ventriculostomy), a subarachnoid bolt, an epidural or subdural catheter, or a fiberoptic transducer-tipped catheter placed in the subdural space or in the ventricle (Fig. 61-3).

When a **ventriculostomy** or ventricular catheter monitoring device is used for monitoring ICP, a fine-bore catheter is inserted into a lateral ventricle, preferably in the nondominant hemisphere of the brain (Hickey, 2009). The catheter is connected by a fluid-filled system to a transducer, which records the pressure in the form of an electrical impulse. In addition to obtaining continuous ICP recordings, the ventricular catheter allows CSF to drain, particularly during acute increases in pressure. The ventriculostomy can also be

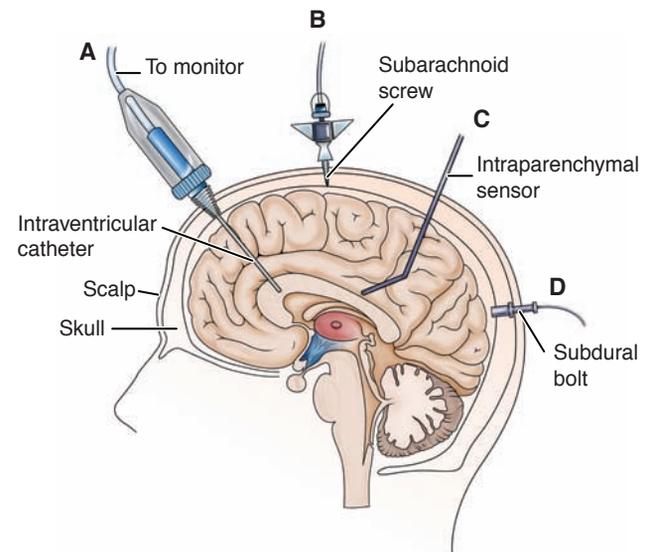

Figure 61-3 Intracranial pressure monitoring. A device may be placed in (A) the ventricle (B) the subarachnoid space (C) the intraparenchymal space or (D) the subdural space.

used to drain blood from the ventricle. Continuous drainage of CSF under pressure control is an effective method of treating intracranial hypertension. Another advantage of a ventricular catheter is access for the intraventricular administration of medications and the occasional instillation of air or a contrast agent for ventriculography. Complications associated with its use include infection, meningitis, ventricular collapse, occlusion of the catheter by brain tissue or blood, and problems with the monitoring system.

The **subarachnoid screw or bolt** is a hollow device that is inserted through the skull and dura mater into the cranial subarachnoid space (Hickey, 2009). It has the advantage of not requiring a ventricular puncture. The subarachnoid screw is attached to a pressure transducer, and the output is recorded on an oscilloscope. The hollow screw technique also has the advantage of avoiding complications from brain shift and small ventricle size. Complications include infection and blockage of the screw by clot or brain tissue, which leads to a loss of pressure tracing and a decrease in accuracy at high ICP readings.

An **epidural monitor** uses a pneumatic flow sensor to detect ICP. The epidural ICP monitoring system has a low incidence of infection and complications and appears to read pressures accurately. Calibration of the system is maintained automatically, and abnormal pressure waves trigger an alarm system. One disadvantage of the epidural catheter is the inability to withdraw CSF for analysis.

A **fiberoptic monitor**, or transducer-tipped catheter, is an alternative to other intraventricular, subarachnoid, and subdural systems (Haitsma & Maas, 2007). The miniature transducer reflects pressure changes, which are converted to electrical signals in an amplifier and displayed on a digital monitor. The catheter can be inserted into the ventricle, subarachnoid space, subdural space, or brain parenchyma or under a bone flap. If inserted into the ventricle, it can also be used in conjunction with a CSF drainage device.

Interpreting Intracranial Pressure Waveforms

Waves of high pressure and troughs of relatively normal pressure indicate changes in ICP. Waveforms are captured and recorded on an oscilloscope. These waves have been classified as A waves (plateau waves), B waves, and C waves (Fig. 61-4). The plateau waves (A waves) are transient, paroxysmal, recurring elevations of ICP that may last 5 to 20 minutes and range in amplitude from 50 to 100 mm Hg (AANN, 2005). Plateau waves have clinical significance and indicate changes in vascular volume within the intracranial compartment that are beginning to compromise cerebral perfusion. The A waves may increase in amplitude and frequency, reflecting cerebral ischemia and brain damage that can occur before overt signs and symptoms of raised ICP are seen clinically. B waves are shorter (30 seconds to 2 minutes) and have smaller amplitude (up to 50 mm Hg). They have less clinical significance, but if seen in a series in a patient with depressed consciousness, they may precede the appearance of A waves. B waves may be seen in patients with intracranial hypertension and decreased intracranial compliance. C waves are small, rhythmic oscillations with frequencies of approximately six per minute. They appear to be related to rhythmic variations of the systemic arterial blood pressure and respirations. The clinical significance of C waves is unknown (Littlejohns & Bader, 2009).

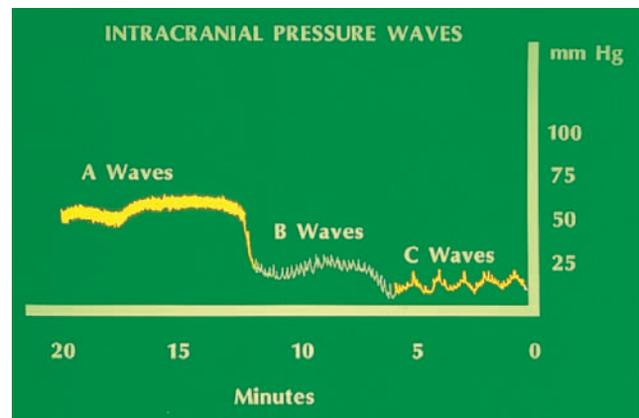

Figure 61-4 Intracranial pressure waves. Composite diagram of A (plateau) waves, which indicate cerebral ischemia; B waves, which indicate intracranial hypertension and variations in the respiratory cycle; and C waves, which relate to variations in systemic arterial pressure and respirations.

Other Neurologic Monitoring Systems

Additional trends in neurologic monitoring include **microdialysis** of the patient with a brain injury (McAdoo & Wu, 2008). Cortical probes are placed near the injured area and are used to measure levels of glutamate, lactate, pyruvate, and glucose, substances that reflect the metabolic function of the brain. Some researchers theorize that direct measurements of glucose and energy byproducts in the brain will lead to better management of these patients and, ultimately, to improved outcomes.

An additional trend is monitoring of cerebral oxygenation through monitoring of the oxygen saturation in the jugular venous bulb ($SjvO_2$) or via a catheter in the brain. Cerebral oxygenation is thought to be important because changes in cerebral perfusion may reflect an increase in ICP. Readings taken from a catheter residing in the jugular outflow tract allow for a comparison of arterial and venous oxygen saturation, and the balance of cerebral oxygen supply and demand is demonstrated. Venous jugular desaturations can reflect early cerebral ischemia, alerting the clinician before an increase in ICP occurs. Minimizing cerebral desaturations can potentially improve outcomes (Haitsma & Maas, 2007). This type of monitoring is now widely available and has been successfully used to identify secondary brain insults. A limiting factor is that this saturation reflects overall perfusion of the brain rather than that of a specific injured area (Lescot, Abdennour, Boch, et al., 2008).

Another method of measuring cerebral oxygenation and temperature is by inserting a fiberoptic catheter into the brain matter (Jaeger, Soehle & Meixenberger, 2005). The most common system is LICOX (manufactured by Integra NeuroSciences, Plainsboro, NJ; Fig. 61-5). The system includes a monitor with a screen for the display of oxygen and temperature values and cables that connect to the monitoring probes in the brain (Hickey, 2009).

Decreasing Cerebral Edema

Osmotic diuretics such as mannitol may be administered to dehydrate the brain tissue and reduce cerebral edema. They

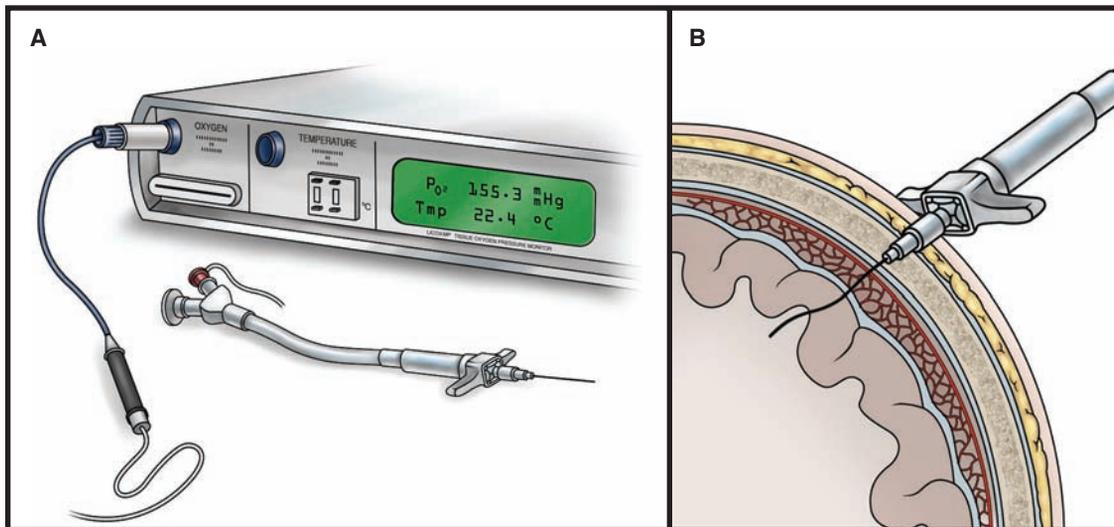

Figure 61-5 LICOX catheter system. **A**, The brain tissue oxygen catheter and monitor. **B**, Placement of the catheter in brain white matter. Redrawn with permission of Integra NeuroSciences, Plainsboro, NJ.

act by drawing water across intact membranes, thereby reducing the volume of the brain and extracellular fluid. An indwelling urinary catheter is usually inserted to monitor urinary output and to manage the resulting diuresis. If the patient is receiving osmotic diuretics, serum osmolality should be determined to assess hydration status. If a brain tumor is the cause of the increased ICP, corticosteroids (eg, dexamethasone) help reduce the edema surrounding the tumor.

Another method for decreasing cerebral edema is fluid restriction (Hickey, 2009). Limiting overall fluid intake leads to dehydration and hemoconcentration, which draws fluid across the osmotic gradient and decreases cerebral edema. Conversely, overhydration of the patient with increased ICP is avoided, because it increases cerebral edema.

Researchers have long hypothesized that lowering body temperature would decrease cerebral edema by reducing the oxygen and metabolic requirements of the brain, thus protecting the brain from continued ischemia. If body metabolism can be reduced by lowering the body temperature, the collateral circulation in the brain may be able to provide an adequate blood supply to the brain. The effect of hypothermia on ICP requires more study; thus far, induced hypothermia has not consistently been shown to be beneficial for patients with brain injury. Inducing and maintaining hypothermia is a major clinical treatment and requires knowledge and skilled nursing observation and management. The type and length of rewarming techniques after hypothermia may also be factors in the outcome of patients with neurologic injuries (Lescot, et al., 2008).

Maintaining Cerebral Perfusion

Cardiac output may be manipulated to provide adequate perfusion to the brain. Improvements in cardiac output are made using fluid volume and inotropic agents such as dobutamine (Dobutrex) and norepinephrine (Levophed). The effectiveness of the cardiac output is reflected in the CPP, which is maintained at greater than 70 mm Hg (Lescot,

et al., 2008). A lower CPP indicates that the cardiac output is insufficient to maintain adequate cerebral perfusion. $SjvO_2$ and LICOX, described earlier, assist in monitoring cerebral perfusion.

Reducing Cerebrospinal Fluid and Intracranial Blood Volume

CSF drainage is frequently performed, because the removal of CSF with a ventriculostomy drain can dramatically reduce ICP and restore CPP. Caution should be used in draining CSF, however, because excessive drainage may result in collapse of the ventricles and herniation. The reduction in $PaCO_2$ may result in hypoxia, ischemia, and an increase in cerebral lactate levels. Maintaining the $PaCO_2$ at greater than 30 mm Hg may prove beneficial (Hickey, 2009).

Controlling Fever

Preventing a temperature elevation is critical, because fever increases cerebral metabolism and the rate at which cerebral edema forms. Strategies to reduce body temperature include administration of antipyretic medications, as prescribed, and use of a hypothermia blanket. Additional strategies for reducing fever were previously discussed in the Nursing Process section on altered LOC. The patient's temperature is monitored closely, and the patient is observed for shivering, which should be avoided because it is associated with increased oxygen consumption, increased levels of circulating catecholamines, and increased vasoconstriction (Mcilvoy, 2007).

Maintaining Oxygenation and Reducing Metabolic Demands

Arterial blood gases and pulse oximetry are monitored to ensure that systemic oxygenation remains optimal. Metabolic demands may be reduced through the administration of high doses of barbiturates if the patient is unresponsive to conventional treatment. The mechanism by which barbiturates decrease ICP and protect the brain is uncertain, but

the resultant comatose state is thought to reduce the metabolic requirements of the brain, thus providing cerebral protection (Bader, Arbour & Palmer, 2005).

Another method of reducing cellular metabolic demand and improving oxygenation is the administration of paralyzing medication such as propofol (Diprivan). The patient who receives these agents cannot move; this decreases the metabolic demands and results in a decrease in cerebral oxygen demand. Paralyzing agents do not produce either sedation or analgesia, which must be provided, because the patient cannot respond to or report pain. The most common agents used for barbiturate or paralytic therapy are pentobarbital (Nembutal), thiopental (Pentothal), and propofol (Bader, et al., 2005).

If barbiturates or paralyzing agents are used, the ability to perform serial neurologic assessments is lost. Therefore, other monitoring tools are needed to assess the patient's status and response to therapy. Important parameters that must be assessed include ICP, blood pressure, heart rate, respiratory rate, and the patient's response to ventilator therapy (eg, "bucking the ventilator"). The level of pharmacologic paralysis is adjusted based on serum levels of the medications administered and the assessed parameters. Potential complications include hypotension caused by decreased sympathetic tone and myocardial depression.

Patients receiving high doses of barbiturates or pharmacologic paralyzing agents require continuous cardiac monitoring, endotracheal intubation, mechanical ventilation, and arterial pressure monitoring, as well as ICP monitoring. In addition, serum barbiturate levels must be routinely monitored (Lescot, et al., 2008).

NURSING PROCESS

THE PATIENT WITH INCREASED INTRACRANIAL PRESSURE

Assessment

Initial assessment of the patient with increased ICP includes obtaining a history of events leading to the present illness and the pertinent past medical history. It is usually necessary to obtain this information from family or friends. The neurologic examination should be as complete as the patient's condition allows. It includes an evaluation of mental status, LOC, cranial nerve function, cerebellar function (balance and coordination), reflexes, and motor and sensory function. Because the patient is critically ill, ongoing assessment is more focused, including pupil checks, assessment of selected cranial nerves, frequent measurements of vital signs and ICP, and use of the Glasgow Coma Scale. Assessment of the patient with altered LOC is summarized in Table 61-1.

Diagnosis

Nursing Diagnoses

Based on the assessment data, the major nursing diagnoses for patients with increased ICP include the following:

- Ineffective airway clearance related to diminished protective reflexes (cough, gag)

- Ineffective breathing patterns related to neurologic dysfunction (brain stem compression, structural displacement)
- Ineffective cerebral tissue perfusion related to the effects of increased ICP
- Deficient fluid volume related to fluid restriction
- Risk for infection related to ICP monitoring system (fiberoptic or intraventricular catheter)

Other relevant nursing diagnoses are included in the section on altered LOC.

Collaborative Problems/Potential Complications

Based on the assessment data, potential complications include:

- Brain stem herniation
- Diabetes insipidus
- SIADH

Planning and Goals

The goals for the patient include maintenance of a patent airway, normalization of respiration, adequate cerebral tissue perfusion through reduction in ICP, restoration of fluid balance, absence of infection, and absence of complications.

Nursing Interventions

Maintaining a Patent Airway

The patency of the airway is assessed. Secretions that are obstructing the airway must be suctioned with care, because transient elevations of ICP occur with suctioning (Hickey, 2009). Hypoxia caused by poor oxygenation leads to cerebral ischemia and edema. Coughing is discouraged because it increases ICP. The lung fields are auscultated at least every 8 hours to determine the presence of adventitious sounds or any areas of congestion. Elevating the head of the bed may aid in clearing secretions and improve venous drainage of the brain.

Achieving an Adequate Breathing Pattern

The patient must be monitored constantly for respiratory irregularities. Increased pressure on the frontal lobes or deep midline structures may result in Cheyne-Stokes respirations, whereas pressure in the midbrain can cause hyperventilation. If the lower portion of the brain stem (the pons and medulla) is involved, respirations become irregular and eventually cease.

If hyperventilation therapy is deemed appropriate to reduce ICP (by causing cerebral vasoconstriction and a decrease in cerebral blood volume), the nurse collaborates with the respiratory therapist in monitoring the PaCO₂, which is usually maintained at less than 30 mm Hg (Hickey, 2009).

A neurologic observation record (Fig. 61-6) is maintained, and all observations are made in relation to the patient's baseline condition. Repeated assessments of the patient are made (sometimes minute by minute) so that improvement or deterioration may be noted immediately. If the patient's condition deteriorates, preparations are made for surgical intervention.

Optimizing Cerebral Tissue Perfusion

In addition to ongoing nursing assessment, strategies are initiated to reduce factors contributing to the elevation of ICP (Table 61-2).

Figure 61-6 (Continued).

Factor	Physiology	Interventions	Rationale
Cerebral edema	Can be caused by contusion, tumor, or abscess; water intoxication (hypo-osmolality); alteration in the blood–brain barrier (protein leaks into the tissue, causing water to follow)	Administer osmotic diuretics as prescribed (monitor serum osmolality). Maintain head of bed elevated 30 degrees.	Promotes venous return Prevents impairment of venous return through the jugular veins
Hypoxia	A decrease in the PaO ₂ causes cerebral vasodilation at <60 mm Hg.	Maintain alignment of the head. Maintain PaO ₂ >60 mm Hg. Maintain oxygen therapy. Monitor arterial blood gas values. Suction when needed.	Prevents hypoxia and vasodilation
Hypercapnia (elevated PaCO ₂)	Causes vasodilation	Maintain a patent airway. Maintain PaCO ₂ (normally 35–45 mm Hg) by establishing ventilation.	Normalizing PaCO ₂ minimizes vasodilation and thus reduces the cerebral blood volume
Impaired venous return	Increases the cerebral blood volume	Maintain head alignment. Elevate head of bed 30 degrees.	Hyperextension, rotation, or hyperflexion of the neck causes decreased venous return
Increase in intrathoracic or abdominal pressure	An increase in these pressures due to coughing, PEEP, or Valsalva maneuver causes a decrease in venous return.	Monitor arterial blood gas values and keep PEEP as low as possible. Provide humidified oxygen. Administer stool softeners as prescribed.	To keep secretions loose and easy to suction or expectorate Soft bowel movements will prevent straining or Valsalva maneuver

Proper positioning helps reduce ICP. The patient's head is kept in a neutral (midline) position, maintained with the use of a cervical collar if necessary, to promote venous drainage. Elevation of the head is maintained at 30 to 45 degrees unless contraindicated (Littlejohns & Bader, 2009). Extreme rotation of the neck and flexion of the neck are avoided, because compression or distortion of the jugular veins increases ICP. Extreme hip flexion is also avoided, because this position causes an increase in intra-abdominal and intrathoracic pressures, which can produce an increase in ICP. Relatively minor changes in position can significantly affect ICP. If monitoring reveals that turning the patient raises ICP, rotating beds, turning sheets, and holding the patient's head during turning may minimize the stimuli that increase ICP.

The Valsalva maneuver, which can be produced by straining at defecation or even moving in bed, raises ICP and is to be avoided. Stool softeners may be prescribed. If the patient is alert and able to eat, a diet high in fiber may be indicated. Abdominal distention, which increases intra-abdominal and intrathoracic pressure and ICP, should be noted. Enemas and cathartics are avoided if possible. When moving or being turned in bed, the patient can be instructed to exhale (which opens the glottis) to avoid the Valsalva maneuver.

Mechanical ventilation presents unique problems for the patient with increased ICP. Before suctioning, the patient should be preoxygenated and briefly hyperventilated using 100% oxygen on the ventilator. Suctioning should not last longer than 15 seconds. High levels of positive end-expiratory pressure (PEEP) are avoided, because they may decrease venous return to the heart and decrease venous drainage from the brain through increased intrathoracic pressure (Littlejohns & Bader, 2009).

Activities that increase ICP, as indicated by changes in waveforms, should be avoided if possible. Spacing of nursing interventions may prevent transient increases in ICP.

During nursing interventions, the ICP should not increase more than 25 mm Hg, and it should return to baseline levels within 5 minutes. Patients with increased ICP should not demonstrate a significant increase in pressure or change in the ICP waveform. Patients with the potential for a significant increase in ICP may need sedation and a paralytic agent before initiation of nursing activities (Olsen & Graffagnino, 2005).

Emotional stress and frequent arousal from sleep are avoided. A calm atmosphere is maintained. Environmental stimuli (eg, noise, conversation) should be minimal.

Maintaining Negative Fluid Balance

The administration of osmotic and loop diuretics is part of the treatment protocol to reduce ICP. Corticosteroids may be used to reduce cerebral edema (except when it results from trauma), and fluids may be restricted. All of these treatment modalities promote dehydration.

Skin turgor, mucous membranes, urine output, and serum and urine osmolality are monitored to assess fluid status. If IV fluids are prescribed, the nurse ensures that they are administered at a slow to moderate rate with an IV infusion pump, to prevent too-rapid administration and avoid overhydration. For the patient receiving mannitol, the nurse observes for the possible development of heart failure and pulmonary edema, because the intent of treatment is to promote a shift of fluid from the intracellular to the intravascular compartment, thus controlling cerebral edema.

For patients undergoing dehydrating procedures, vital signs, including blood pressure, must be monitored to assess fluid volume status. An indwelling urinary catheter is inserted to permit assessment of renal function and fluid status. During the acute phase, urine output is monitored hourly. An output greater than 200 mL/h for 2 consecutive hours may indicate the onset of diabetes insipidus (Hickey, 2009).

These patients need careful oral hygiene, because mouth dryness occurs with dehydration. Frequently rinsing the mouth with nondrying solutions, lubricating the lips, and removing encrustations relieve dryness and promote comfort.

Preventing Infection

The risk of infection is greatest when ICP is monitored with an intraventricular catheter and increases with the duration of the monitoring. Most health care facilities have written protocols for managing these systems and maintaining their sterility; strict adherence to the protocols is essential.

Aseptic technique must be used when managing the system and changing the ventricular drainage bag. The drainage system is also checked for loose connections, because they can cause leakage and contamination of the CSF as well as inaccurate readings of ICP. The nurse observes the character of the CSF drainage and reports increasing cloudiness or blood. The patient is monitored for signs and symptoms of meningitis: fever, chills, nuchal (neck) rigidity, and increasing or persistent headache. (See Chapter 64 for a discussion of meningitis.)

Monitoring and Managing Potential Complications

The primary complication of increased ICP is brain herniation resulting in death (see Fig. 61-2). Nursing management focuses on detecting early signs of increasing ICP, because medical interventions are usually ineffective once later signs develop. Frequent neurologic assessments and documentation and analysis of trends will reveal the subtle changes that may indicate increasing ICP.

DETECTING EARLY INDICATIONS OF INCREASING INTRACRANIAL PRESSURE. The nurse assesses for and immediately reports any of the following early signs or symptoms of increasing ICP:

- Disorientation, restlessness, increased respiratory effort, purposeless movements, and mental confusion; these are early clinical indications of increasing ICP because the brain cells responsible for cognition are extremely sensitive to decreased oxygenation
- Pupillary changes and impaired extraocular movements; these occur as the increasing pressure displaces the brain against the oculomotor and optic nerves (cranial nerves II, III, IV, and VI), which arise from the midbrain and brain stem (see Chapter 60)
- Weakness in one extremity or on one side of the body; this occurs as increasing ICP compresses the pyramidal tracts
- Headache that is constant, increasing in intensity, and aggravated by movement or straining; this occurs as increasing ICP causes pressure and stretching of venous and arterial vessels in the base of the brain

DETECTING LATER INDICATIONS OF INCREASING INTRACRANIAL PRESSURE. As ICP increases, the patient's condition worsens, as manifested by the following signs and symptoms:

- The LOC continues to deteriorate until the patient is comatose.
- The pulse rate and respiratory rate decrease or become erratic, and the blood pressure and temperature increase. The pulse pressure (the difference between the

systolic and the diastolic pressures) widens. The pulse fluctuates rapidly, varying from bradycardia to tachycardia.

- Altered respiratory patterns develop, including Cheyne-Stokes breathing (rhythmic waxing and waning of rate and depth of respirations alternating with brief periods of apnea) and ataxic breathing (irregular breathing with a random sequence of deep and shallow breaths).
- Projectile vomiting may occur with increased pressure on the reflex center in the medulla.
- Hemiplegia or decorticate or decerebrate posturing may develop as pressure on the brain stem increases; bilateral flaccidity occurs before death.
- Loss of brain stem reflexes, including pupillary, corneal, gag, and swallowing reflexes, is an ominous sign of approaching death.

MONITORING INTRACRANIAL PRESSURE. Because clinical assessment is not always a reliable guide in recognizing increased ICP, especially in comatose patients, monitoring of ICP and cerebral oxygenation is an essential part of management. ICP is monitored closely for continuous elevation or significant increase over baseline. The trend of ICP measurements over time is an important indication of the patient's underlying status. Vital signs are assessed when an increase in ICP is noted.

Strict aseptic technique is used when handling any part of the monitoring system. The insertion site is inspected for signs of infection. Temperature, pulse, and respirations are closely monitored for systemic signs of infection. All connections and stopcocks are checked for leaks, because even small leaks can distort pressure readings and lead to infection (Littlejohns & Bader, 2009).

When ICP is monitored with a fluid system, the transducer is calibrated at a particular reference point, usually 2.5 cm (1 inch) above the ear with the patient in the supine position; this point corresponds to the level of the foramen of Monro (Fig. 61-7). CSF pressure readings depend on the patient's position. For subsequent pressure readings, the head should be in the same position relative to the transducer. Fiberoptic catheters are calibrated before insertion and do not require further referencing; they do not require the head of the bed to be at a specific position to obtain an accurate reading.

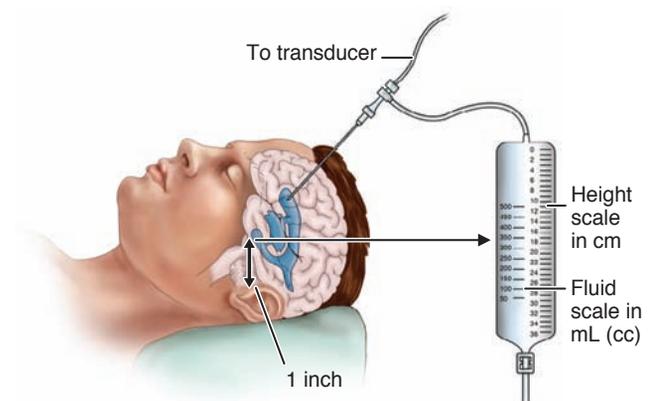

Figure 61-7 Location of the foramen of Monro for calibration of intracranial pressure monitoring system.

When technology is associated with patient management, the nurse must be certain that the technologic equipment is functioning properly. The most important concern must be the patient to whom equipment is attached. The patient and family must be informed about the technology and the goals of its use. The patient's response is monitored, and appropriate comfort measures are implemented to ensure that the patient's stress is minimized.

ICP measurement is only one parameter; repeated neurologic checks and clinical examinations remain important measures. Astute observation, comparison of findings with previous observations, and interventions can assist in preventing life-threatening ICP elevations.

MONITORING FOR SECONDARY COMPLICATIONS. The nurse also assesses for complications of increased ICP, including diabetes insipidus and SIADH (see Chapters 14 and 42). Urine output should be monitored closely. Diabetes insipidus requires fluid and electrolyte replacement, along with the administration of vasopressin, to replace and slow the urine output. Serum electrolyte levels are monitored for imbalances. SIADH requires fluid restriction and monitoring of serum electrolyte levels.

Evaluation

Expected Patient Outcomes

Expected patient outcomes may include the following:

1. Maintains patent airway
2. Attains optimal breathing pattern
 - a. Breathes in a regular pattern
 - b. Attains or maintains arterial blood gas values within acceptable range
3. Demonstrates optimal cerebral tissue perfusion
 - a. Increasingly oriented to time, place, and person
 - b. Follows verbal commands; answers questions correctly
4. Attains desired fluid balance
 - a. Maintains fluid restriction
 - b. Demonstrates serum and urine osmolality values within acceptable range
5. Has no signs or symptoms of infection
 - a. Has no fever
 - b. Shows no redness, swelling, or drainage at arterial, IV, and urinary catheter sites
 - c. Has no redness, swelling, or purulent drainage from invasive intracranial monitoring device
6. Absence of complications
 - a. Has ICP values that remain within normal limits
 - b. Demonstrates urine output and serum electrolyte levels within acceptable limits

INTRACRANIAL SURGERY

A **craniotomy** involves opening the skull surgically to gain access to intracranial structures. This procedure is performed to remove a tumor, relieve elevated ICP, evacuate a

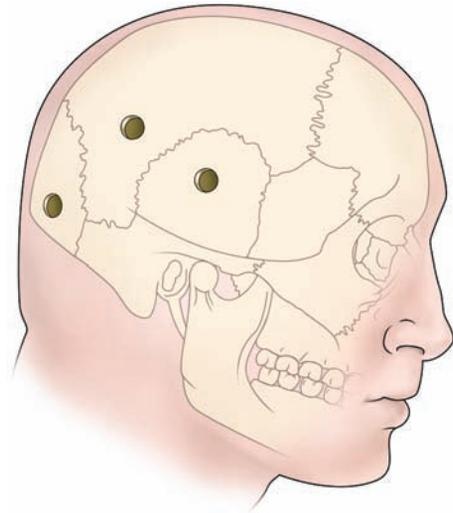

Figure 61-8 Burr holes may be used in neurosurgical procedures to make a bone flap in the skull, to aspirate a brain abscess, or to evacuate a hematoma.

blood clot, or control hemorrhage. The surgeon cuts the skull to create a bony flap, which can be repositioned after surgery and held in place by periosteal or wire sutures. One of two approaches through the skull is used: (1) above the tentorium (supratentorial craniotomy) into the supratentorial compartment, or (2) below the tentorium into the infratentorial (posterior fossa) compartment. A third approach, the **transsphenoidal** approach (through the mouth and nasal sinuses) is often used to gain access to the pituitary gland (Musleh, Sonabend & Lesniak, 2006). Table 61-3 compares the three different surgical approaches: supratentorial, infratentorial, and transsphenoidal.

Alternatively, intracranial structures may be approached through burr holes (Fig. 61-8), which are circular openings made in the skull by either a hand drill or an automatic craniotome (which has a self-controlled system to stop the drill when the bone is penetrated). Burr holes may be used to determine the presence of cerebral swelling and injury and the size and position of the ventricles. They are also a means of evacuating an intracranial hematoma or abscess and for making a bone flap in the skull that allows access to the ventricles for decompression, ventriculography, or shunting procedures. Other cranial procedures include **craniectomy** (excision of a portion of the skull) and **cranioplasty** (repair of a cranial defect using a plastic or metal plate).

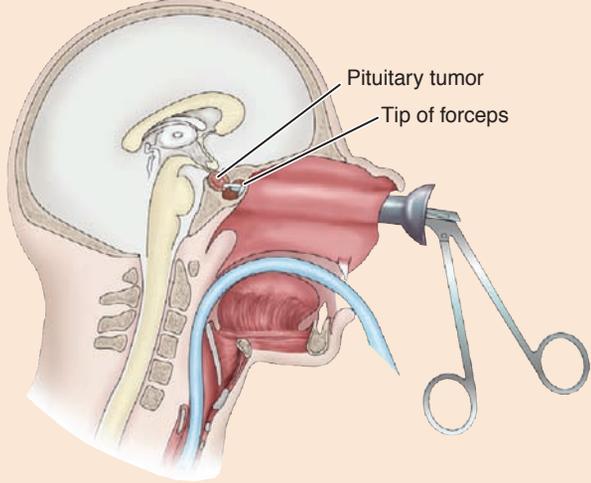

Supratentorial and Infratentorial Approaches

PREOPERATIVE MANAGEMENT

Medical Management

Preoperative diagnostic procedures may include a CT scan to demonstrate the lesion and show the degree of surrounding brain edema, the ventricular size, and the displacement. An MRI scan provides information similar to that of a CT scan with improved tissue contrast, resolution,

and anatomic definition. Cerebral angiography may be used to study a tumor's blood supply or obtain information about vascular lesions. Transcranial Doppler flow studies are used to evaluate the blood flow within intracranial blood vessels.

Most patients are prescribed an antiseizure medication such as phenytoin (Dilantin) or a phenytoin metabolite (Cerebyx) before surgery to reduce the risk of postoperative **seizures** (paroxysmal transient disturbances of the brain resulting from a discharge of abnormal electrical activity) (Karch, 2008). Before surgery, corticosteroids such as dexamethasone (Decadron) may be administered to reduce cerebral edema if the patient has a brain tumor. Fluids may be restricted. A hyperosmotic agent (mannitol) and a diuretic agent such as furosemide (Lasix) may be administered IV immediately before and sometimes during surgery if the patient tends to retain fluid, as do many who have intracranial dysfunction. Antibiotics may be administered if there is a chance of cerebral contamination; diazepam (Valium) or lorazepam (Ativan) may be prescribed before surgery to allay anxiety.

Nursing Management

The preoperative assessment serves as a baseline against which postoperative status and recovery are compared. This assessment includes evaluating the LOC and responsiveness to stimuli and identifying any neurologic deficits, such as paralysis, visual dysfunction, alterations in personality or speech, and bladder and bowel disorders. Distal and proximal motor strength in both upper and lower extremities is recorded on a 5-point scale. Testing of motor function is discussed in Chapter 60.

The patient's and family's understanding of and reactions to the anticipated surgical procedure and its possible sequelae are assessed, as is the availability of support systems for the patient and family. Adequate preparation for surgery, with attention to the patient's physical and emotional status, can reduce the risk of anxiety, fear, and postoperative complications. The patient is assessed for neurologic deficits and their potential impact after surgery. For motor deficits or weakness or paralysis of the arms or legs, trochanter rolls are applied to the extremities, and the feet are positioned

against a footboard or the ankles are supported in a neutral position with orthotic boots. A patient who can ambulate is encouraged to do so. If the patient is aphasic, writing materials or picture and word cards showing the bedpan, glass of water, blanket, and other frequently used items may help improve communication.

Preparation of the patient and family includes providing information about what to expect during and after surgery. Hair is removed with the use of clippers and the surgical site prepared immediately before surgery (usually in the operating room), to decrease the chance of infection. An indwelling urinary catheter is inserted in the operating room to drain the bladder during the administration of diuretics and to permit urinary output to be monitored. The patient may have a central and arterial line placed for fluid administration and monitoring of pressures after surgery. The large head dressing applied after surgery may impair hearing temporarily. Vision may be limited if the eyes are swollen shut. If a tracheostomy or endotracheal tube is in place, the patient will be unable to speak until the tube is removed, so an alternative method of communication must be established.

An altered cognitive state may make the patient unaware of the impending surgery (Chart 61-1). Even so, encouragement and attention to the patient's needs are necessary. Whatever the state of awareness of the patient, the family needs reassurance and support, because they usually recognize the seriousness of brain surgery.

POSTOPERATIVE MANAGEMENT

Postoperatively, an arterial line and a central venous pressure line may be in place to monitor and manage blood pressure and central venous pressure. The patient may be intubated and may receive supplemental oxygen therapy. Ongoing postoperative management is aimed at detecting and reducing cerebral edema, relieving pain and preventing seizures, and monitoring ICP and neurologic status.

CHART
61-1

Ethics and Related Issues

What Ethical Principles Are Involved With Surrogate Consent?

Situation

A 35-year-old woman has had a brain injury, is in and out of a comatose state, and needs a craniotomy for removal of an epidural hematoma. The health care provider determines that the patient is unable to give informed consent for the procedure, so consent is obtained from the next of kin.

Dilemma

The principle of autonomy for the patient conflicts with the principle of paternalism for the health care providers.

Discussion

1. What are the essential elements of informed consent pertinent to this situation?
2. What mechanisms can the nursing staff use to assist them in resolving any dilemma they have regarding the patient's right to autonomy?

Reducing Cerebral Edema

Medications to reduce cerebral edema include mannitol, which increases serum osmolality and draws free water from areas of the brain (with an intact blood-brain barrier). The fluid is then excreted by osmotic diuresis. Dexamethasone (Decadron) may be administered IV every 6 hours for 24 to 72 hours; the route is changed to oral as soon as possible, and the dosage is tapered over 5 to 7 days (Karch, 2008).

Relieving Pain and Preventing Seizures

Acetaminophen is usually prescribed for temperatures exceeding 37.5°C (99.6°F) and for pain. The patient usually has a headache after a craniotomy as a result of stretching and irritation of nerves in the scalp during surgery. Codeine, administered IV, is often sufficient to relieve headache. Morphine sulfate may also be used in the management of postoperative pain in patients who have undergone a craniotomy (Nemergut, Durieaux, Missaghi, et al., 2007).

Antiseizure medication (phenytoin, diazepam) is often prescribed prophylactically for patients who have undergone supratentorial craniotomy because of the high risk of seizures after these procedures (Hickey, 2009). Serum levels are monitored to check that the medication levels are within the therapeutic range.

Monitoring Intracranial Pressure

A patient undergoing intracranial surgery may have an ICP or cerebral oxygenation monitor inserted during surgery. Strict adherence to written protocols for managing these systems is essential, as discussed earlier, for preventing infection and managing ICP. The system is removed after the ICP or cerebral oxygenation is normal and stable. The neurosurgeon must be notified immediately if the system is not functioning.

NURSING PROCESS

THE PATIENT WHO HAS UNDERGONE INTRACRANIAL SURGERY

Assessment

After surgery, the frequency of postoperative monitoring is based on the patient's clinical status. Assessing respiratory function is essential, because even a small degree of hypoxia can increase cerebral ischemia. The respiratory rate and pattern are monitored, and arterial blood gas values are assessed frequently. Fluctuations in vital signs are carefully monitored and documented, because they may indicate increased ICP. The patient's temperature is measured to assess for hyperthermia secondary to infection or damage to the hypothalamus. Neurologic checks are made frequently to detect increased ICP resulting from cerebral edema or bleeding. A change in LOC or response to stimuli may be the first sign of increasing ICP.

The surgical dressing is inspected for evidence of bleeding and CSF drainage. The incision is monitored for redness, tenderness, bulging, separation, or foul odor. Sodium retention may occur in the immediate postoperative period. Serum and urine electrolytes, BUN, blood glucose, weight,

and clinical status are monitored. Intake and output are measured in view of losses associated with fever, respiration, and CSF drainage. The nurse must be alert to the development of complications; all assessments are carried out with these problems in mind. Seizures are a potential complication, and any seizure activity is carefully recorded and reported. Restlessness may occur as the patient becomes more responsive, or restlessness may be caused by pain, confusion, hypoxia, or other stimuli.

Diagnosis

Nursing Diagnoses

Based on the assessment data, the patient's major nursing diagnoses after intracranial surgery may include the following:

- Ineffective cerebral tissue perfusion related to cerebral edema
- Risk for imbalanced body temperature related to damage to the hypothalamus, dehydration, and infection
- Potential for impaired gas exchange related to hypoventilation, aspiration, and immobility
- Disturbed sensory perception related to periorbital edema, head dressing, endotracheal tube, and effects of ICP
- Body image disturbance related to change in appearance or physical disabilities

Other nursing diagnoses may include impaired communication (aphasia) related to insult to brain tissue and high risk for impaired skin integrity related to immobility, pressure, and incontinence; impaired physical mobility related to a neurologic deficit secondary to the neurosurgical procedure or to the underlying disorder may also occur.

Collaborative Problems/Potential Complications

Potential complications include the following:

- Increased ICP
- Bleeding and hypovolemic shock
- Fluid and electrolyte disturbances
- Infection
- Seizures

Planning and Goals

The major goals for the patient include neurologic homeostasis to improve cerebral tissue perfusion, adequate thermoregulation, normal ventilation and gas exchange, ability to cope with sensory deprivation, adaptation to changes in body image, and absence of complications.

Nursing Interventions

Maintaining Cerebral Tissue Perfusion

Attention to the patient's respiratory status is essential, because even slight decreases in the oxygen level (hypoxia) or slight increases in the carbon dioxide level (hypercarbia) can affect cerebral perfusion, the clinical course, and the patient's outcome. The endotracheal tube is left in place until the patient shows signs of awakening and has adequate spontaneous ventilation, as evaluated clinically and by arterial blood gas analysis. Secondary brain damage can result from impaired cerebral oxygenation.

Some degree of cerebral edema occurs after brain surgery; it tends to peak 24 to 36 hours after surgery, producing decreased responsiveness on the second postoperative day. The control of cerebral edema was discussed earlier. Nursing strategies used to control factors that may raise ICP were presented in the previous Nursing Process section on increased ICP. Intraventricular drainage is carefully monitored, using strict asepsis when any part of the system is handled.

Vital signs and neurologic status (LOC and responsiveness, pupillary and motor responses) are assessed every 15 to 60 minutes. Extreme head rotation is avoided, because this raises ICP. After supratentorial surgery, the patient is placed on his or her back or side (on the unoperated side if a large lesion was removed) with one pillow under the head. The head of the bed may be elevated 30 degrees, depending on the level of the ICP and the neurosurgeon's preference. After posterior fossa (infratentorial) surgery, the patient is kept flat on one side (off the back) with the head on a small, firm pillow. The patient may be turned on either side, keeping the neck in a neutral position. When the patient is being turned, the body should be turned as a unit to prevent placing strain on the incision and possibly tearing the sutures. The head of the bed may be elevated slowly as tolerated by the patient.

The patient's position is changed every 2 hours, and skin care is given frequently. During position changes, care is taken to prevent disruption of the ICP monitoring system. A turning sheet placed under the patient's head to midhigh makes it easier to move and turn the patient safely.

Regulating Temperature

Moderate temperature elevation can be expected after intracranial surgery because of the reaction to blood at the operative site or in the subarachnoid space. Injury to the hypothalamic centers that regulate body temperature can occur during surgery. Fever is treated vigorously to combat the effect of an elevated temperature on brain metabolism and function.

Nursing interventions include monitoring the patient's temperature and using the following measures to reduce body temperature: removing blankets, applying ice bags to axilla and groin areas, using a hypothermia blanket as prescribed, and administering prescribed medications to reduce fever (Thompson, Kirkness, Mitchell, et al., 2007).

Conversely, hypothermia may be seen after lengthy neurosurgical procedures. Therefore, frequent measurements of rectal temperatures are necessary. Rewarming should occur slowly to prevent shivering, which increases cellular oxygen demands.

Improving Gas Exchange

The patient undergoing neurosurgery is at risk for impaired gas exchange and pulmonary infections due to immobility, immunosuppression, decreased LOC, and fluid restriction. Immobility compromises the respiratory system by causing pooling and stasis of secretions in dependent areas and the development of atelectasis. The patient whose fluid intake is restricted may be more vulnerable to atelectasis as a result of inability to expectorate thickened secretions. Pneumonia can develop due to aspiration and restricted mobility.

Repositioning the patient every 2 hours helps to mobilize pulmonary secretions and prevent stasis. After the patient regains consciousness, additional measures to expand collapsed alveoli can be instituted, such as yawning, sighing, deep breathing, incentive spirometry, and coughing (unless contraindicated). If necessary, the oropharynx and trachea are suctioned to remove secretions that cannot be raised by coughing; however, coughing and suctioning increase ICP. Therefore, suctioning should be used cautiously. Increasing the humidity in the oxygen delivery system may help to loosen secretions. The nurse and the respiratory therapist work together to monitor the effects of chest physical therapy.

Managing Sensory Deprivation

Periorbital edema is a common consequence of intracranial surgery, because fluid drains into the dependent periorbital areas when the patient has been positioned in a prone position during surgery. A hematoma may form under the scalp and spread down to the orbit, producing an area of ecchymosis (black eye).

Before surgery, the patient and family should be informed that one or both eyes may be edematous temporarily after surgery. After surgery, elevating the head of the bed (if not contraindicated) and applying cold compresses over the eyes will help reduce the edema. If periorbital edema increases significantly, the surgeon is notified, because this may indicate that a postoperative clot is developing or that there is increasing ICP and poor venous drainage. Health care personnel should announce their presence when entering the room to avoid startling the patient whose vision is impaired due to periorbital edema or neurologic deficits.

Additional factors that can affect sensation include a bulky head dressing, the presence of an endotracheal tube, and effects of increased ICP. The first postoperative dressing change is usually performed by the neurosurgeon. In the absence of bleeding or a CSF leak, every effort is made to minimize the size of the head dressing. If the patient requires an endotracheal tube for mechanical ventilation, every effort is made to extubate the patient as soon as clinical signs indicate it is possible. The patient is monitored closely for the effects of elevated ICP.

Enhancing Self-Image

The patient is encouraged to verbalize feelings and frustrations about any change in appearance. Nursing support is based on the patient's reactions and feelings. Factual information may need to be provided if the patient has misconceptions about puffiness about the face, periorbital bruising, and hair loss. Attention to grooming, the use of the patient's own clothing, and covering the head with a turban (and later a wig until hair growth occurs) are encouraged. Social interaction with close friends, family, and hospital personnel may increase the patient's sense of self-worth.

The family and social support system can be of assistance while the patient recovers from surgery.

Monitoring and Managing Potential Complications

The nurse must be vigilant for complications that may develop within hours of surgery and require close collaboration with the neurosurgeon. These include increased ICP,

bleeding and hypovolemic shock, altered fluid and electrolyte balance (eg, water intoxication and diabetes insipidus), infection, and seizures.

MONITORING FOR INCREASED INTRACRANIAL PRESSURE AND BLEEDING. Increased ICP and bleeding are life-threatening to the patient who has undergone intracranial surgery. The following points must be kept in mind when caring for any patient who has undergone such surgery:

- An increase in blood pressure and decrease in pulse with respiratory failure may indicate increased ICP.
- An accumulation of blood under the bone flap (extradural, subdural, or intracerebral hematoma) may pose a threat to life. A clot must be suspected in any patient who does not awaken as expected or whose condition deteriorates. An intracranial hematoma is suspected if the patient has any new postoperative neurologic deficits (especially a dilated pupil on the operative side). In these circumstances, the patient is returned to the operating room immediately for evacuation of the clot if indicated.
- Cerebral edema, infarction, metabolic disturbances, and hydrocephalus are conditions that may mimic the clinical manifestations of a clot.

The patient is monitored closely for indicators of complications, and early signs and trends in clinical status are reported to the surgeon. Treatments are initiated promptly, and the nurse assists in evaluating the patient's response to treatment. The nurse also provides support to the patient and family.

If signs and symptoms of increased ICP occur, efforts to decrease the ICP are initiated: alignment of the head in a neutral position without flexion to promote venous drainage, elevation of the head of the bed to 30 degrees (when prescribed), administration of mannitol (an osmotic diuretic), and possible administration of pharmacologic paralyzing agents.

MANAGING FLUID AND ELECTROLYTE DISTURBANCES. Fluid and electrolyte imbalances may occur because of the patient's underlying condition and its management or as complications of surgery. These disturbances can contribute to the development of cerebral edema.

The postoperative fluid regimen depends on the type of neurosurgical procedure and is determined on an individual basis. The volume and composition of fluids are adjusted based on daily serum electrolyte values, along with fluid intake and output. Fluids may have to be restricted in patients with cerebral edema.

Oral fluids are usually resumed after the first 24 hours. The presence of gag and swallowing reflexes must be checked before initiation of oral fluids. Some patients with posterior fossa tumors have impaired swallowing, so fluids may need to be administered by alternative routes. The patient should be observed for signs and symptoms of nausea and vomiting as the diet is progressed (Hickey, 2009).

Patients undergoing surgery for brain tumors often receive large doses of corticosteroids and therefore tend to develop hyperglycemia. Serum glucose levels are measured every 4 to 6 hours. These patients are prone to stress ulcers, so histamine-2 receptor antagonists (H₂ blockers) are

prescribed to suppress the secretion of gastric acid. Patients also are monitored for bleeding and assessed for gastric pain.

If the surgical site is near to (or causes edema to) the pituitary gland and hypothalamus, the patient may develop symptoms of diabetes insipidus, which is characterized by excessive urinary output, elevated serum osmolality, decreased urine osmolality, hypernatremia, and a low urine specific gravity. The urine specific gravity is measured hourly, and fluid intake and output are monitored. Fluid replacement must compensate for urine output, and serum potassium levels must be monitored.

SIADH, which results in water retention with hyponatremia and serum hypo-osmolality, occurs in a wide variety of central nervous system disorders (eg, brain tumor, head trauma) causing fluid disturbances. Nursing management includes careful intake and output measurements, specific gravity determinations of urine, and monitoring of serum and urine electrolyte levels while following directives for fluid restriction. SIADH is usually self-limited.

PREVENTING INFECTION. The patient undergoing neurosurgery is at risk for infection related to the neurosurgical procedure (brain exposure, bone exposure, wound hematomas) and the presence of IV and arterial lines for fluid administration and monitoring. Risk for infection is increased in patients who undergo lengthy intracranial operations, in those who have external ventricular drains in place longer than 5 days, and with those who have ventricular catheters placed outside of the operating room (March, 2005).

The dressing is often stained with blood in the immediate postoperative period. Because blood is an excellent culture medium for bacteria, the dressing is reinforced with sterile pads so that contamination and infection are avoided. A heavily stained or displaced dressing should be reported immediately. A drain is sometimes placed in the craniotomy incision to facilitate drainage.

After suboccipital surgical procedures, CSF may leak through the incision. This complication is dangerous because of the possibility of meningitis. Any sudden discharge of fluid from a cranial incision is reported at once, because a massive leak requires surgical repair. Attention should be paid to the patient who complains of a salty taste or “postnasal drip,” because this can be caused by CSF trickling down the throat. After a craniotomy, the patient is instructed to avoid coughing, sneezing, or nose blowing, which can cause CSF leakage by creating pressure on the operative site.

Aseptic technique is used when handling dressings, drainage systems, and IV and arterial lines. The patient is monitored carefully for signs and symptoms of infection, and cultures are obtained if infection is suspected. Appropriate antibiotics are administered as prescribed. Other causes of infection in the patient undergoing intracranial surgery, such as pneumonia and urinary tract infections, are similar to those in other postoperative patients.

MONITORING FOR SEIZURE ACTIVITY. Seizures may occur as complications after any intracranial neurosurgical procedure. Preventing seizures is essential to avoid further cerebral edema. Administering the prescribed antiseizure medication before and after surgery may prevent the development of seizures in subsequent months and years. **Status epilepticus** (prolonged seizures without recovery of consciousness in the

intervals between seizures) may occur after craniotomy and also may be related to the development of complications (hematoma, ischemia). The management of status epilepticus is described later in this chapter.

MONITORING AND MANAGING OTHER COMPLICATIONS. Other complications may occur during the first 2 weeks or later and may compromise the patient’s recovery. The most important of these are thromboembolic complications (DVT, pulmonary embolism), pulmonary and urinary tract infection, and pressure ulcers. Most of these complications may be avoided with frequent changes of position, adequate suctioning of secretions, thrombosis prophylaxis, early ambulation, and skin care.

Promoting Home and Community-Based Care

TEACHING PATIENTS SELF-CARE. The recovery of a neurosurgical patient at home depends on the extent of the surgical procedure and its success. The patient’s strengths as well as limitations are assessed and explained to the family, along with the family’s part in promoting recovery. Because administration of antiseizure medication is a priority, the patient and family are taught to use a check-off system, pill boxes, and alarms to ensure that the medication is taken as prescribed.

The patient and family are taught what to expect after surgery. Dietary restrictions usually are not required unless another health problem necessitates a special diet. Although showering or tub bathing is permitted, the scalp should be kept dry until all the sutures have been removed. A clean scarf or cap may be worn until a wig or hairpiece is purchased. If skull bone has been removed, the neurosurgeon may prescribe a protective helmet. After a craniotomy, the patient may require rehabilitation, depending on the postoperative level of function. The patient may require physical therapy for residual weakness and mobility issues. An occupational therapist is consulted to assist with self-care issues. If the patient is aphasic, speech therapy may be necessary.

CONTINUING CARE. Barring complications, patients are discharged from the hospital as soon as possible. Patients with severe motor deficits require extensive physical therapy and rehabilitation. Those with postoperative cognitive and speech impairments require psychological evaluation, speech therapy, and rehabilitation. The nurse collaborates with the physician and other health care professionals during hospitalization and home care to achieve as complete a rehabilitation as possible and to assist the patient in living with residual disability.

If tumor, injury, or disease makes the prognosis poor, care is directed toward making the patient as comfortable as possible. With return of the tumor or cerebral compression, the patient becomes less alert and aware. Other possible consequences include paralysis, blindness, and seizures. The home care nurse, hospice nurse, and social worker collaborate with the family to plan for additional home health care or hospice services or placement of the patient in an extended-care facility (see also the section on cerebral metastases in Chapter 65). The patient and family are encouraged to discuss end-of-life preferences for care; the patient’s end-of-life preferences must be respected (see Chapter 17). The nurse involved in home and continuing care of patients after cranial surgery also needs to remind patients and family

members of the need for health promotion and recommended health screening.

Evaluation

Expected Patient Outcomes

Expected patient outcomes may include the following:

1. Achieves optimal cerebral tissue perfusion
 - a. Opens eyes on request; uses recognizable words, progressing to normal speech
 - b. Obeys commands with appropriate motor responses
2. Maintains normal body temperature
 - a. Registers normal body temperature
3. Has normal gas exchange
 - a. Has arterial blood gas values within normal ranges
 - b. Breathes easily; lung sounds are clear without adventitious sounds
 - c. Takes deep breaths and changes position as directed
4. Copes with sensory deprivation
5. Demonstrates improving self-concept
 - a. Pays attention to grooming
 - b. Visits and interacts with others
6. Exhibits absence of complications
 - a. Exhibits ICP within normal range
 - b. Has minimal bleeding at surgical site; surgical incision is healing without evidence of infection
 - c. Shows fluid balance and electrolyte levels within desired ranges
 - d. Exhibits no evidence of seizures

Transsphenoidal Approach

Tumors within the sella turcica and small adenomas of the pituitary can be removed through a transsphenoidal approach: An incision is made beneath the upper lip, and entry is then gained successively into the nasal cavity, sphenoidal sinus, and sella turcica (see Table 61-3). Although an otorhinolaryngologist may make the initial opening, the neurosurgeon completes the opening into the sphenoidal sinus and exposes the floor of the sella. Microsurgical techniques provide improved illumination, magnification, and visualization so that nearby vital structures can be avoided.

The transsphenoidal approach offers direct access to the sella turcica with minimal risk of trauma and hemorrhage (Musleh, et al., 2006). It avoids many of the risks of craniotomy, and the postoperative discomfort is similar to that of other transnasal surgical procedures. It may also be used for pituitary ablation (destruction) in patients with disseminated breast or prostatic cancer.

Complications

Manipulation of the posterior pituitary gland during surgery may produce transient diabetes insipidus of several days' duration (Hickey, 2009). It is treated with vasopressin but

occasionally persists. Other complications include CSF leakage, visual disturbances, postoperative meningitis, pneumocephalus (air in the intracranial cavity), and SIADH (see Chapter 42).

PREOPERATIVE MANAGEMENT

Medical Management

The preoperative workup includes a series of endocrine tests, rhinologic evaluation (to assess the status of the sinuses and nasal cavity), and neuroradiologic studies. Funduscopic examination and visual field determinations are performed, because the most serious effect of pituitary tumor is localized pressure on the optic nerve or chiasm. In addition, the nasopharyngeal secretions are cultured, because a sinus infection is a contraindication to an intracranial procedure using this approach. Corticosteroids may be administered before and after surgery, because the surgery involves removal of the pituitary, the source of adrenocorticotropic hormone (ACTH). Antibiotics may or may not be administered prophylactically.

Nursing Management

Deep breathing is taught before surgery. The patient is instructed that after the surgery he or she will need to avoid vigorous coughing, blowing the nose, sucking through a straw, or sneezing, because these actions may place increased pressure at the surgical site and cause a CSF leak (Hickey, 2009).

POSTOPERATIVE MANAGEMENT

Medical Management

Because the procedure disrupts the oral and nasal mucous membranes, management focuses on preventing infection and promoting healing. Medications include antimicrobial agents (which are continued until the nasal packing inserted at the time of surgery is removed), corticosteroids, analgesic agents for discomfort, and agents for the control of diabetes insipidus if necessary (Hickey, 2009).

Nursing Management

Vital signs are measured to monitor hemodynamic, cardiac, and ventilatory status. Because of the anatomic proximity of the pituitary gland to the optic chiasm, visual acuity and visual fields are assessed at regular intervals. One method is to ask the patient to count the number of fingers held up by the nurse. Evidence of decreasing visual acuity suggests an expanding hematoma.

The head of the bed is raised to decrease pressure on the sella turcica and to promote normal drainage. The patient is cautioned against blowing the nose or engaging in any activity that raises ICP, such as bending over or straining during urination or defecation.

Intake and output are measured as a guide to fluid and electrolyte replacement and to assess for diabetes insipidus. The urine specific gravity is measured after each voiding. Daily weight is monitored. Fluids are usually given after nausea ceases, and the patient then progresses to a regular diet.

The nasal packing inserted during surgery is checked frequently for blood or CSF drainage. The major discomfort is related to the nasal packing and to mouth dryness and thirst caused by mouth breathing. Oral care is provided every 4 hours or more frequently. Usually, the teeth are not brushed until the incision above the teeth has healed. Warm saline mouth rinses and the use of a cool mist vaporizer are helpful. Petrolatum is soothing when applied to the lips. A room humidifier assists in keeping the mucous membranes moist. The packing is removed in 3 to 4 days, and only then can the area around the nares be cleaned with the prescribed solution to remove crusted blood and moisten the mucous membranes (Hickey, 2009).

Home care considerations include advising the patient to use a room humidifier to keep the mucous membranes moist and to soothe irritation. The head of the bed is elevated for at least 2 weeks after surgery.

SEIZURE DISORDERS

Seizures are episodes of abnormal motor, sensory, autonomic, or psychic activity (or a combination of these) that result from sudden excessive discharge from cerebral neurons (Hickey, 2009). A part or all of the brain may be involved. The international classification of seizures differentiates between two main types: partial seizures that begin in one part of the brain, and generalized seizures that involve electrical discharges in the whole brain (Chart 61-2). In a simple partial seizure, consciousness remains intact,

whereas in a complex partial seizure, consciousness is impaired. Unclassified seizures are so termed because of incomplete data.

The underlying cause is an electrical disturbance (dysrhythmia) in the nerve cells in one section of the brain; these cells emit abnormal, recurring, uncontrolled electrical discharges. The characteristic seizure is a manifestation of this excessive neuronal discharge. Associated loss of consciousness, excess movement or loss of muscle tone or movement, and disturbances of behavior, mood, sensation, and perception may also occur.

The specific causes of seizures are varied and can be categorized as idiopathic (genetic, developmental defects) and acquired. Causes of acquired seizures include:

- Cerebrovascular disease
- Hypoxemia of any cause, including vascular insufficiency
- Fever (childhood)
- Head injury
- Hypertension
- Central nervous system infections
- Metabolic and toxic conditions (eg, renal failure, hyponatremia, hypocalcemia, hypoglycemia, pesticide exposure)
- Brain tumor
- Drug and alcohol withdrawal
- Allergies

Nursing Management

During a Seizure

A major responsibility of the nurse is to observe and record the sequence of signs. The nature of the seizure usually indicates the type of treatment that is required (AANN, 2007). Before and during a seizure, the patient is assessed and the following items are documented:

- The circumstances before the seizure (visual, auditory, or olfactory stimuli; tactile stimuli; emotional or psychological disturbances; sleep; hyperventilation) (Chart 61-3)
- The occurrence of an aura (a premonitory or warning sensation, which can be visual, auditory, or olfactory)
- The first thing the patient does in the seizure—where the movements or the stiffness begins, conjugate gaze position, and the position of the head at the beginning of the seizure. This information gives clues to the location of the seizure origin in the brain. (In recording, it is important to state whether the beginning of the seizure was observed.)
- The type of movements in the part of the body involved
- The areas of the body involved (turn back bedding to expose patient)
- The size of both pupils and whether the eyes are open
- Whether the eyes or head turned to one side
- The presence or absence of automatisms (involuntary motor activity, such as lip smacking or repeated swallowing)
- Incontinence of urine or stool
- Duration of each phase of the seizure
- Unconsciousness, if present, and its duration

Chart 61-2 • International Classification of Seizures

Partial Seizures (seizures beginning locally)

Simple Partial Seizures (with elementary symptoms, generally without impairment of consciousness)

- With motor symptoms
- With special sensory or somatosensory symptoms
- With autonomic symptoms
- Compound forms

Complex Partial Seizures (with complex symptoms, generally with impairment of consciousness)

- With impairment of consciousness only
- With cognitive symptoms
- With affective symptoms
- With psychosensory symptoms
- With psychomotor symptoms (automatisms)
- Compound forms

Partial Seizures Secondarily Generalized

Generalized Seizures (convulsive or nonconvulsive, bilaterally symmetric, without local onset)

- Tonic-clonic seizures
- Tonic seizures
- Clonic seizures
- Absence (petit mal) seizures
- Atonic seizures
- Myoclonic seizures (bilaterally massive epileptic)
- Unclassified seizures

NURSING RESEARCH PROFILE

61-3

Seizure Events During Computer-Based Assessment

Dilorio, C., Reisinger, E. L., Yeager, K., et al. (2008). A descriptive analysis of seizure events among adults who participated in a computer-based assessment. *Journal of Neuroscience Nursing, 40*(3), 134–141.

Purpose

It is known that seizures can be induced by visual stimuli such as television and video games in some people; therefore, it is important to understand how computer monitors affect people with epilepsy. This study both documented seizure events associated with a computer-based assessment and described contextual factors surrounding seizure episodes.

Design

This descriptive study was part of a larger, longitudinal study of self-management in adults with epilepsy. For this portion of the study, participants underwent three computer-based assessments at baseline, 3 months, and 6 months. Investigators collected data on demographic characteristics and seizure characteristics and used various psychosocial instruments to assess self-management practices.

Findings

A total of 14 seizure events occurred during the 896 computer-based assessments, which constituted 1.6% of the assessments and affected 4.4% of the participants. The mean age of people who experienced the seizure events was 41 years; 70% were female, and 70% were Caucasian. Contextual factors that could have precipitated seizure events included hunger, fatigue, stress, and medication changes. In two instances, participants indicated that the computer monitor could have triggered their seizure.

Nursing Implications

Although some seizures can be induced by visual stimuli, nurses working with people with epilepsy can be fairly confident that computer-based assessments pose minimal risks for inducing seizures. With increases in computer technology use in health care, these are reassuring findings for nurses and patients.

- Any obvious paralysis or weakness of arms or legs after the seizure
- Inability to speak after the seizure
- Movements at the end of the seizure
- Whether or not the patient sleeps afterward
- Cognitive status (confused or not confused) after the seizure

In addition to providing data about the seizure, nursing care is directed at preventing injury and supporting the patient, not only physically but also psychologically. Consequences such as anxiety, embarrassment, fatigue, and depression can be devastating to the patient.

After a Seizure

After a patient has a seizure, the nurse's role is to document the events leading to and occurring during and after the seizure and to prevent complications (eg, aspiration, injury). The patient is at risk for hypoxia, vomiting, and pulmonary aspiration. To prevent complications, the patient is placed in the side-lying position to facilitate drainage of oral secretions, and suctioning is performed, if needed, to maintain a patent airway and prevent aspiration (Chart 61-4). Seizure precautions are maintained, including having available functioning suction equipment with a suction catheter and oral airway. The bed is placed in a low position with two to three side rails up and padded, if necessary, to prevent injury to the patient. The patient may be drowsy and may wish to sleep after the seizure; he or she may not remember events leading up to the seizure and for a short time thereafter.

The Epilepsies

Epilepsy is a group of syndromes characterized by unprovoked, recurring seizures (AANN, 2007). Epileptic syndromes are classified by specific patterns of clinical features,

including age at onset, family history, and seizure type. Types of epilepsies are differentiated by how the seizure activity manifests (see Chart 61-3), the most common syndromes being those with generalized seizures and those with partial-onset seizures (Hickey, 2009). Epilepsy can be primary (idiopathic) or secondary (when the cause is known and the epilepsy is a symptom of another underlying condition, such as a brain tumor).

Epilepsy affects an estimated 3% of people during their lifetime, and most forms of epilepsy occur in childhood. The improved treatment of cerebrovascular disorders, head injuries, brain tumors, meningitis, and encephalitis has increased the number of patients at risk for seizures after recovery from these conditions. Also, advances in EEG have aided in the diagnosis of epilepsy. The general public has been educated about epilepsy, which has reduced the stigma associated with it; as a result, more people are willing to acknowledge that they have epilepsy.

Although some evidence suggests that susceptibility to some types of epilepsy may be inherited, the cause of seizures in many people is idiopathic (unknown). Epilepsy can follow birth trauma, asphyxia neonatorum, head injuries, some infectious diseases (bacterial, viral, parasitic), toxicity (carbon monoxide and lead poisoning), circulatory problems, fever, metabolic and nutritional disorders, or drug or alcohol intoxication. It is also associated with brain tumors, abscesses, and congenital malformations.

Pathophysiology

Messages from the body are carried by the neurons (nerve cells) of the brain by means of discharges of electrochemical energy that sweep along them. These impulses occur in bursts whenever a nerve cell has a task to perform. Sometimes, these cells or groups of cells continue firing after a task is finished. During the period of unwanted discharges,

CHART
61-4

Guidelines for Seizure Care

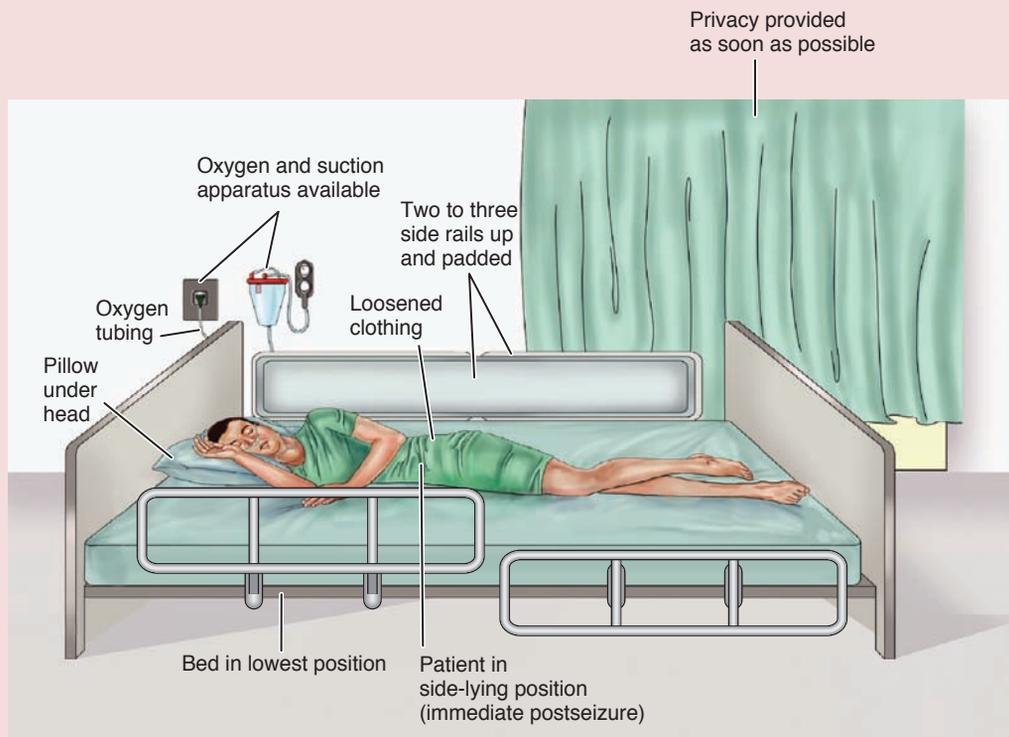

Nursing Care During a Seizure

- Provide privacy and protect the patient from curious onlookers. (The patient who has an aura [warning of an impending seizure] may have time to seek a safe, private place.)
- Ease the patient to the floor, if possible.
- Protect the head with a pad to prevent injury (from striking a hard surface).
- Loosen constrictive clothing.
- Push aside any furniture that may injure the patient during the seizure.
- If the patient is in bed, remove pillows and raise side rails.
- If an aura precedes the seizure, insert an oral airway to reduce the possibility of the patient's biting the tongue or cheek.
- *Do not attempt to pry open jaws that are clenched in a spasm or to insert anything.* Broken teeth and injury to the lips and tongue may result from such an action.
- No attempt should be made to restrain the patient during the seizure, because muscular contractions are strong and restraint can produce injury.

- If possible, place the patient on one side with head flexed forward, which allows the tongue to fall forward and facilitates drainage of saliva and mucus. If suction is available, use it if necessary to clear secretions.

Nursing Care After the Seizure

- Keep the patient on one side to prevent aspiration. Make sure the airway is patent.
- There is usually a period of confusion after a grand mal seizure.
- A short apneic period may occur during or immediately after a generalized seizure.
- The patient, on awakening, should be reoriented to the environment.
- If the patient becomes agitated after a seizure (postictal), use persuasion and gentle restraint to assist him or her to stay calm.

parts of the body controlled by the errant cells may perform erratically. Resultant dysfunction ranges from mild to incapacitating and often causes loss of consciousness (Hickey, 2009). If these uncontrolled, abnormal discharges occur repeatedly, a person is said to have an epileptic syndrome. Epilepsy is not associated with intellectual level. People who have epilepsy without other brain or nervous system disabilities fall within the same intelligence ranges as the overall population. Epilepsy is not synonymous with mental

retardation or illness. However, many people who have developmental disabilities because of serious neurologic damage also have epilepsy.

Clinical Manifestations

Depending on the location of the discharging neurons, seizures may range from a simple staring episode (absence seizure) to prolonged convulsive movements with loss of consciousness.

The initial pattern of the seizures indicates the region of the brain in which the seizure originates (see Chart 61-3). In simple partial seizures, only a finger or hand may shake, or the mouth may jerk uncontrollably. The person may talk unintelligibly; may be dizzy; and may experience unusual or unpleasant sights, sounds, odors, or tastes, but without loss of consciousness (Hickey, 2009).

In complex partial seizures, the person either remains motionless or moves automatically but inappropriately for time and place, or he or she may experience excessive emotions of fear, anger, elation, or irritability. Whatever the manifestations, the person does not remember the episode when it is over.

Generalized seizures, previously referred to as grand mal seizures, involve both hemispheres of the brain, causing both sides of the body to react (Hickey, 2009). Intense rigidity of the entire body may occur, followed by alternating muscle relaxation and contraction (generalized tonic-clonic contraction). The simultaneous contractions of the diaphragm and chest muscles may produce a characteristic epileptic cry. The tongue is often chewed, and the patient is incontinent of urine and feces. After 1 or 2 minutes, the convulsive movements begin to subside; the patient relaxes and lies in deep coma, breathing noisily. The respirations at this point are chiefly abdominal. In the postictal state (after the seizure), the patient is often confused and hard to arouse and may sleep for hours. Many patients report headache, sore muscles, fatigue, and depression (AANN, 2007).

Assessment and Diagnostic Findings

The diagnostic assessment is aimed at determining the type of seizures, their frequency and severity, and the factors that precipitate them. A developmental history is taken, including events of pregnancy and childbirth, to seek evidence of preexisting injury. The patient is also questioned about illnesses or head injuries that may have affected the brain. In addition to physical and neurologic evaluations, diagnostic examinations include biochemical, hematologic, and serologic studies. MRI is used to detect structural lesions such as focal abnormalities, cerebrovascular abnormalities, and cerebral degenerative changes (AANN, 2007).

The EEG furnishes diagnostic evidence for a substantial proportion of patients with epilepsy and assists in classifying the type of seizure (Karpoff & Labus, 2008). Abnormalities in the EEG usually continue between seizures or, if not apparent, may be elicited by hyperventilation or during sleep (Kotagal & Yardi, 2008). Microelectrodes (depth electrodes) can be inserted deep in the brain to probe the action of single brain cells. Some people with clinical seizures have normal EEGs, whereas others who have never had seizures have abnormal EEGs. Telemetry and computerized equipment are used to monitor electrical brain activity while the patient pursues his or her normal activities and to store the readings on computer tapes for analysis. Video recording of seizures taken simultaneously with EEG telemetry is useful in determining the type of seizure as well as its duration and magnitude. This type of intensive monitoring is changing the treatment of severe epilepsy (Dilorio, Reisinger, Yeager, et al., 2008).

SPECT is an additional tool that is sometimes used in the diagnostic workup. It is useful for identifying the epileptogenic zone so that the area in the brain giving rise to seizures can be removed surgically (AANN, 2007).

Epilepsy in Women

More than 1 million American women have epilepsy, and they face particular needs associated with the syndrome. Women with epilepsy often note an increase in seizure frequency during menses; this has been linked to the increase in sex hormones that alter the excitability of neurons in the cerebral cortex. The effectiveness of contraceptives is decreased by antiseizure medications. Therefore, patients should be encouraged to discuss family planning with their primary health care provider and to obtain preconception counseling if they are considering childbearing (Meador, Pennell, Harden, et al., 2008).

Women of childbearing age who have epilepsy require special care and guidance before, during, and after pregnancy. Many women note a change in the pattern of seizure activity during pregnancy. The risk of congenital fetal anomaly is two to three times higher in women with epilepsy. Maternal seizures, antiseizure medications, and genetic predisposition all contribute to possible malformations. Women who take certain antiseizure medications for epilepsy are at risk and need careful monitoring, including blood studies to detect the level of antiseizure medications taken throughout pregnancy. High-risk mothers (teenagers, women with histories of difficult deliveries, women who use illicit drugs [eg, crack, cocaine], and women with diabetes or hypertension) should be identified and monitored closely during pregnancy, because damage to the fetus during pregnancy and delivery can increase the risk of epilepsy. All of these issues need further study (Meador, et al., 2008).

Because of bone loss associated with the long-term use of antiseizure medications, patients receiving antiseizure agents should be assessed for low bone mass and osteoporosis. They should be instructed about strategies to reduce their risks of osteoporosis (AANN, 2007).

Gerontologic Considerations

Elderly people have a high incidence of new-onset epilepsy (Hickey, 2009). Cerebrovascular disease is the leading cause of seizures in the elderly. The increased incidence is also associated with stroke, head injury, dementia, infection, alcoholism, and aging. Treatment depends on the underlying cause. Because many elderly people have chronic health problems, they may be taking other medications that can interact with medications prescribed for seizure control. In addition, the absorption, distribution, metabolism, and excretion of medications are altered in the elderly as a result of age-related changes in renal and liver function. Therefore, elderly patients must be monitored closely for adverse and toxic effects of antiseizure medications and for osteoporosis. The cost of antiseizure medications can lead to poor adherence to the prescribed regimen in elderly patients on fixed incomes.

Prevention

Society-wide efforts are the key to prevention of epilepsy. Head injury is one of the main causes of epilepsy that can be prevented. Through highway safety programs and occupational safety precautions, lives can be saved and epilepsy due to head injury prevented; these programs are discussed in Chapter 63.

Medical Management

The management of epilepsy is individualized to meet the needs of each patient and not just to manage and prevent seizures. Management differs from patient to patient, because some forms of epilepsy arise from brain damage and others result from altered brain chemistry.

Pharmacologic Therapy

Many medications are available to control seizures, although the exact mechanisms of action are unknown. The objective is to achieve seizure control with minimal side effects. Medication therapy controls rather than cures seizures. Medications are selected on the basis of the type of seizure being treated and the effectiveness and safety of the medications. If properly prescribed and taken, medications control seizures in 70% to 80% of patients with seizures. However, 20% of patients with generalized seizures and 30% of those with partial seizures do not demonstrate improvement with any prescribed medication or may be unable to tolerate the side effects of medications (AANN, 2007). Table 61-4 lists the medications in current use.

NURSING ALERT

Nurses must take care when administering lamotrigine (Lamictal), an antiseizure medication. The drug packaging was recently changed in an attempt to reduce medication errors, because this medication has been confused with terbinafine (Lamisil), labetalol hydrochloride (Trandate), lamivudine (Epivir), maprotiline (Ludiomil), and the combination of diphenoxylate and atropine (Lomotil). Patients with epilepsy are at risk for status epilepticus from having their medication regimen interrupted.

Treatment usually starts with a single medication. The starting dose and the rate at which the dosage is increased depend on the occurrence of side effects. The medication levels in the blood are monitored, because the rate of drug absorption varies among patients. Changing to another medication may be necessary if seizure control is not achieved or if toxicity makes it impossible to increase the dosage. The medication may need to be adjusted because of concurrent illness, weight changes, or increases in stress. Side effects of antiseizure medications may be divided into three groups: (1) idiosyncratic or allergic disorders, which manifest primarily as skin reactions; (2) acute toxicity, which may occur when the medication is initially prescribed; and (3) chronic toxicity, which occurs late in the course of therapy.

The manifestations of drug toxicity are variable, and any organ system may be involved. Gingival hyperplasia

Table 61-4 MAJOR ANTISEIZURE MEDICATIONS

Medication	Dose-Related Side Effects	Toxic Effects
carbamazepine (Tegretol)	Dizziness, drowsiness, unsteadiness, nausea and vomiting, diplopia, mild leukopenia	Severe skin rash, blood dyscrasias, hepatitis
clonazepam (Klonopin)	Drowsiness, behavior changes, headache, hirsutism, alopecia, palpitations	Hepatotoxicity, thrombocytopenia, bone marrow failure, ataxia
ethosuximide (Zarontin)	Nausea and vomiting, headache, gastric distress	Skin rash, blood dyscrasias, hepatitis, systemic lupus erythematosus
felbamate (Felbatol)	Cognitive impairments, insomnia, nausea, headache, fatigue	Aplastic anemia, hepatotoxicity
gabapentin (Neurotonin)	Dizziness, drowsiness, somnolence, fatigue, ataxia, weight gain, nausea	Leukopenia, hepatotoxicity
lamotrigine (Lamictal)	Drowsiness, tremor, nausea, ataxia, dizziness, headache, weight gain	Severe rash (Stevens-Johnson syndrome)
levetiracetam (Keppra)	Somnolence, dizziness, fatigue	Unknown
oxcarbazepine (Trileptal)	Dizziness, somnolence, double vision, fatigue, nausea, vomiting, loss of coordination, abnormal vision, abdominal pain, tremor, abnormal gait	Hepatotoxicity
phenobarbital (Luminal)	Sedation, irritability, diplopia, ataxia	Skin rash, anemia
phenytoin (Dilantin)	Visual problems, hirsutism, gingival hyperplasia, dysrhythmias, dysarthria, nystagmus	Severe skin reaction, peripheral neuropathy, ataxia, drowsiness, blood dyscrasias
primidone (Mysoline)	Lethargy, irritability, diplopia, ataxia, impotence	Skin rash
tiagabine (Gabitril)	Dizziness, fatigue, nervousness, tremor, difficulty concentrating, dysarthria, weak or buckling knees, abdominal pain	Unknown
topiramate (Topamax)	Fatigue, somnolence, confusion, ataxia, anorexia, depression, weight loss	Nephrolithiasis
valproate (Depakote, Depakene)	Nausea and vomiting, weight gain, hair loss, tremor, menstrual irregularities	Hepatotoxicity, skin rash, blood dyscrasias, nephritis
zonisamide (Zonegran, Excegran)	Somnolence, dizziness, anorexia, headache, nausea, agitation, rash	Leukopenia, hepatotoxicity

(swollen and tender gums) can be associated with long-term use of phenytoin (Dilantin), for example (Karch, 2008). Periodic physical and dental examinations and laboratory tests are performed for patients receiving medications that are known to have hematopoietic, genitourinary, or hepatic effects.

Surgical Management

Surgery is indicated for patients whose epilepsy results from intracranial tumors, abscesses, cysts, or vascular anomalies. Some patients have intractable seizure disorders that do not respond to medication. A focal atrophic process may occur secondary to trauma, inflammation, stroke, or anoxia. If the seizures originate in a reasonably well-circumscribed area of the brain that can be excised without producing significant neurologic deficits, the removal of the area generating the seizures may produce long-term control and improvement (AANN, 2007).

This type of neurosurgery has been aided by several advances, including microsurgical techniques, EEGs with depth electrodes, improved illumination and hemostasis, and the introduction of neuroleptanalgesic agents (droperidol and fentanyl). These techniques, combined with use of local anesthetic agents, enable the neurosurgeon to perform surgery on an alert and cooperative patient. Using special testing devices, electrocortical mapping, and the patient's responses to stimulation, the boundaries of the epileptogenic focus (ie, abnormal area of the brain) are determined. Any abnormal epileptogenic focus is then excised (AANN, 2007). Resection surgery significantly reduces the incidence of seizures in patients with refractory epilepsy.

When seizures are refractory to medication in adolescents and adults with partial seizures, a generator may be implanted under the clavicle. The device is connected to the vagus nerve in the cervical area, where it delivers electrical signals to the brain to control and reduce seizure activity (AANN, 2007). An external programming system is used by the physician to change stimulator settings. Patients can turn the stimulator on and off with a magnet (Krapohl, Deutinger & Komurcu, 2007).

More research is needed to determine the effects of the various surgical approaches on complication rates, quality of life, anxiety, and depression, all of which are issues for patients with epilepsy.

The effects of epilepsy on the patient's lifestyle are assessed (AANN, 2007). What limitations are imposed by the seizure disorder? Does the patient participate in any recreational activities? Have any social contacts? Is the patient working, and is it a positive or stressful experience? What coping mechanisms are used?

Diagnosis

Nursing Diagnoses

Based on the assessment data, the patient's major nursing diagnoses may include the following:

- Risk for injury related to seizure activity
- Fear related to the possibility of seizures
- Ineffective individual coping related to stresses imposed by epilepsy
- Deficient knowledge related to epilepsy and its control

Collaborative Problems/Potential Complications

The major potential complications for patients with epilepsy are status epilepticus and medication side effects (toxicity).

Planning and Goals

The major goals for the patient may include prevention of injury, control of seizures, achievement of a satisfactory psychosocial adjustment, acquisition of knowledge and understanding about the condition, and absence of complications.

Nursing Interventions

Preventing Injury

Injury prevention for the patient with seizures is a priority. Patients for whom seizure precautions are instituted should have pads applied to the side rails while in bed. Steps to prevent or minimize injury are presented in Chart 61-4.

Reducing Fear of Seizures

Fear that a seizure may occur unexpectedly can be reduced by the patient's adherence to the prescribed treatment regimen. Cooperation of the patient and family and their trust in the prescribed regimen are essential for control of seizures. The nurse emphasizes that the prescribed anti-seizure medication must be taken on a continuing basis and that drug dependence or addiction does not occur. Periodic monitoring is necessary to ensure the adequacy of the treatment regimen, to prevent side effects, and to monitor for drug resistance (Hickey, 2009).

In an effort to control seizures, factors that may precipitate them are identified, such as emotional disturbances, new environmental stressors, onset of menstruation in female patients, or fever (AANN, 2007). The patient is encouraged to follow a regular and moderate routine in lifestyle, diet (avoiding excessive stimulants), exercise, and rest (sleep deprivation may lower the seizure threshold). Moderate activity is therapeutic, but excessive exercise should be avoided. An additional dietary intervention, referred to as the ketogenic diet, may be helpful for control of seizures in some patients. This high-protein, low-carbohydrate, high-fat diet is most effective in children whose seizures have not been controlled with two

NURSING PROCESS

THE PATIENT WITH EPILEPSY

Assessment

The nurse elicits information about the patient's seizure history. The patient is asked about the factors or events that may precipitate the seizures. Alcohol intake is documented. The nurse determines whether the patient has an aura before an epileptic seizure, which may indicate the origin of the seizure (eg, seeing a flashing light may indicate that the seizure originated in the occipital lobe). Observation and assessment during and after a seizure assist in identifying the type of seizure and its management.

antiepileptic medications, but it is sometimes used for adults who have had poor seizure control (Yudkoff, Daikhin, Melo, et al., 2007).

Photic stimulation (eg, bright flickering lights, television viewing) may precipitate seizures; wearing dark glasses or covering one eye may be preventive. Tension states (anxiety, frustration) induce seizures in some patients. Classes in stress management may be of value. Because seizures are known to occur with alcohol intake, alcoholic beverages should be avoided.

Improving Coping Mechanisms

The social, psychological, and behavioral problems that frequently accompany epilepsy can be more of a disability than the actual seizures. Epilepsy may be accompanied by feelings of stigmatization, alienation, depression, and uncertainty. The patient must cope with the constant fear of a seizure and the psychological consequences (AANN, 2007). Children with epilepsy may be ostracized and excluded from school and peer activities. These problems are compounded during adolescence and add to the challenges of dating, not being able to drive, and feeling different from other people. Adults face these problems in addition to the burden of finding employment, concerns about relationships and childbearing, insurance problems, and legal barriers. Alcohol abuse may complicate matters. Family reactions may vary from outright rejection of the person with epilepsy to overprotection.

Counseling assists the patient and family to understand the condition and the limitations it imposes. Social and recreational opportunities are necessary for good mental health. Nurses can improve the quality of life for patients with epilepsy by teaching them and their families about symptoms and their management (AANN, 2007) (see Chart 61-3).

Providing Patient and Family Education

Perhaps the most valuable facets of care contributed by the nurse to the person with epilepsy are education and efforts to modify the attitudes of the patient and family toward the disorder. The person who experiences seizures may consider every seizure a potential source of humiliation and shame. This may result in anxiety, depression, hostility, and secrecy on the part of the patient and family. Ongoing education and encouragement should be given to patients to enable them to overcome these reactions. The patient with epilepsy should carry an emergency medical identification card or wear a medical information bracelet. The patient and family need to be educated about medications as well as care during a seizure.

Monitoring and Managing Potential Complications

Status epilepticus, the major complication, is described later in this chapter. Another complication is the toxicity of medications. The patient and family are instructed about side effects and are given specific guidelines to assess and report signs and symptoms that indicate medication overdose. Antiseizure medications require careful monitoring for therapeutic levels. The patient should plan to have serum drug levels assessed at regular intervals. Many known drug interactions occur with antiseizure medications. A complete

pharmacologic profile should be reviewed with the patient to avoid interactions that either potentiate or inhibit the effectiveness of the medications.

Promoting Home and Community-Based Care

TEACHING PATIENTS SELF-CARE. Thorough oral hygiene after each meal, gum massage, daily flossing, and regular dental care are essential to prevent or control gingival hyperplasia in patients receiving phenytoin (Dilantin). The patient is also instructed to inform all health care providers of the medication being taken, because of the possibility of drug interactions. An individualized comprehensive teaching plan is needed to assist the patient and family to adjust to this chronic disorder. Written patient education materials must be appropriate for the patient's reading level and must be provided in alternative formats if warranted. See Chart 61-5 for home care instruction points.

CONTINUING CARE. Because epilepsy is a long-term disorder, the use of costly medications can create a significant financial burden. The Epilepsy Foundation of America (EFA) offers a mail-order program to provide medications at minimal cost and access to life insurance. This organization also serves as a referral source for special services for people with epilepsy.

For many, overcoming employment problems is a challenge. State vocational rehabilitation agencies can provide information about job training. The EFA has a training and placement service. If seizures are not well controlled, information about sheltered workshops or home employment programs may be obtained. Federal and state agencies and federal legislation may be of assistance to people with epilepsy who experience job discrimination. As a result of the Americans with Disabilities Act, the number of employers who knowingly hire people with epilepsy is increasing, but barriers to employment still exist.

People who have uncontrollable seizures accompanied by psychological and social difficulties can be referred to comprehensive epilepsy centers where continuous audio-video and EEG monitoring, specialized treatment, and rehabilitation services are available (AANN, 2007). Patients and their families need to be reminded of the importance of following the prescribed treatment regimen and of keeping follow-up appointments. In addition, they are reminded of the importance of participating in health promotion activities and recommended health screenings to promote a healthy lifestyle. Genetic and preconception counseling is advised.

Evaluation

Expected Patient Outcomes

Expected patient outcomes may include the following:

1. Sustains no injury during seizure activity
 - a. Complies with treatment regimen and identifies the hazards of stopping the medication
 - b. Can identify appropriate care during seizure; caregivers can also do so
2. Indicates a decrease in fear
3. Displays effective individual coping
4. Exhibits knowledge and understanding of epilepsy
 - a. Identifies the side effects of medications

CHART
61-5

HOME CARE CHECKLIST

The Patient With Epilepsy

At the completion of the home instruction, the patient and caregiver will be able to:	PATIENT	CAREGIVER
• Take medications daily as prescribed to keep the drug level constant to prevent seizures. The patient should never discontinue medications, even if there is no seizure activity.	✓	
• Keep a medication and seizure chart, noting when medications are taken and any seizure activity.	✓	✓
• Notify the patient's physician if patient cannot take medications due to illness.	✓	✓
• Have antiseizure medication serum levels checked regularly. When testing is prescribed, the patient should report to the laboratory for blood sampling before taking morning medication.	✓	
• Avoid activities that require alertness and coordination (driving, operating machinery) until after the effects of the medication have been evaluated.	✓	
• Report signs of toxicity so dosage can be adjusted. Common signs include drowsiness, lethargy, dizziness, difficulty walking, hyperactivity, confusion, inappropriate sleep, and visual disturbances.	✓	✓
• Avoid over-the-counter medications unless approved by the patient's physician.	✓	
• Carry a medical alert bracelet or identification card specifying the name of the patient's antiseizure medication and physician.	✓	
• Avoid seizure triggers, such as alcoholic beverages, electrical shocks, stress, caffeine, constipation, fever, hyperventilation, and hypoglycemia.	✓	
• Take showers rather than tub baths to avoid drowning if seizure occurs; never swim alone.	✓	
• Exercise in moderation in a temperature-controlled environment to avoid excessive heat.	✓	
• Develop regular sleep patterns to minimize fatigue and insomnia.	✓	✓
• Use the Epilepsy Foundation of America's special services, including help in obtaining medications, vocational rehabilitation, and coping with epilepsy.	✓	✓

- b. Avoids factors or situations that may precipitate seizures (eg, flickering lights, hyperventilation, alcohol)
 - c. Follows a healthy lifestyle by getting adequate sleep and eating meals at regular times to avoid hypoglycemia
5. Absence of complications

Status Epilepticus

Status epilepticus (acute prolonged seizure activity) is a series of generalized seizures that occur without full recovery of consciousness between attacks (Tocco, 2007). The term has been broadened to include continuous clinical or electrical seizures (on EEG) lasting at least 30 minutes, even without impairment of consciousness. It is considered a medical emergency. Status epilepticus produces cumulative effects. Vigorous muscular contractions impose a heavy metabolic demand and can interfere with respirations. Some respiratory arrest at the height of each seizure produces venous congestion and hypoxia of the brain. Repeated episodes of cerebral anoxia and edema may lead to irreversible and fatal brain damage. Factors that precipitate status epilepticus include withdrawal of antiseizure medication, fever, and concurrent infection.

Medical Management

The goals of treatment are to stop the seizures as quickly as possible, to ensure adequate cerebral oxygenation, and to maintain the patient in a seizure-free state. An airway and adequate oxygenation are established. If the patient remains unconscious and unresponsive, a cuffed endotracheal tube is inserted. IV diazepam (Valium), lorazepam (Ativan), or fosphenytoin (Cerebyx) is administered slowly in an attempt to halt seizures immediately. Other medications (phenytoin, phenobarbital) are administered later to maintain a seizure-free state.

An IV line is established, and blood samples are obtained to monitor serum electrolytes, glucose, and phenytoin levels. EEG monitoring may be useful in determining the nature of the seizure activity. Vital signs and neurologic signs are monitored on a continuing basis. An IV infusion of dextrose is administered if the seizure is caused by hypoglycemia. If initial treatment is unsuccessful, general anesthesia with a short-acting barbiturate may be used. The serum concentration of the antiseizure medication is measured, because a low level suggests that the patient was not taking the medication or that the dosage was too low. Cardiac involvement or respiratory depression may be life-threatening. The potential for postictal cerebral edema also exists.

Nursing Management

The nurse initiates ongoing assessment and monitoring of respiratory and cardiac function because of the risk for delayed depression of respiration and blood pressure secondary

to administration of antiseizure medications and sedatives to halt the seizures. Nursing assessment also includes monitoring and documenting the seizure activity and the patient's responsiveness.

The patient is turned to a side-lying position, if possible, to assist in draining pharyngeal secretions. Suction equipment must be available because of the risk of aspiration. The IV line is closely monitored, because it may become dislodged during seizures.

A person who has received long-term antiseizure therapy has a significant risk for fractures resulting from bone disease (osteoporosis, osteomalacia, and hyperparathyroidism), a side effect of therapy. Therefore, during seizures, the patient is protected from injury with the use of seizure precautions and is monitored closely. The patient having seizures can inadvertently injure nearby people, so nurses should protect themselves. Additional nursing interventions for the person having seizures are presented in Chart 61-4.

HEADACHE

Headache, or cephalgia, is one of the most common of all human physical complaints. Headache is a symptom rather than a disease entity; it may indicate organic disease (neurologic or other disease), a stress response, vasodilation (migraine), skeletal muscle tension (tension headache), or a combination of factors. A **primary headache** is one for which no organic cause can be identified. These types of headache include migraine, tension-type, and cluster headaches (Hickey, 2009). Cranial arteritis is another common cause of headache. A classification of headaches was issued first by the Headache Classification Committee of the International Headache Society in 1988. The International Headache Society revised the headache classification in 2004; an abbreviated list is shown in Chart 61-6.

Chart 61-6 • International Headache Society Classification of Headache

1. Migraine
2. Tension-type headache
3. Cluster headache and other trigeminal-autonomic cephalgias
4. Other primary headaches
5. Headache attributed to head and/or neck trauma
6. Headache attributed to cranial or cervical vascular disorder
7. Headache attributed to nonvascular intracranial disorder
8. Headache attributed to a substance or its withdrawal
9. Headache attributed to infection
10. Headache attributed to disorder of homeostasis
11. Headache or facial pain attributed to disorder of cranium, neck, eyes, ears, nose, sinuses, teeth, mouth, or other facial or cranial structures
12. Headache attributed to psychiatric disorder
13. Cranial neuralgias and central causes of facial pain
14. Other headache

From Headache Classification Subcommittee of the International Headache Society. (2004). International classification of headache disorders (2nd ed.). *Cephalgia*, 24(Suppl 1), 1–150.

Migraine is a complex of symptoms characterized by periodic and recurrent attacks of severe headache lasting from 4 to 72 hours in adults. The cause of migraine has not been clearly demonstrated, but it is primarily a vascular disturbance that occurs more commonly in women and has a strong familial tendency. The typical time of onset is at puberty, and the incidence is 18% in women and 6% in men (Lipton, Bigal, Diamond, et al., 2007).

There are six subtypes of **migraine headache**, including migraine with and without aura. Most patients have migraine without an aura. *Tension-type headaches* tend to be chronic and less severe and are probably the most common type of headache. *Cluster headaches* are a severe form of vascular headache. They are seen five times more frequently in men than in women. Types of headaches not subsumed under these categories fall into the *Other Primary Headache* group and include headaches triggered by cough, exertion, and sexual activity.

Cranial arteritis is a cause of headache in the older population, reaching its greatest incidence in those older than 70 years of age. Inflammation of the cranial arteries is characterized by a severe headache localized in the region of the temporal arteries. The inflammation may be generalized (in which case cranial arteritis is part of a vascular disease) or focal (in which case only the cranial arteries are involved).

A **secondary headache** is a symptom associated with an organic cause, such as a brain tumor or an aneurysm. Although most headaches do not indicate serious disease, persistent headaches require further investigation. Serious disorders related to headache include brain tumors, subarachnoid hemorrhage, stroke, severe hypertension, meningitis, and head injuries.

Pathophysiology

The cerebral signs and symptoms of *migraine* result from dysfunction of the brain stem pathways that normally modulate sensory input. Abnormal metabolism of serotonin, a vasoactive neurotransmitter found in platelets and cells of the brain, plays a major role. The headache is preceded by a rise in plasma serotonin, which dilates the cerebral vessels, but migraines are more than just vascular headaches. The exact mechanism of pain in migraine is poorly understood but is thought to be related to the cranial blood vessels, the innervation of the vessels, and the reflex connections in the brain stem (Porth & Matfin, 2009).

Migraines can be triggered by menstrual cycles, bright lights, stress, depression, sleep deprivation, fatigue, overuse of certain medications, and certain foods containing tyramine, monosodium glutamate, nitrites, or milk products. Food triggers also include aged cheese and many processed foods. Use of oral contraceptives may be associated with increased frequency and severity of attacks in some women (Kelman, 2007).

Emotional or physical stress may cause contraction of the muscles in the neck and scalp, resulting in *tension* headache. The pathophysiology of *cluster* headache is not fully understood. One theory is that it is caused by dilation of orbital and nearby extracranial arteries. *Cranial arteritis* is thought to represent an immune vasculitis in which immune complexes are deposited within the walls of affected blood vessels,

producing vascular injury and inflammation. A biopsy may be performed on the involved artery to make the diagnosis.

Clinical Manifestations

Migraine

The migraine with aura can be divided into four phases: prodrome, aura, the headache, and recovery (headache termination and postdrome).

Prodrome Phase

The prodrome phase is experienced by 60% of patients, with symptoms that occur hours to days before a migraine headache. Symptoms may include depression, irritability, feeling cold, food cravings, anorexia, change in activity level, increased urination, diarrhea, or constipation. Patients usually experience the same prodrome with each migraine headache.

Aura Phase

Aura occurs in a minority of patients who experience migraines (Cutrer & Heurter, 2007). The aura usually lasts less than 1 hour and may provide enough time for the patient to take the prescribed medication to avert an attack (see later discussion). This period is characterized by focal neurologic symptoms. Visual disturbances (ie, light flashes and bright spots) are most common and may be hemianopic (affecting only half of the visual field). Other symptoms that may follow include numbness and tingling of the lips, face, or hands; mild confusion; slight weakness of an extremity; drowsiness; and dizziness.

This period of aura corresponds to the phenomenon of cortical spreading depression that is associated with reduced metabolic demand in abnormally functioning neurons. This is associated with decreased blood flow that is the initial physiologic change characteristic of classic migraine (Cutrer & Heurter, 2007). Cerebral blood flow studies performed during migraine headaches demonstrate that during all phases of migraine, cerebral blood flow is reduced throughout the brain, with subsequent loss of autoregulation and impaired carbon dioxide responsiveness.

Headache Phase

As vasodilation and a decline in serotonin levels occur, a throbbing headache (unilateral in 60% of patients) intensifies over several hours. This headache is severe and incapacitating and is often associated with photophobia, nausea, and vomiting. Its duration varies, ranging from 4 to 72 hours (Hickey, 2009).

Recovery Phase

In the recovery phase (termination and postdrome), the pain gradually subsides. Muscle contraction in the neck and scalp is common, with associated muscle ache and localized tenderness, exhaustion, and mood changes. Any physical exertion exacerbates the headache pain. During this post-headache phase, patients may sleep for extended periods.

Other Headache Types

The *tension-type headache* is characterized by a steady, constant feeling of pressure that usually begins in the forehead, temple, or back of the neck. It is often bandlike or may be described as “a weight on top of my head.”

Cluster headaches are unilateral and come in clusters of one to eight daily, with excruciating pain localized to the eye and orbit and radiating to the facial and temporal regions. The pain is accompanied by watering of the eye and nasal congestion. Each attack lasts 15 minutes to 3 hours and may have a crescendo–decrescendo pattern (Hickey, 2009). The headache is often described as penetrating.

Cranial arteritis often begins with general manifestations, such as fatigue, malaise, weight loss, and fever. Clinical manifestations associated with inflammation (heat, redness, swelling, tenderness, or pain over the involved artery) usually are present. Sometimes a tender, swollen, or nodular temporal artery is visible. Visual problems are caused by ischemia of the involved structures.

Assessment and Diagnostic Findings

The diagnostic evaluation includes a detailed history, a physical assessment of the head and neck, and a complete neurologic examination. Headaches may manifest differently in the same person over the course of a lifetime, and the same type of headache may manifest differently from patient to patient. The health history focuses on assessing the headache itself, with emphasis on the factors that precipitate or provoke it. The patient is asked to describe the headache in his or her own words.

Because headache is often the presenting symptom of various physiologic and psychological disturbances, a general health history is an essential component of the patient database. Headache may be a symptom of endocrine, hematologic, gastrointestinal, infectious, renal, cardiovascular, or psychiatric disease. Therefore, questions addressed in the health history should cover major medical and surgical illness as well as a body systems review.

The medication history can provide insight into the patient's overall health status and indicate medications that may be provoking headaches. Antihypertensive agents, diuretic medications, anti-inflammatory agents, and monoamine oxidase (MAO) inhibitors are a few of the categories of medications that can provoke headaches. Emotional factors can play a role in precipitating headaches. Stress is thought to be a major initiating factor in migraine headaches; therefore, sleep patterns, level of stress, recreational interests, appetite, emotional problems, and family stressors are relevant. There is a strong familial tendency for headache disorders, and a positive family history may help in making a diagnosis.

A direct relationship may exist between exposure to toxic substances and headache. Careful questioning may uncover chemicals to which a worker has been exposed. Under the Right to Know law, employees have access to the material safety data sheets (commonly referred to as MSDSs) for all the substances with which they come in contact in the workplace. The occupational history also includes assessment of the workplace as a possible source of stress and for a possible ergonomic basis of muscle strain and headache.

A complete description of the headache itself is crucial. The nurse reviews the age at onset of headache; the headache's frequency, location, and duration; the type of pain; factors that relieve and precipitate the event; and associated symptoms. The data obtained should include the

patient's own words about the headache in response to the following questions:

- What is the location? Is it unilateral or bilateral? Does it radiate?
- What is the quality—dull, aching, steady, boring, burning, intermittent, continuous, paroxysmal?
- How many headaches occur during a given period of time?
- What are the precipitating factors, if any—environmental (eg, sunlight, weather change), foods, exertion, other?
- What makes the headache worse (eg, coughing, straining)?
- What time (day or night) does it occur?
- How long does a typical headache last?
- Are there any associated symptoms, such as facial pain, lacrimation (excessive tearing), or scotomas (blind spots in the field of vision)?
- What usually relieves the headache (aspirin, nonsteroidal anti-inflammatory drugs, ergot preparation, food, heat, rest, neck massage)?
- Does nausea, vomiting, weakness, or numbness in the extremities accompany the headache?
- Does the headache interfere with daily activities?
- Do you have any allergies?
- Do you have insomnia, poor appetite, loss of energy?
- Is there a family history of headache?
- What is the relationship of the headache to your lifestyle or physical or emotional stress?
- What medications are you taking?

Diagnostic testing often is not helpful in the investigation of headache, because often there are few objective findings. In patients who demonstrate abnormalities on the neurologic examination, CT, cerebral angiography, or MRI may be used to detect underlying causes, such as tumor or aneurysm. Electromyography (EMG) may reveal a sustained contraction of the neck, scalp, or facial muscles. Laboratory tests may include complete blood count, erythrocyte sedimentation rate, electrolytes, glucose, creatinine, and thyroid hormone levels.

Prevention

Prevention begins by having the patient avoid specific triggers that are known to initiate the headache syndrome. Preventive medical management of migraine involves the daily use of one or more agents that are thought to block the physiologic events leading to an attack. Treatment regimens vary greatly, as do patient responses; therefore, close monitoring is indicated.

Several widely used medications for the prevention of migraine are available. Two beta-blocking agents, propranolol (Inderal) and metoprolol (Lopressor), inhibit the action of beta-receptors—cells in the heart and brain that control the dilation of blood vessels. This is thought to be a major reason for their antimigraine action. Other medications that are prescribed for migraine prevention include amitriptyline hydrochloride (Elavil), divalproex (Valproate), flunarizine (Sibelium), and serotonin antagonists (Pizotyline) (Bigal & Lipton, 2007).

Calcium antagonists (eg, verapamil) are widely used but may require several weeks at a therapeutic dosage before im-

provement is noted. Calcium channel blockers are not as effective as beta-blockers for prevention but may be more appropriate for some patients, such as those with bradycardia, diabetes mellitus, or asthma (Bigal & Lipton, 2007).

Researchers are evaluating several antiseizure medications for migraine prevention. Topiramate (Topamax), the most extensively studied preventive agent, has been shown to be effective. Started at a low dose, topiramate is titrated to 100 to 200 mg/day in divided doses (Bigal & Lipton, 2007). Other research suggests that the use of topiramate and gabapentin (Neurontin), another antiseizure medication, for migraine prevention may impair cognitive ability (Salinsky, Strorzbach, Spencer, et al., 2005).

Alcohol, nitrites, vasodilators, and histamines may precipitate cluster headaches. Elimination of these factors helps prevent the headaches. Other prophylactic medication therapy may include antiseizure medications, ergotamine tartrate (occasionally), lithium, naproxen (Naprosyn), and methysergide (Sansert) (Bigal & Lipton, 2007).

Medical Management

Therapy for migraine headache is divided into abortive (symptomatic) and preventive approaches. The abortive approach, best used in those patients who have less frequent attacks, is aimed at relieving or limiting a headache at the onset or while it is in progress. The preventive approach is used in patients who experience more frequent attacks at regular or predictable intervals and may have a medical condition that precludes the use of abortive therapies (Hickey, 2009).

The triptans, serotonin receptor agonists, are the most specific antimigraine agents available. These agents cause vasoconstriction, reduce inflammation, and may reduce pain transmission. The five triptans in routine clinical use include sumatriptan (Imitrex), naratriptan (Amerge), rizatriptan (Maxalt), zolmitriptan (Zomig), and almotriptan (Axert) (Mett & Tfelt-Hansen, 2008). Numerous serotonin receptor agonists are under study. Many of the triptan medications are available in a variety of formulations, such as nasal sprays, inhalers, suppositories, or injections. The nasal sprays are useful for patients experiencing nausea and vomiting (Hickey, 2009).

The most widely used triptan is sumatriptan succinate (Imitrex) and is effective for the treatment of acute migraine and cluster headaches in adults (Bigal & Lipton, 2007). The subcutaneous form usually relieves symptoms within 1 hour and is available in an autoinjector for immediate patient use, although this form is expensive. Sumatriptan has been found to be effective in relieving moderate to severe migraine headaches in a large number of adult patients. Sumatriptan can cause chest pain and is contraindicated in patients with ischemic heart disease. Careful administration and dosing instructions to patients are important to prevent adverse reactions such as increased blood pressure, drowsiness, muscle pain, sweating, and anxiety. Interactions are possible if the medication is taken in conjunction with St. John's wort (Karch, 2008).

Ergotamine preparations (taken orally, sublingually, subcutaneously, intramuscularly, by rectum, or by inhalation) may be effective in aborting the headache if taken early in the migraine process. They are low in cost. Ergotamine

tartrate acts on smooth muscle, causing prolonged constriction of the cranial blood vessels. Each patient's dosage is based on individual needs. Side effects include aching muscles, paresthesias (numbness and tingling), nausea, and vomiting. Cafergot, a combination of ergotamine and caffeine, can arrest or reduce the severity of the headache if it is taken at the first sign of an attack (Karch, 2008). None of the triptan medications should be taken concurrently with medications containing ergotamine, because of the potential for a prolonged vasoactive reaction (Karch, 2008).

The medical management of an acute attack of cluster headaches may include 100% oxygen by face mask for 15 minutes, ergotamine tartrate, sumatriptan, corticosteroids, or a percutaneous sphenopalatine ganglion blockade (Hickey, 2009).

The medical management of cranial arteritis consists of early administration of a corticosteroid to prevent the possibility of loss of vision due to vascular occlusion or rupture of the involved artery. The patient is instructed not to stop the medication abruptly, because this can lead to relapse. Analgesic agents are prescribed for comfort.

Nursing Management

When migraine or the other types of headaches have been diagnosed, the goal of nursing management is to enhance pain relief. It is reasonable to try nonpharmacologic interventions first, but the use of medications should not be delayed. The goal is to treat the acute event of the headache and to prevent recurrent episodes. Prevention involves patient education regarding precipitating factors, possible lifestyle or habit changes that may be helpful, and pharmacologic measures.

Relieving Pain

Individualized treatment depends on the type of headache and differs for migraine, cluster headaches, cranial arteritis, and tension headache. Nursing care is directed toward treat-

ment of the acute episode. A migraine or a cluster headache in the early phase requires abortive medication therapy instituted as soon as possible. Some headaches can be prevented if the appropriate medications are taken before the onset of pain. Nursing care during an attack includes comfort measures such as a quiet, dark environment; elevation of the head of the bed to 30 degrees; and symptomatic treatment (ie, administration of antiemetic medication) (Hickey, 2009).

Symptomatic pain relief for tension headache may be obtained by application of local heat or massage. Additional strategies may include administration of analgesic agents, antidepressant medications, and muscle relaxants.

Promoting Home and Community-Based Care

Teaching Patients Self-Care

Headaches, especially migraines, are more likely to occur when the patient is ill, overly tired, or stressed. Nonpharmacologic therapies are important and include patient education about the type of headache, its mechanism (if known), and appropriate changes in lifestyle to avoid triggers. Regular sleep, meals, exercise, relaxation, and avoidance of dietary triggers may be helpful in avoiding headaches (Hickey, 2009).

The patient with tension headaches needs teaching and reassurance that the headache is not the result of a brain tumor; this is a common unspoken fear. Stress reduction techniques, such as biofeedback, exercise programs, and meditation, are examples of nonpharmacologic therapies that may prove helpful. The patient and family need to be reminded of the importance of following the prescribed treatment regimen for headache and keeping follow-up appointments. In addition, the patient is reminded of the importance of participating in health promotion activities and recommended health screenings to promote a healthy lifestyle. Chart 61-7 presents a home care checklist for the patient with migraine headaches.

CHART 61-7 HOME CARE CHECKLIST The Patient With Migraine Headaches

At the completion of the home instruction, the patient or caregiver will be able to:	PATIENT	CAREGIVER
• Define migraine headaches and describe characteristics and manifestations.	✓	✓
• Identify triggers of migraine headaches and how to avoid such triggers as:		
• Foods that contain tyramine, such as chocolate, cheese, coffee, dairy products	✓	✓
• Dietary habits that result in long periods between meals	✓	✓
• Menstruation and ovulation (caused by hormone fluctuation)	✓	✓
• Alcohol (causes vasodilation of blood vessels)	✓	✓
• Fatigue and fluctuations in sleep patterns	✓	✓
• State importance of developing and using a headache diary.	✓	✓
• State stress management and lifestyle changes to minimize the frequency of headaches.	✓	✓
• State pharmacologic management: acute therapy and prophylaxis, to include medication regimen and side effects.	✓	✓
• Identify comfort measures during headache attacks, such as resting in a quiet and dark environment, applying cold compresses to the painful area, and elevating the head.	✓	✓
• Identify resources for education and support, such as the National Headache Foundation.	✓	✓

Continuing Care

The National Headache Foundation (see Resources) provides a list of clinics in the United States and the names of physicians who specialize in headache and who are members of the American Association for the Study of Headache.

CRITICAL THINKING EXERCISES

EBP 1 Your 25-year-old patient with a brain injury has signs of ICP. Describe the nursing measures that are indicated. How would you determine whether your interventions were effective in alleviating the increased ICP? What is the evidence base for practices to decrease ICP? Identify the criteria used to evaluate the strength of the evidence for these practices.

2 A patient is admitted to your unit after undergoing transphenoidal surgery for a pituitary tumor. Describe the major complications to assess for, along with the signs and symptoms of each. Describe the pharmacologic treatment and nursing measures that are indicated postoperatively. What patient and family teaching is important for the patient and family? How would you modify your teaching and discharge planning if the patient understands little English?

EBP 3 You are caring for a 35-year-old patient who is admitted to the hospital for evaluation of her seizures. What resources would you use to identify the current guidelines for classification and treatment of seizures? What is the evidence base for treatment practices? Identify the criteria used to evaluate the strength of the evidence for these practices.

Management of Patients With Cerebrovascular Disorders

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

- 1 Describe the incidence and social impact of cerebrovascular disorders.
- 2 Identify the risk factors for cerebrovascular disorders and related measures for prevention.
- 3 Compare the various types of cerebrovascular disorders: their causes, clinical manifestations, and medical management.
- 4 Apply the principles of nursing management to the care of a patient in the acute stage of an ischemic stroke.
- 5 Use the nursing process as a framework for care of a patient recovering from an ischemic stroke.
- 6 Use the nursing process as a framework for care of a patient with a hemorrhagic stroke.
- 7 Identify essential elements for family teaching and preparation for home care of the patient who has had a stroke.

GLOSSARY

agnosia: failure to recognize familiar objects perceived by the senses

aneurysm: a weakening or bulge in an arterial wall

aphasia: inability to express oneself or to understand language

apraxia: inability to perform previously learned purposeful motor acts on a voluntary basis

dysarthria: defects of articulation due to neurologic causes

expressive aphasia: inability to express oneself; often associated with damage to the left frontal lobe area

hemianopsia: blindness of half of the field of vision in one or both eyes

hemiplegia/hemiparesis: weakness/paralysis of one side of the body, or part of it, due to an injury in the motor area of the brain

infarction: a zone of tissue deprived of blood supply

Korsakoff's syndrome: disorder characterized by psychosis, disorientation, delirium, insomnia, and hallucinations

penumbra region: area of low cerebral blood flow

receptive aphasia: inability to understand what someone else is saying; often associated with damage to the temporal lobe area

Cerebrovascular disorders is an umbrella term that refers to a functional abnormality of the central nervous system (CNS) that occurs when the normal blood supply to the brain is disrupted. Stroke is the primary cerebrovascular disorder in the United States, and it is the third leading cause of death after heart disease and cancer. Approximately 780,000 people experience a stroke each year in the United States. Approximately 600,000 of these are new strokes, and 180,000 are recurrent strokes (Rosamond, Flegal, Furie, et al., 2008). About 5.6 million noninstitutionalized stroke survivors are alive today; stroke is a leading cause of serious, long-term disability in the United States. The financial impact of stroke is profound, with estimated direct and indirect costs of \$65.5 billion in 2008 (Rosamond, et al., 2008).

Strokes can be divided into two major categories: ischemic (85%), in which vascular occlusion and significant hypoperfusion occur, and hemorrhagic (15%), in which there is extravasation of blood into the brain or subarachnoid space (Hinkle & Guanci, 2007). Although there are some similarities between the two broad types of stroke, differences exist in etiology, pathophysiology, medical management, surgical management, and nursing care. Table 62-1 compares ischemic and hemorrhagic strokes.

Ischemic Stroke

An ischemic stroke, cerebrovascular accident (CVA), or “brain attack” is a sudden loss of function resulting from disruption of the blood supply to a part of the brain. The term *brain attack* is being used to suggest to health care practitioners and the public that a stroke is an urgent health care issue similar to a heart attack. With the approval of thrombolytic therapy for the treatment of acute ischemic stroke in 1996 came a revolution in the care of patients after a stroke. Early treatment with thrombolytic therapy for ischemic stroke results in fewer stroke symptoms and less loss of function (National Institute of Neurologic Disorders and Stroke [NINDS], 1995). Currently approved thrombolytic therapy has a treatment window of only 3 hours after the onset of a stroke. Urgency is needed on the part of the public and health care practitioners for rapid transport of the patient to a hospital for assessment and administration of the medication.

Ischemic strokes are subdivided into five different types based on the cause: large artery thrombotic strokes (20%), small penetrating artery thrombotic strokes (25%), cardioembolic strokes (20%), cryptogenic strokes (30%),

and other (5%) (see Table 62-1). Large artery thrombotic strokes are caused by atherosclerotic plaques in the large blood vessels of the brain. Thrombus formation and occlusion at the site of the atherosclerosis result in ischemia and **infarction** (deprivation of blood supply) (Hinkle & Guanci, 2007).

Small penetrating artery thrombotic strokes affect one or more vessels and are the most common type of ischemic stroke. Small artery thrombotic strokes are also called lacunar strokes because of the cavity that is created after the death of infarcted brain tissue (American Association of Neuroscience Nurses [AANN], 2008).

Cardiogenic embolic strokes are associated with cardiac dysrhythmias, usually atrial fibrillation. Embolic strokes can also be associated with valvular heart disease and thrombi in the left ventricle. Emboli originate from the heart and circulate to the cerebral vasculature, most commonly the left middle cerebral artery, resulting in a stroke. Embolic strokes may be prevented by the use of anticoagulation therapy in patients with atrial fibrillation.

The last two classifications of ischemic strokes are cryptogenic strokes, which have no known cause, and strokes from other causes, such as illicit drug use, coagulopathies, migraine, and spontaneous dissection of the carotid or vertebral arteries.

Pathophysiology

In an ischemic brain attack, there is disruption of the cerebral blood flow due to obstruction of a blood vessel. This disruption in blood flow initiates a complex series of cellular metabolic events referred to as the ischemic cascade (Fig. 62-1).

The ischemic cascade begins when cerebral blood flow decreases to less than 25 mL per 100 g of blood per minute. At this point, neurons are no longer able to maintain aerobic respiration. The mitochondria must then switch to anaerobic respiration, which generates large amounts of lactic acid, causing a change in the pH. This switch to the less efficient anaerobic respiration also renders the neuron incapable of producing sufficient quantities of adenosine triphosphate (ATP) to fuel the depolarization processes. The membrane pumps that maintain electrolyte balances begin to fail, and the cells cease to function.

Early in the cascade, an area of low cerebral blood flow, referred to as the **penumbra region**, exists around the area of infarction. The penumbra region is ischemic brain tissue that may be salvaged with timely intervention. The ischemic cascade threatens cells in the penumbra because

Table 62-1 COMPARISON OF MAJOR TYPES OF STROKE

Item	Ischemic	Hemorrhagic
Causes	Large artery thrombosis Small penetrating artery thrombosis Cardiogenic embolic Cryptogenic (no known cause) Other	Intracerebral hemorrhage Subarachnoid hemorrhage Cerebral aneurysm Arteriovenous malformation
Main presenting symptoms	Numbness or weakness of the face, arm, or leg, especially on one side of the body	“Exploding headache” Decreased level of consciousness
Functional recovery	Usually plateaus at 6 months	Slower, usually plateaus at about 18 months

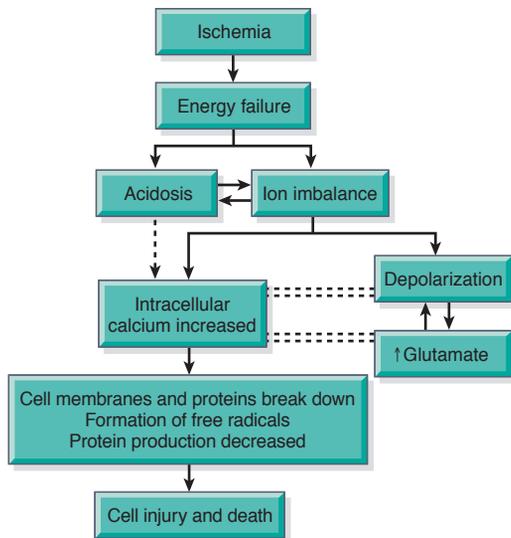

Figure 62-1 Processes contributing to ischemic brain cell injury. Courtesy of National Stroke Association, Englewood, Colorado.

membrane depolarization of the cell wall leads to an increase in intracellular calcium and the release of glutamate. The influx of calcium and the release of glutamate, if continued, activate a number of damaging pathways that result in the destruction of the cell membrane, the release of more calcium and glutamate, vasoconstriction, and the generation of free radicals. These processes enlarge the area of infarction into the penumbra, extending the stroke. A person experiencing a stroke typically loses 1.9 million neurons each minute that a stroke is not treated, and the ischemic brain ages 3.6 years each hour without treatment (Saver, 2006).

Each step in the ischemic cascade represents an opportunity for intervention to limit the extent of secondary brain damage caused by a stroke. The penumbra area may be revitalized by administration of tissue plasminogen activator (t-PA). Medications that protect the brain from secondary injury are called neuroprotectants. A number of ongoing clinical trials focus on neuroprotective medications and strategies to improve stroke recovery and survival (Lapchak & Araujo, 2007).

Clinical Manifestations

An ischemic stroke can cause a wide variety of neurologic deficits, depending on the location of the lesion (which vessels are obstructed), the size of the area of inadequate perfusion, and the amount of collateral (secondary or accessory) blood flow (see Chapter 60 for discussion of anatomy and brain blood supply). The patient may present with any of the following signs or symptoms:

- Numbness or weakness of the face, arm, or leg, especially on one side of the body
- Confusion or change in mental status
- Trouble speaking or understanding speech
- Visual disturbances
- Difficulty walking, dizziness, or loss of balance or coordination
- Sudden severe headache

Motor, sensory, cranial nerve, cognitive, and other functions may be disrupted. Table 62-2 reviews the neurologic deficits frequently seen in patients with strokes. Table 62-3 compares the symptoms and behaviors seen in right hemispheric stroke with those seen in left hemispheric stroke.

Motor Loss

A stroke is an upper motor neuron lesion and results in loss of voluntary control over motor movements. Because the upper motor neurons decussate (cross), a disturbance of voluntary motor control on one side of the body may reflect damage to the upper motor neurons on the opposite side of the brain. The most common motor dysfunction is **hemiplegia** (paralysis of one side of the body) caused by a lesion of the opposite side of the brain. **Hemiparesis**, or weakness of one side of the body, is another sign. The concept of upper and lower motor neuron lesions is described in more detail in Table 60-4 in Chapter 60.

In the early stage of stroke, the initial clinical features may be flaccid paralysis and loss of or decrease in the deep tendon reflexes. When these deep reflexes reappear (usually by 48 hours), increased tone is observed along with spasticity (abnormal increase in muscle tone) of the extremities on the affected side.

Communication Loss

Other brain functions affected by stroke are language and communication. In fact, stroke is the most common cause of aphasia. The following are dysfunctions of language and communication:

- **Dysarthria** (difficulty in speaking), caused by paralysis of the muscles responsible for producing speech
- **Dysphasia** (impaired speech) or **aphasia** (loss of speech), which can be **expressive aphasia**, **receptive aphasia**, or global (mixed) aphasia
- **Apraxia** (inability to perform a previously learned action), as may be seen when a patient makes verbal substitutions for desired syllables or words

Perceptual Disturbances

Perception is the ability to interpret sensation. Stroke can result in visual-perceptual dysfunctions, disturbances in visual-spatial relations, and sensory loss.

Visual-perceptual dysfunctions are caused by disturbances of the primary sensory pathways between the eye and visual cortex. Homonymous **hemianopsia** (loss of half of the visual field) may occur from stroke and may be temporary or permanent. The affected side of vision corresponds to the paralyzed side of the body.

Disturbances in visual-spatial relations (perceiving the relationship of two or more objects in spatial areas) are frequently seen in patients with right hemispheric damage.

Sensory Loss

The sensory losses from stroke may take the form of slight impairment of touch, or it may be more severe, with loss of proprioception (ability to perceive the position and motion of body parts) as well as difficulty in interpreting visual, tactile, and auditory stimuli. **Agnosias** are deficits in the ability to recognize previously familiar objects perceived by one or more of the senses.

Table 62-2 NEUROLOGIC DEFICITS OF STROKE: MANIFESTATIONS AND NURSING IMPLICATIONS		
Neurologic Deficit	Manifestation	Nursing Implications/Patient Teaching Applications
Visual Field Deficits		
Homonymous hemianopsia (loss of half of the visual field)	<ul style="list-style-type: none"> Unaware of persons or objects on side of visual loss Neglect of one side of the body Difficulty judging distances 	<p>Place objects within intact field of vision.</p> <p>Approach the patient from side of intact field of vision.</p> <p>Instruct/remind the patient to turn head in the direction of visual loss to compensate for loss of visual field.</p> <p>Encourage the use of eyeglasses if available.</p> <p>When teaching the patient, do so within patient's intact visual field.</p>
Loss of peripheral vision	<ul style="list-style-type: none"> Difficulty seeing at night Unaware of objects or the borders of objects 	<p>Place objects in center of patient's intact visual field.</p> <p>Encourage the use of a cane or other object to identify objects in the periphery of the visual field.</p> <p>Driving ability will need to be evaluated.</p>
Diplopia	<ul style="list-style-type: none"> Double vision 	<p>Explain to the patient the location of an object when placing it near the patient.</p> <p>Consistently place patient care items in the same location.</p>
Motor Deficits		
Hemiparesis	<ul style="list-style-type: none"> Weakness of the face, arm, and leg on the same side (due to a lesion in the opposite hemisphere) 	<p>Place objects within the patient's reach on the nonaffected side.</p> <p>Instruct the patient to exercise and increase the strength on the unaffected side.</p>
Hemiplegia	<ul style="list-style-type: none"> Paralysis of the face, arm, and leg on the same side (due to a lesion in the opposite hemisphere) 	<p>Encourage the patient to provide range-of-motion exercises to the affected side.</p> <p>Provide immobilization as needed to the affected side.</p> <p>Maintain body alignment in functional position.</p> <p>Exercise unaffected limb to increase mobility, strength, and use.</p> <p>Support patient during the initial ambulation phase.</p> <p>Provide supportive device for ambulation (walker, cane).</p> <p>Instruct the patient not to walk without assistance or supportive device.</p>
Ataxia	<ul style="list-style-type: none"> Staggering, unsteady gait Unable to keep feet together; needs a broad base to stand 	<p>Support patient during the initial ambulation phase.</p> <p>Provide supportive device for ambulation (walker, cane).</p> <p>Instruct the patient not to walk without assistance or supportive device.</p>
Dysarthria	<ul style="list-style-type: none"> Difficulty in forming words 	<p>Provide the patient with alternative methods of communicating.</p> <p>Allow the patient sufficient time to respond to verbal communication.</p> <p>Support patient and family to alleviate frustration related to difficulty in communicating.</p>
Dysphagia	<ul style="list-style-type: none"> Difficulty in swallowing 	<p>Test the patient's pharyngeal reflexes before offering food or fluids.</p> <p>Assist the patient with meals.</p> <p>Place food on the unaffected side of the mouth.</p> <p>Allow ample time to eat.</p>
Sensory Deficits		
Paresthesia (occurs on the side opposite the lesion)	<ul style="list-style-type: none"> Numbness and tingling of extremity Difficulty with proprioception 	<p>Instruct patient that sensation may be altered.</p> <p>Provide range of motion to affected areas and apply corrective devices as needed.</p>
Verbal Deficits		
Expressive aphasia	<ul style="list-style-type: none"> Unable to form words that are understandable; may be able to speak in single-word responses 	<p>Encourage patient to repeat sounds of the alphabet.</p> <p>Explore the patient's ability to write as an alternative means of communication.</p>
Receptive aphasia	<ul style="list-style-type: none"> Unable to comprehend the spoken word; can speak but may not make sense 	<p>Speak slowly and clearly to assist the patient in forming the sounds.</p> <p>Explore the patient's ability to read as an alternative means of communication.</p>
Global (mixed) aphasia	<ul style="list-style-type: none"> Combination of both receptive and expressive aphasia 	<p>Speak clearly and in simple sentences; use gestures or pictures when able.</p> <p>Establish alternative means of communication.</p>
Cognitive Deficits		
	<ul style="list-style-type: none"> Short- and long-term memory loss Decreased attention span Impaired ability to concentrate Poor abstract reasoning Altered judgment 	<p>Reorient patient to time, place, and situation frequently.</p> <p>Use verbal and auditory cues to orient patient.</p> <p>Provide familiar objects (family photographs, favorite objects).</p> <p>Use noncomplicated language.</p> <p>Match visual tasks with a verbal cue; holding a toothbrush, simulate brushing of teeth while saying, "I would like you to brush your teeth now."</p> <p>Minimize distracting noises and views when teaching the patient.</p> <p>Repeat and reinforce instructions frequently.</p>
Emotional Deficits		
	<ul style="list-style-type: none"> Loss of self-control Emotional lability Decreased tolerance to stressful situations Depression Withdrawal Fear, hostility, and anger Feelings of isolation 	<p>Support patient during uncontrollable outbursts.</p> <p>Discuss with the patient and family that the outbursts are due to the disease process.</p> <p>Encourage patient to participate in group activity.</p> <p>Provide stimulation for the patient.</p> <p>Control stressful situations, if possible.</p> <p>Provide a safe environment.</p> <p>Encourage patient to express feelings and frustrations related to disease process.</p>

Table 62-3 COMPARISON OF LEFT AND RIGHT HEMISPHERIC STROKES

Left Hemispheric Stroke	Right Hemispheric Stroke
Paralysis or weakness on right side of body	Paralysis or weakness on left side of body
Right visual field deficit	Left visual field deficit
Aphasia (expressive, receptive, or global)	Spatial-perceptual deficits
Altered intellectual ability	Increased distractibility
Slow, cautious behavior	Impulsive behavior and poor judgment
	Lack of awareness of deficits

Adapted from Hickey, J. V. (2009). *The clinical practice of neurological and neurosurgical nursing* (6th ed., p. 600). Philadelphia: Lippincott Williams & Wilkins.

Cognitive Impairment and Psychological Effects

If damage has occurred to the frontal lobe, learning capacity, memory, or other higher cortical intellectual functions may be impaired. Such dysfunction may be reflected in a limited attention span, difficulties in comprehension, forgetfulness, and a lack of motivation. These changes can cause the patient to become easily frustrated during rehabilitation. Depression is common and may be exaggerated by the patient's natural response to this catastrophic event. Emotional lability, hostility, frustration, resentment, lack of cooperation, and other psychological problems may occur.

Assessment and Diagnostic Findings

Any patient with neurologic deficits needs a careful history and a complete physical and neurologic examination. Initial assessment focuses on airway patency, which may be compromised by loss of gag or cough reflexes and altered respiratory pattern; cardiovascular status (including blood pressure, cardiac rhythm and rate, carotid bruit); and gross neurologic deficits.

Patients may present to the acute care facility with temporary neurologic symptoms. A transient ischemic attack (TIA) is a neurologic deficit typically lasting less than 1 hour. A TIA is manifested by a sudden loss of motor, sensory, or visual function. The symptoms result from temporary ischemia (impairment of blood flow) to a specific region of the brain but when brain imaging is performed there is no evidence of ischemia. A TIA may serve as a warning of impending stroke. Lack of evaluation and treatment of a patient who has experienced previous TIAs may result in a stroke and irreversible deficits (Lewandowski, Rao & Silver, 2008).

The initial diagnostic test for a stroke is usually a non-contrast computed tomography (CT) scan performed emergently to determine if the event is ischemic or hemorrhagic (the category of stroke determines treatment). Further diagnostic workup for ischemic stroke involves attempting to identify the source of the thrombi or emboli. A 12-lead electrocardiogram (ECG) and a carotid ultrasound are standard tests. Other studies may include CT angiography or magnetic resonance imaging and angiography (MRI and MRA) of the brain and neck vessels; transcranial Doppler flow studies; transthoracic or transesophageal echocardiography; xenon-enhanced CT scan; and single photon emission CT (SPECT) scan (Adams, Zoppo, Alberts, et al., 2007).

Prevention

Primary prevention of ischemic stroke remains the best approach. Leading a healthy lifestyle, which includes not smoking, maintaining a healthy weight, following a healthy

diet (including modest alcohol consumption), and daily exercise, can reduce the risk of having a stroke by about one half (Chiuve, Rexrode, Spiegelman, et al., 2008). The risk of coronary heart disease and stroke has decreased in women on the Dietary Approaches to Stop Hypertension (DASH) diet. The DASH diet is high in fruits and vegetables, moderate in low-fat dairy products, and low in animal protein (has a substantial amount of plant protein from legumes and nuts) (Fung, Chiuve, McCullough, et al., 2008). Stroke risk screenings are an ideal opportunity to lower stroke risk by identifying people or groups of people who are at high risk for stroke and by educating patients and the community about recognition and prevention of stroke. Research findings suggest that low-dose aspirin may lower the risk of stroke in women who are at risk (Ridker, Cook, Lee, et al., 2005).

Advanced age, gender, and race are well-known non-modifiable risk factors for stroke. High-risk groups include people older than 55 years of age; the incidence of stroke more than doubles in each successive decade. Men have a higher rate of stroke than that of women. Another high-risk group is African Americans; the incidence of first stroke in African Americans is almost twice that in Caucasian Americans (Rosamond, et al., 2008).

Modifiable risk factors for ischemic stroke include hypertension, atrial fibrillation, hyperlipidemia, obesity, smoking, and diabetes (Chart 62-1). For people who are at high risk, interventions that alter modifiable factors, such as treating hypertension and hyperglycemia and stopping smoking, reduce stroke risk. Other treatable conditions that increase risk of stroke are asymptomatic carotid stenosis and valvular heart disease (eg, endocarditis, prosthetic heart valves). Periodontal disease has also been linked to stroke risk. The association between periodontal disease and stroke may result from the host inflammatory response and the chronic bacterial infection, but the exact mechanism is not fully understood. Periodontal disease is a treatable and preventable condition.

Several methods of preventing recurrent stroke have been identified for patients with TIAs or ischemic stroke. Patients with moderate to severe carotid stenosis are treated with carotid endarterectomy (Sacco, Adams, Albers, et al., 2006). In patients with atrial fibrillation, which increases the risk of emboli, administration of warfarin (Coumadin), an anticoagulant that inhibits clot formation, may prevent both thrombotic and embolic strokes.

CHART
62-1

Modifiable Risk Factors for Ischemic Stroke

- Hypertension (controlling hypertension, the major risk factor, is the key to preventing stroke)
- Atrial fibrillation
- Hyperlipidemia
- Diabetes mellitus (associated with accelerated atherosclerosis)
- Smoking
- Asymptomatic carotid stenosis
- Obesity
- Excessive alcohol consumption

Medical Management

Patients who have experienced a TIA or stroke should have medical management for secondary prevention. Those with atrial fibrillation (or cardioembolic strokes) are treated with dose-adjusted warfarin (Coumadin) unless contraindicated. The international normalized ratio (INR) target is 2 to 3. If warfarin is contraindicated, aspirin is the best option, although other medications may be used if both are contraindicated (Karch, 2008).

Platelet-inhibiting medications, including aspirin, extended-release dipyridamole (Persantine) plus aspirin, clopidogrel (Plavix), and ticlopidine (Ticlid), decrease the incidence of cerebral infarction in patients who have experienced TIAs and stroke from suspected embolic or thrombotic causes. The specific medication that is used is based on the patient's health history.

Research has found that medications classified as 3-hydroxy-2-methyl-glutaryl-coenzyme A reductase inhibitors (also known as statins) reduce coronary events and strokes. Benefits were independent of cholesterol levels, and these medications are now widely used for stroke prevention. The U.S. Food and Drug Administration (FDA) has recently updated indications for a statin medication, such as simvastatin (Zocor), to include secondary stroke prevention (Nassief & Marsh, 2008). After the acute stroke period, antihypertensive medications are also used, if indicated, for secondary stroke prevention. Angiotensin-converting enzyme (ACE) inhibitors and thiazide diuretics may also have benefits in stroke prevention (Luders, 2007).

Ongoing research is focusing on several aspects of the medical management of acute ischemic stroke. The FDA has approved a clot retrieval device (shaped like a tiny corkscrew) that opens the blocked artery and restores blood flow to the brain (Felton, Ogden, Pena, et al., 2005). Other clot retrieval devices are under investigation, including catheters using vacuum and ultrasound techniques to assist in the removal of clots in the brain.

Thrombolytic Therapy

Thrombolytic agents are used to treat ischemic stroke by dissolving the blood clot that is blocking blood flow to the brain. Recombinant t-PA is a genetically engineered form of t-PA, a thrombolytic substance made naturally by the body. It works by binding to fibrin and converting plasminogen to plasmin, which stimulates fibrinolysis of the atherosclerotic lesion. Rapid diagnosis of stroke and initiation of thrombolytic therapy (within 3 hours) in patients with ischemic stroke leads to a decrease in the size of the stroke and an overall improvement in functional outcome after 3 months (Adams, et al., 2007; NINDS, 1995). Ongoing clinical trials continue to investigate other thrombolytic agents (Lapchak & Araujo, 2007).

To realize the full potential of thrombolytic therapy, community education directed at recognizing the symptoms of stroke and obtaining appropriate emergency care is necessary to ensure rapid transport to a hospital and initiation of therapy within the 3-hour period. Delays make the patient ineligible for thrombolytic therapy, because revascularization of necrotic tissue (which develops after 3 hours) increases the risk of cerebral edema and hemorrhage.

Enhancing Prompt Diagnosis

After being notified by emergency medical service personnel, the emergency department contacts the appropriate staff (neurologist, neuroradiologist, radiology department, nursing staff, ECG, and laboratory technicians) and informs them of the patient's imminent arrival at the hospital. Many institutions have acute stroke teams that respond rapidly, ensuring that treatment occurs within the allotted period (AANN, 2008).

Initial management requires the definitive diagnosis of an ischemic stroke by brain imaging and a careful history to determine whether the patient meets the criteria for t-PA therapy (Chart 62-2). Some of the absolute contraindications for thrombolytic therapy include symptom onset greater than 3 hours before admission, a patient who is anticoagulated (with an INR above 1.7), or a patient who has recently had any type of intracranial pathology (eg, previous stroke, head injury, trauma). Once it is determined that the patient is a candidate for t-PA therapy, no anticoagulants are administered for the next 24 hours.

Before receiving t-PA, the patient is assessed using the National Institutes of Health Stroke Scale (NIHSS), a standardized assessment tool that helps evaluate stroke severity (Table 62-4). Total NIHSS scores range from 0 (normal) to 42 (severe stroke) (Kasner, 2006). Certification in the administration of the scale is recommended and is available for nurses and other health care professionals.

Dosage and Administration

The patient is weighed to determine the dose of t-PA. The dosage for t-PA is 0.9 mg/kg, with a maximum dose of 90 mg. Ten percent of the calculated dose is administered as an intravenous (IV) bolus over 1 minute. The remaining dose (90%) is administered IV over 1 hour via an infusion pump.

The patient is admitted to the intensive care unit or an acute stroke unit, where continuous cardiac monitoring and frequent neurologic assessments are conducted. Vital signs are obtained frequently, with particular attention to blood

Chart 62-2 • Eligibility Criteria for t-PA Administration

- Age 18 years or older
- Clinical diagnosis of ischemic stroke
- Time of onset of stroke known and is 3 hours or less
- Systolic blood pressure \leq 185 mm Hg; diastolic \leq 110 mm Hg
- Not a minor stroke or rapidly resolving stroke
- No seizure at onset of stroke
- Not taking warfarin (Coumadin)
- Prothrombin time \leq 15 seconds or INR \leq 1.7
- Not receiving heparin during the past 48 hours with elevated partial thromboplastin time
- Platelet count \geq 100,000/mm³
- No prior intracranial hemorrhage, neoplasm, arteriovenous malformation, or aneurysm
- No major surgical procedures within 14 days
- No stroke, serious head injury, or intracranial surgery within 3 months
- No gastrointestinal or urinary bleeding within 21 days

Table 62-4 SUMMARY OF NATIONAL INSTITUTES OF HEALTH STROKE SCALE (NIHSS)

Category	Description	Score
1a. Level of consciousness (LOC)	Alert	0
	Arousable by minor stimulation	1
	Obtunded, strong stimulation to attend	2
	Unresponsive, or reflexic responses only	3
1b. LOC questions (month, age)	Answers both correctly	0
	Answers one correctly	1
	Both incorrect	2
1c. LOC commands (open, close eyes; make fist, let go)	Obeys both correctly	0
	Obeys one correctly	1
	Both incorrect	2
2. Best gaze (eyes open—patient follows examiner's finger or face)	Normal	0
	Partial gaze palsy	1
	Forced deviation	2
3. Visual (introduce visual stimulus/threat to patient's visual field quadrants)	No visual loss	0
	Partial hemianopsia	1
	Complete hemianopsia	2
	Bilateral hemianopsia	3
4. Facial palsy (show teeth, raise eyebrows and squeeze eyes shut)	Normal	0
	Minor	1
	Partial	2
	Complete	3
5a. Motor; arm—left (elevate extremity to 90° and score drift/movement)	No drift	0
	Drift but maintains in air	1
	Unable to maintain in air	2
	No effort against gravity	3
	No movement	4
Amputation, joint fusion (explain)	N/A	
5b. Motor; arm—right (elevate extremity to 90° and score drift/movement)	No drift	0
	Drift but maintains in air	1
	Unable to maintain in air	2
	No effort against gravity	3
	No movement	4
Amputation, joint fusion (explain)	N/A	
6a. Motor; leg—left (elevate extremity to 30° and score drift/movement)	No drift	0
	Drift but maintains in air	1
	Unable to maintain in air	2
	No effort against gravity	3
	No movement	4
Amputation, joint fusion (explain)	N/A	
6b. Motor; leg—right (elevate extremity to 30° and score drift/movement)	No drift	0
	Drift but maintains in air	1
	Unable to maintain in air	2
	No effort against gravity	3
	No movement	4
Amputation, joint fusion (explain)	N/A	
7. Limb ataxia (finger-to-nose and heel-to-shin testing)	Absent	0
	Present in one limb	1
	Present in two limbs	2
8. Sensory (pinprick to face, arm, trunk, and leg—compare side to side)	Normal	0
	Mild to moderate loss	1
	Severe to total loss	2
9. Best language (name items, describe a picture and read sentences)	No aphasia	0
	Mild to moderate aphasia	1
	Severe aphasia	2
	Mute	3
10. Dysarthria (evaluate speech clarity by having patient repeat words)	Normal	0
	Mild to moderate dysarthria	1
	Severe dysarthria, mostly unintelligible or worse	2
	Intubated or other physical barrier	N/A
11. Extinction and inattention (use information from prior testing to score)	No abnormality	0
	Visual, tactile, auditory, or other extinction to bilateral simultaneous stimulation	1
	Profound hemiattention or extinction to more than one modality.	2
Total score		

Adapted from the version available at the National Institute of Neurological Disorders and Stroke, National Institutes of Health, Bethesda, MD 20892, www.ninds.nih.gov/doctors/NIH_Stroke_Scale.pdf. It is recommended that the full scale with all instructions be used.

pressure (with the goal of lowering the risk of intracranial hemorrhage). An example of a standard protocol would be to obtain vital signs every 15 minutes for the first 2 hours, every 30 minutes for the next 6 hours, then every hour until 24 hours after treatment. Blood pressure should be maintained with the systolic pressure less than 180 mm Hg and the diastolic pressure less than 105 mm Hg (Adams, et al., 2007). Airway management is instituted based on the patient's clinical condition and arterial blood gas values.

Side Effects

Bleeding is the most common side effect of t-PA administration, and the patient is closely monitored for any bleeding (IV insertion sites, urinary catheter site, endotracheal tube, nasogastric tube, urine, stool, emesis, other secretions). A 24-hour delay in placement of nasogastric tubes, urinary catheters, and intra-arterial pressure catheters is recommended. Intracranial bleeding is a major complication that occurred in approximately 6.4% of patients in the initial t-PA study (NINDS, 1995). A number of factors are associated with the occurrence of symptomatic intracranial bleeding: age greater than 70 years, baseline NIHSS score greater than 20, serum glucose concentration 300 mg/dL or higher, and edema or mass effect observed on the patient's initial CT scan.

Therapy for Patients With Ischemic Stroke Not Receiving t-PA

Not all patients are candidates for t-PA therapy. Other treatments may include anticoagulant administration (IV heparin or low-molecular-weight heparin). Because of the risks associated with anticoagulation, their general use is no longer recommended for patients with acute ischemic stroke, whether treated with t-PA or not (Adams, et al., 2007).

Careful maintenance of cerebral hemodynamics to maintain cerebral perfusion is extremely important after a stroke. Increased intracranial pressure (ICP) from brain edema, and associated complications, may occur after a large ischemic stroke. Interventions during this period include measures to reduce ICP, such as administering an osmotic diuretic (eg, mannitol), maintaining the partial pressure of carbon dioxide (PaCO_2) within the range of 30 to 35 mm Hg, and positioning to avoid hypoxia. Other treatment measures include the following:

- Elevation of the head of the bed to promote venous drainage and to lower increased ICP
- Possible hemicraniectomy for increased ICP from brain edema in a very large stroke
- Intubation with an endotracheal tube to establish a patent airway, if necessary
- Continuous hemodynamic monitoring (the goals for blood pressure remain controversial for a patient who has not received thrombolytic therapy; antihypertensive treatment may be withheld unless the systolic blood pressure exceeds 220 mm Hg or the diastolic blood pressure exceeds 120 mm Hg)
- Neurologic assessment to determine if the stroke is evolving and if other acute complications are developing; such complications may include seizures, bleeding from anticoagulation, or medication-

induced bradycardia, which can result in hypotension and subsequent decreases in cardiac output and cerebral perfusion pressure

An acute ischemic stroke clinical pathway is shown in Appendix B.

Managing Potential Complications

Adequate cerebral blood flow is essential for cerebral oxygenation. If cerebral blood flow is inadequate, the amount of oxygen supplied to the brain will decrease, and tissue ischemia will result. Adequate oxygenation begins with pulmonary care, maintenance of a patent airway, and administration of supplemental oxygen as needed. The importance of adequate gas exchange in these patients cannot be overemphasized as many are at risk for aspiration pneumonia.

Other potential complications after a stroke include urinary tract infections, cardiac dysrhythmias, and complications of immobility.

Surgical Prevention of Ischemic Stroke

The main surgical procedure for selected patients with TIAs and mild stroke is carotid endarterectomy, which is currently the most frequently performed noncardiac vascular procedure. A carotid endarterectomy is the removal of an atherosclerotic plaque or thrombus from the carotid artery to prevent stroke in patients with occlusive disease of the extracranial cerebral arteries (Fig. 62-2). This surgery is indicated for patients with symptoms of TIA or mild stroke found to be caused by severe (70% to 99%) carotid artery stenosis or moderate (50% to 69%) stenosis with other significant risk factors (Chaturvedi, Bruno, Feasby, et al., 2005).

Carotid stenting, with or without angioplasty, is a less invasive procedure that is used, at times, for severe stenosis. It is used for selected patients who are at high risk for surgery, and its efficacy continues to be investigated. In a recent

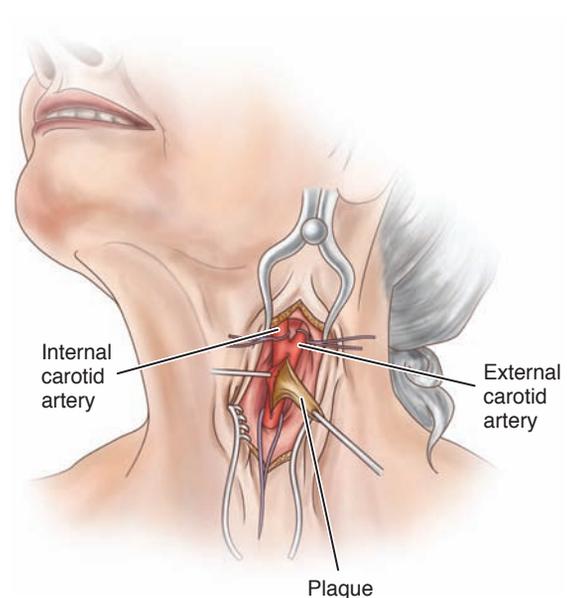

Figure 62-2 Plaque, a potential source of emboli in transient ischemic attack and stroke, is surgically removed from the carotid artery.

Table 62-5 SELECTED COMPLICATIONS OF CAROTID ENDARTERECTOMY AND NURSING INTERVENTIONS

Complication	Characteristics	Nursing Interventions
Incision hematoma	Occurs in 5.5% of patients. Large or rapidly expanding hematomas require emergency treatment. If the airway is obstructed by the hematoma, the incision may be opened at the bedside.	Monitor neck discomfort and wound expansion. Report swelling, subjective feelings of pressure in the neck, difficulty breathing.
Hypertension	Poorly controlled hypertension increases the risk of postoperative complications, including hematoma and hyperperfusion syndrome. There is an increased incidence of neurologic impairment and death due to intracerebral hemorrhage. May be related to surgically induced abnormalities of carotid baroreceptor sensitivity.	Risk is highest in the first 48 h after surgery. Check blood pressure frequently and report deviations from baseline. Observe for and report new onset of neurologic deficits.
Postoperative hypotension	Occurs in approximately 5% of patients. Treated with fluids and low-dose phenylephrine infusion. Usually resolves in 24–48 h. Patients with hypotension should have serial ECGs to rule out myocardial infarction.	Monitor blood pressure and observe for signs and symptoms of hypotension.
Hyperperfusion syndrome	Occurs when cerebral vessel autoregulation fails. Arteries accustomed to diminished blood flow may be permanently dilated; increased blood flow after endarterectomy coupled with insufficient vasoconstriction leads to capillary bed damage, edema, and hemorrhage.	Observe for severe unilateral headache improved by sitting upright or standing.
Intracerebral hemorrhage	Occurs infrequently, but is often fatal (60%) or results in serious neurologic impairment. Can occur secondary to hyperperfusion syndrome. Increased risk with advanced age, hypertension, presence of high-grade stenosis, poor collateral flow, and slow flow in the region of the middle cerebral artery.	Monitor neurologic status and report any changes in mental status or neurologic functioning immediately.

study, 334 patients with severe carotid artery stenosis and at high risk for surgery underwent stenting with the use of an emboli protection device or carotid endarterectomy. This study demonstrated that this procedure is not inferior to carotid endarterectomy as it resulted in similar long-term outcomes (Gurm, Yadav, Fayad, et al., 2008).

Nursing Management

The primary complications of carotid endarterectomy are stroke, cranial nerve injuries, infection or hematoma at the incision, and carotid artery disruption. It is important to maintain adequate blood pressure levels in the immediate postoperative period. Hypotension is avoided to prevent cerebral ischemia and thrombosis. Uncontrolled hypertension may precipitate cerebral hemorrhage, edema, hemorrhage at the surgical incision, or disruption of the arterial reconstruction. Medications are used to reduce the blood pressure to previous levels. Close cardiac monitoring is necessary, because these patients have a high incidence of coronary artery disease.

After carotid endarterectomy, a neurologic flow sheet is used to monitor and document assessment parameters for all body systems, with particular attention to neurologic status. The surgeon is notified immediately if a neurologic deficit develops. Formation of a thrombus at the site of the endarterectomy is suspected if there is a sudden increase in neurologic deficits, such as weakness on one side of the body. The patient should be prepared for repeat endarterectomy.

Difficulty in swallowing, hoarseness, or other signs of cranial nerve dysfunction must be assessed. The nurse focuses on assessment of the following cranial nerves: facial (VII), vagus (X), spinal accessory (XI), and hypoglossal (XII). Some edema in the neck after surgery is expected;

however, extensive edema and hematoma formation can obstruct the airway. Emergency airway supplies, including those needed for a tracheostomy, must be available. Table 62-5 provides more information about potential complications of carotid surgery.

NURSING PROCESS

THE PATIENT RECOVERING FROM AN ISCHEMIC STROKE

The acute phase of an ischemic stroke may last 1 to 3 days, but ongoing monitoring of all body systems is essential as long as the patient requires care. The patient who has had a stroke is at risk for multiple complications, including deconditioning and other musculoskeletal problems, swallowing difficulties, bowel and bladder dysfunction, inability to perform self-care, and skin breakdown. After the stroke is complete, management focuses on the prompt initiation of rehabilitation for any deficits.

Assessment

During the acute phase, a neurologic flow sheet is maintained to provide data about the following important measures of the patient's clinical status:

- Change in level of consciousness or responsiveness as evidenced by movement, resistance to changes of position, and response to stimulation; orientation to time, place, and person
- Presence or absence of voluntary or involuntary movements of the extremities; muscle tone; body posture; and position of the head

- Stiffness or flaccidity of the neck
- Eye opening, comparative size of pupils and pupillary reactions to light, and ocular position
- Color of the face and extremities; temperature and moisture of the skin
- Quality and rates of pulse and respiration; arterial blood gas values as indicated, body temperature, and arterial pressure
- Ability to speak
- Volume of fluids ingested or administered; volume of urine excreted each 24 hours
- Presence of bleeding
- Maintenance of blood pressure within the desired parameters

After the acute phase, the nurse assesses mental status (memory, attention span, perception, orientation, affect, speech/language), sensation/perception (usually the patient has decreased awareness of pain and temperature), motor control (upper and lower extremity movement), swallowing ability, nutritional and hydration status, skin integrity, activity tolerance, and bowel and bladder function. Ongoing nursing assessment continues to focus on any impairment of function in the patient's daily activities, because the quality of life after stroke is closely related to the patient's functional status.

Diagnosis

Nursing Diagnoses

Based on the assessment data, the major nursing diagnoses for a patient with a stroke may include the following:

- Impaired physical mobility related to hemiparesis, loss of balance and coordination, spasticity, and brain injury
- Acute pain (painful shoulder) related to hemiplegia and disuse
- Self-care deficits (bathing, hygiene, toileting, dressing, grooming, and feeding) related to stroke sequelae
- Disturbed sensory perception (kinesthetic, tactile or visual) related to altered sensory reception, transmission, and/or integration
- Impaired swallowing
- Impaired urinary elimination related to flaccid bladder, detrusor instability, confusion, or difficulty in communicating
- Disturbed thought processes related to brain damage
- Impaired verbal communication related to brain damage
- Risk for impaired skin integrity related to hemiparesis, hemiplegia, or decreased mobility
- Interrupted family processes related to catastrophic illness and caregiving burdens
- Sexual dysfunction related to neurologic deficits or fear of failure

Collaborative Problems/Potential Complications

Potential complications include:

- Decreased cerebral blood flow due to increased ICP
- Inadequate oxygen delivery to the brain
- Pneumonia

Planning and Goals

Although rehabilitation begins on the day the patient has the stroke, the process is intensified during convalescence

and requires a coordinated team effort. It is helpful for the team to know what the patient was like before the stroke: his or her illnesses, abilities, mental and emotional state, behavioral characteristics, and activities of daily living (ADLs). It is also helpful for clinicians to be knowledgeable about the relative importance of predictors of stroke outcome (age, NIHSS score, and level of consciousness at time of admission) in order to provide stroke survivors and their families with realistic goals (Adams, et al., 2007).

The major goals for the patient (and family) may include improved mobility, avoidance of shoulder pain, achievement of self-care, relief of sensory and perceptual deprivation, prevention of aspiration, continence of bowel and bladder, improved thought processes, achieving a form of communication, maintaining skin integrity, restored family functioning, improved sexual function, and absence of complications.

Nursing Interventions

Nursing care has a significant impact on the patient's recovery. Often, many body systems are impaired as a result of the stroke, and conscientious care and timely interventions can prevent debilitating complications. During and after the acute phase, nursing interventions focus on the whole person. In addition to providing physical care, the nurse encourages and fosters recovery by listening to the patient and asking questions to elicit the meaning of the stroke experience.

Improving Mobility and Preventing Joint Deformities

A patient with hemiplegia has unilateral paralysis (paralysis on one side). When control of the voluntary muscles is lost, the strong flexor muscles exert control over the extensors. The arm tends to adduct (adductor muscles are stronger than abductors) and to rotate internally. The elbow and the wrist tend to flex, the affected leg tends to rotate externally at the hip joint and flex at the knee, and the foot at the ankle joint supinates and tends toward plantar flexion.

Correct positioning is important to prevent contractures; measures are used to relieve pressure, assist in maintaining good body alignment, and prevent compressive neuropathies, especially of the ulnar and peroneal nerves. Because flexor muscles are stronger than extensor muscles, a splint applied at night to the affected extremity may prevent flexion and maintain correct positioning during sleep. (See Chapter 11 for additional information.)

PREVENTING SHOULDER ADDUCTION. To prevent adduction of the affected shoulder while the patient is in bed, a pillow is placed in the axilla when there is limited external rotation; this keeps the arm away from the chest. A pillow is placed under the arm, and the arm is placed in a neutral (slightly flexed) position, with distal joints positioned higher than the more proximal joints (ie, the elbow is positioned higher than the shoulder and the wrist higher than the elbow). This helps to prevent edema and the resultant joint fibrosis that will limit range of motion if the patient regains control of the arm (Fig. 62-3).

POSITIONING THE HAND AND FINGERS. The fingers are positioned so that they are barely flexed. The hand is placed in slight supination (palm faces upward), which is its most functional position. If the upper extremity is flaccid, a splint can be used to support the wrist and hand in a functional

Figure 62-3 Correct positioning to prevent shoulder adduction.

position. If the upper extremity is spastic, a hand roll is not used, because it stimulates the grasp reflex. In this instance a dorsal wrist splint is useful in allowing the palm to be free of pressure. Every effort is made to prevent hand edema.

Spasticity, particularly in the hand, can be a disabling complication after stroke. Researchers have reported that repeated intramuscular injections of botulinum toxin type A into wrist and finger muscles reduced upper limb spasticity after stroke, resulting in significant and sustained improvements in muscle tone, lessened disability, and improved quality of life (Elovic, Brashear, Kaelin, et al., 2008). Other treatments for spasticity may include stretching and splinting.

CHANGING POSITIONS. The patient's position should be changed every 2 hours. To place a patient in a lateral (side-lying) position, a pillow is placed between the legs before the patient is turned. To promote venous return and prevent edema, the upper thigh should not be acutely flexed. The patient may be turned from side to side, but if sensation is impaired, the amount of time spent on the affected side should be limited.

If possible, the patient is placed in a prone position for 15 to 30 minutes several times a day. A small pillow or a support is placed under the pelvis, extending from the level of the umbilicus to the upper third of the thigh (Fig. 62-4). This position helps promote hyperextension of the hip joints, which is essential for normal gait and helps prevent knee and hip flexion contractures. The prone position also helps drain bronchial secretions and prevents contractural deformities of the shoulders and knees. During positioning, it is important to reduce pressure and change position frequently to prevent pressure ulcers.

ESTABLISHING AN EXERCISE PROGRAM. The affected extremities are exercised passively and put through a full range of motion four or five times a day to maintain joint mobility, regain motor control, prevent contractures in the

Figure 62-4 Prone position with pillow support helps prevent hip flexion.

paralyzed extremity, prevent further deterioration of the neuromuscular system, and enhance circulation. Exercise is helpful in preventing venous stasis, which may predispose the patient to thrombosis and pulmonary embolus.

Repetition of an activity forms new pathways in the CNS and therefore encourages new patterns of motion. At first, the extremities are usually flaccid. If tightness occurs in any area, the range-of-motion exercises should be performed more frequently (see Chapter 11).

The patient is observed for signs and symptoms that may indicate pulmonary embolus or excessive cardiac workload during exercise; these include shortness of breath, chest pain, cyanosis, and increasing pulse rate with exercise. Frequent short periods of exercise always are preferable to longer periods at infrequent intervals. Regularity in exercise is most important. Improvement in muscle strength and maintenance of range of motion can be achieved only through daily exercise.

The patient is encouraged and reminded to exercise the unaffected side at intervals throughout the day. It is helpful to develop a written schedule to remind the patient of the exercise activities. The nurse supervises and supports the patient during these activities. The patient can be taught to put the unaffected leg under the affected one to assist in moving it when turning and exercising. Flexibility, strengthening, coordination, endurance, and balancing exercises prepare the patient for ambulation. Quadriceps muscle setting and gluteal setting exercises are started early to improve the muscle strength needed for walking; these are performed at least five times daily for 10 minutes at a time.

PREPARING FOR AMBULATION. As soon as possible, the patient is assisted out of bed and an active rehabilitation program is started. The patient is first taught to maintain balance while sitting and then to learn to balance while standing. If the patient has difficulty in achieving standing balance, a tilt table, which slowly brings the patient to an upright position, can be used. Tilt tables are especially helpful for patients who have been on bed rest for prolonged periods and have orthostatic blood pressure changes.

If the patient needs a wheelchair, the folding type with hand brakes is the most practical because it allows the patient to manipulate the chair. The chair should be low enough to allow the patient to propel it with the uninvolved foot and narrow enough to permit it to be used in the home. When the patient is transferred from the wheelchair, the brakes must be applied and locked on both sides of the chair.

The patient is usually ready to walk as soon as standing balance is achieved. Parallel bars are useful in these first efforts. A chair or wheelchair should be readily available in case the patient suddenly becomes fatigued or feels dizzy.

The training periods for ambulation should be short and frequent. As the patient gains strength and confidence, an adjustable cane can be used for support. Generally, a three- or four-pronged cane provides a stable support in the early phases of rehabilitation.

Preventing Shoulder Pain

As many as 72% of patients who have had a stroke have pain in the shoulder (Duncan, Zorowitz, Bates, et al., 2005). That pain may prevent them from learning new skills and

affect their quality of life (Chae, Mascarenhas, Yu, et al., 2007). Shoulder function is essential in achieving balance and performing transfers and self-care activities. Three problems can occur: painful shoulder, subluxation of the shoulder, and shoulder–hand syndrome.

A flaccid shoulder joint may be overstretched by the use of excessive force in turning the patient or from over strenuous arm and shoulder movement. To prevent shoulder pain, the nurse should never lift the patient by the flaccid shoulder or pull on the affected arm or shoulder. Overhead pulleys should also be avoided. If the arm is paralyzed, subluxation (incomplete dislocation) at the shoulder can occur as a result of overstretching of the joint capsule and musculature by the force of gravity when the patient sits or stands in the early stages after a stroke. This results in severe pain. Shoulder–hand syndrome (painful shoulder and generalized swelling of the hand) can cause a frozen shoulder and ultimately atrophy of subcutaneous tissues. When a shoulder becomes stiff, it is usually painful.

Many shoulder problems can be prevented by proper patient movement and positioning. The flaccid arm is positioned on a table or with pillows while the patient is seated. Some clinicians advocate the use of a properly worn sling when the patient first becomes ambulatory, to prevent the paralyzed upper extremity from dangling without support. Range-of-motion exercises are important in preventing painful shoulder. Over strenuous arm movements are avoided. The patient is instructed to interlace the fingers, place the palms together, and push the clasped hands slowly forward to bring the scapulae forward; he or she then raises both hands above the head. This is repeated throughout the day. The patient is instructed to flex the affected wrist at intervals and move all the joints of the affected fingers. The patient is encouraged to touch, stroke, rub, and look at both hands. Pushing the heel of the hand firmly down on a surface is useful. Elevation of the arm and hand is also important in preventing dependent edema of the hand. Patients with continuing pain after attempted movement and positioning may require the addition of analgesia to their treatment program. Other treatments may include injections to the shoulder joint with corticosteroid medications, electrical stimulation, heat or ice, and soft tissue massage (Duncan, et al., 2005).

Medications are helpful in the management of poststroke pain. Amitriptyline hydrochloride (Elavil) has been used, but it can cause cognitive problems, has a sedating effect, and is not effective in all patients. The antiseizure medications lamotrigine (Lamictal) and pregabalin (Lyrica) have been found to be effective for poststroke pain, and they may serve as alternatives for patients who cannot tolerate amitriptyline (Vranken, Dijkstra, Kruis, et al., 2008).

Enhancing Self-Care

As soon as the patient can sit up, personal hygiene activities are encouraged. The patient is helped to set realistic goals; if feasible, a new task is added daily. The first step is to carry out all self-care activities on the unaffected side. Such activities as combing the hair, brushing the teeth, shaving with an electric razor, bathing, and eating can be carried out with one hand and should be encouraged. Although the patient may feel awkward at first, these motor

Chart 62-3 • Assistive Devices to Enhance Self-Care After Stroke

Eating Devices

- Nonskid mats to stabilize plates
- Plate guards to prevent food from being pushed off plate
- Wide-grip utensils to accommodate a weak grasp

Bathing and Grooming Devices

- Long-handled bath sponge
- Grab bars, nonskid mats, handheld shower heads
- Electric razors with head at 90 degrees to handle
- Shower and tub seats, stationary or on wheels

Toileting Aids

- Raised toilet seat
- Grab bars next to toilet

Dressing Aids

- Velcro closures
- Elastic shoelaces
- Long-handled shoe horn

Mobility Aids

- Canes, walkers, wheelchairs
- Transfer devices such as transfer boards and belts

skills can be learned by repetition, and the unaffected side will become stronger with use. The nurse must be sure that the patient does not neglect the affected side. Assistive devices will help make up for some of the patient's deficits (Chart 62-3). A small towel is easier to control while drying after bathing, and boxed paper tissues are easier to use than a roll of toilet tissue.

Return of functional ability is important to the patient recovering after a stroke. An early baseline assessment of functional ability with an instrument such as the Functional Independence Measure (FIM) is important in team planning and goal setting for the patient. The FIM is a widely used instrument in stroke rehabilitation and provides valuable information about motor, social, and cognitive function (Kasner, 2006). The patient's morale may improve if ambulatory activities are carried out in street clothes. The family is instructed to bring in clothing that is preferably a size larger than that normally worn. Clothing fitted with front or side fasteners or Velcro closures is the most suitable. The patient has better balance if most of the dressing activities are carried out while seated.

Perceptual problems may make it difficult for the patient to dress without assistance because of an inability to match the clothing to the body parts. To assist the patient, the nurse can take steps to keep the environment organized and uncluttered, because the patient with a perceptual problem is easily distracted. The clothing is placed on the affected side in the order in which the garments are to be put on. Using a large mirror while dressing promotes the patient's awareness of what he or she is putting on the affected side. The patient has to make many compensatory movements when dressing; these can produce fatigue and painful twisting of the intercostal muscles. Support and encouragement

are provided to prevent the patient from becoming overly fatigued and discouraged. Even with intensive training, not all patients can achieve independence in dressing.

Managing Sensory-Perceptual Difficulties

Patients with a decreased field of vision should be approached on the side where visual perception is intact. All visual stimuli (eg, clock, calendar, television) should be placed on this side. The patient can be taught to turn the head in the direction of the defective visual field to compensate for this loss. The nurse should make eye contact with the patient and draw his or her attention to the affected side by encouraging the patient to move the head. The nurse may also want to stand at a position that encourages the patient to move or turn to visualize who is in the room. Increasing the natural or artificial lighting in the room and providing eyeglasses are important aids to increasing vision.

The patient with homonymous hemianopsia (loss of half of the visual field) turns away from the affected side of the body and tends to neglect that side and the space on that side; this is called amorphosynthesis. In such instances, the patient cannot see food on half of the tray, and only half of the room is visible. It is important for the nurse to constantly remind the patient of the other side of the body, to maintain alignment of the extremities, and, if possible, to place the extremities where the patient can see them.

Assisting With Nutrition

Stroke can result in swallowing problems (dysphagia) due to impaired function of the mouth, tongue, palate, larynx, pharynx, or upper esophagus. Patients must be observed for paroxysms of coughing, food dribbling out of or pooling in one side of the mouth, food retained for long periods in the mouth, or nasal regurgitation when swallowing liquids. Swallowing difficulties place the patient at risk for aspiration, pneumonia, dehydration, and malnutrition.

A speech therapist will evaluate the patient's swallowing ability. If swallowing function is partially impaired, it may return over time, or the patient may be taught alternative swallowing techniques, advised to take smaller boluses of food, and taught about types of foods that are easier to swallow. The patient may be started on a thick liquid or puréed diet, because these foods are easier to swallow than thin liquids. Having the patient sit upright, preferably out of bed in a chair, and instructing him or her to tuck the chin toward the chest as he or she swallows will help prevent aspiration. The diet may be advanced as the patient becomes more proficient at swallowing. If the patient cannot resume oral intake, a gastrointestinal feeding tube is placed for ongoing tube feedings and medication administration.

Enteral tubes can be either nasogastric (placed in the stomach) or nasoenteral (placed in the duodenum) to reduce the risk of aspiration. Nursing responsibilities in feeding include elevating the head of the bed at least 30 degrees to prevent aspiration, checking the position of the tube before feeding, ensuring that the cuff of the tracheostomy tube (if in place) is inflated, and giving the tube feeding slowly. The feeding tube is aspirated periodically to ensure that the feedings are passing through the gastrointestinal tract. Retained or residual feedings increase the risk of aspiration.

Patients with retained feedings may benefit from the placement of a gastrostomy tube or a percutaneous endoscopic gastrostomy tube. In a patient with a nasogastric tube, the feeding tube should be placed in the duodenum to reduce the risk of aspiration. For long-term feedings, a gastrostomy tube is preferred. Management of patients with tube feedings is discussed in Chapter 36.

Attaining Bowel and Bladder Control

After a stroke, the patient may have transient urinary incontinence due to confusion, inability to communicate needs, and inability to use the urinal or bedpan because of impaired motor and postural control. Occasionally after a stroke, the bladder becomes atonic, with impaired sensation in response to bladder filling. Sometimes control of the external urinary sphincter is lost or diminished. During this period, intermittent catheterization with sterile technique is carried out. After muscle tone increases and deep tendon reflexes return, bladder tone increases and spasticity of the bladder may develop. Because the patient's sense of awareness is clouded, persistent urinary incontinence or urinary retention may be symptomatic of bilateral brain damage. The voiding pattern is analyzed, and the urinal or bedpan is offered on this pattern or schedule. The upright posture and standing position are helpful for male patients during this aspect of rehabilitation.

Patients may have problems with bowel control, particularly constipation. Unless contraindicated, a high-fiber diet and adequate fluid intake (2 to 3 L/day) should be provided and a regular time (usually after breakfast) should be established for toileting. See Chapter 11 for additional information about bowel and bladder control.

Improving Thought Processes

After a stroke, the patient may have problems with cognitive, behavioral, and emotional deficits related to brain damage. However, in many instances, a considerable degree of function can be recovered, because not all areas of the brain are equally damaged; some remain more intact and functional than others.

After assessment that delineates the patient's deficits, the neuropsychologist, in collaboration with the primary care physician, psychiatrist, nurse, and other professionals, structures a training program using cognitive-perceptual retraining, visual imagery, reality orientation, and cueing procedures to compensate for losses.

The role of the nurse is supportive. The nurse reviews the results of neuropsychological testing, observes the patient's performance and progress, gives positive feedback, and, most importantly, conveys an attitude of confidence and hope. Interventions capitalize on the patient's strengths and remaining abilities while attempting to improve performance of affected functions. Other interventions are similar to those for improving cognitive functioning after a head injury (see Chapter 63).

Improving Communication

Aphasia, which impairs the patient's ability to express himself or herself and to understand what is being said, may become apparent in various ways. The cortical area that is responsible for integrating the myriad pathways required for

the comprehension and formulation of language is called Broca's area. It is located in a convolution adjoining the middle cerebral artery. This area is responsible for control of the combinations of muscular movements needed to speak each word. Broca's area is so close to the left motor area that a disturbance in the motor area often affects the speech area. This is why so many patients who are paralyzed on the right side (due to damage or injury to the left side of the brain) cannot speak, whereas those paralyzed on the left side are less likely to have speech disturbances.

The speech therapist assesses the communication needs of the stroke patient, describes the precise deficit, and suggests the best overall method of communication. Most language intervention strategies can be tailored for the individual patient. The patient is expected to take an active part in establishing goals.

A person with aphasia may become depressed. The inability to talk on the telephone, answer a question, or participate in conversation often causes anger, frustration, fear of the future, and hopelessness. Nursing interventions include strategies to make the atmosphere conducive to communication. This includes being sensitive to the patient's reactions and needs and responding to them in an appropriate manner, while always treating the patient as an adult. The nurse provides strong emotional support and understanding to allay anxiety and frustration.

A common pitfall is for the nurse or other health care team member to complete the thoughts or sentences of the patient. This should be avoided, because it causes the patient to become more frustrated at not being allowed to speak and may deter efforts to practice putting thoughts together and completing sentences. A consistent schedule, routines, and repetition help the patient to function despite significant deficits. A written copy of the daily schedule, a folder of personal information (birth date, address, names of relatives), checklists, and an audiotaped list help improve the patient's memory and concentration. The patient may also benefit from a communication board, which has pictures of common needs and phrases. The board may be translated into any language.

When talking with the patient, it is important for the nurse to gain the patient's attention, speak slowly, and keep the language of instruction consistent. One instruction is given at a time, and time is allowed for the patient to process what has been said. The use of gestures may enhance comprehension. Speaking is thinking out loud, and the emphasis is on thinking. Listening and sorting out incoming messages requires mental effort; the patient must struggle against mental inertia and needs time to organize a response.

In working with the patient with aphasia, the nurse must remember to talk to the patient during care activities. This provides social contact for the patient. Chart 62-4 describes points to keep in mind when communicating with the patient with aphasia.

Maintaining Skin Integrity

The patient who has had a stroke may be at risk for skin and tissue breakdown because of altered sensation and inability to respond to pressure and discomfort by turning and moving. Preventing skin and tissue breakdown requires frequent

Chart 62-4 • Communicating With the Patient With Aphasia

- Face the patient and establish eye contact.
- Speak in a normal manner and tone.
- Use short phrases, and pause between phrases to allow the patient time to understand what is being said.
- Limit conversation to practical and concrete matters.
- Use gestures, pictures, objects, and writing.
- As the patient uses and handles an object, say what the object is. It helps to match the words with the object or action.
- Be consistent in using the same words and gestures each time you give instructions or ask a question.
- Keep extraneous noises and sounds to a minimum. Too much background noise can distract the patient or make it difficult to sort out the message being spoken.

assessment of the skin, with emphasis on bony areas and dependent parts of the body. During the acute phase, a specialty bed (eg, low-air-loss bed) may be used until the patient can move independently or assist in moving.

A regular turning schedule (eg, every 2 hours) is adhered to even if pressure-relieving devices are used to prevent tissue and skin breakdown. When the patient is positioned or turned, care must be used to minimize shear and friction forces, which cause damage to tissues and predispose the skin to breakdown.

The patient's skin must be kept clean and dry; gentle massage of healthy (nonreddened) skin and adequate nutrition are other factors that help to maintain normal skin and tissue integrity (see Chapter 11).

Improving Family Coping

Family members play an important role in the patient's recovery. Family members are encouraged to participate in counseling and to use support systems that will help with the emotional and physical stress of caring for the patient. Involving others in the patient's care and teaching stress management techniques and methods for maintaining personal health also facilitate family coping.

The family may have difficulty accepting the patient's disability and may be unrealistic in their expectations. They are given information about the expected outcomes and are counseled to avoid doing activities for the patient that he or she can do. They are assured that their love and interest are part of the patient's therapy.

The family needs to be informed that the rehabilitation of the hemiplegic patient requires many months and that progress may be slow. The gains made by the patient in the hospital or rehabilitation unit must be maintained. All caregivers should approach the patient with a supportive and optimistic attitude, focusing on the patient's remaining abilities. The rehabilitation team, the medical and nursing team, the patient, and the family must all be involved in developing attainable goals for the patient at home.

Most relatives of patients with stroke handle the physical changes better than the emotional aspects of care. The family should be prepared to expect occasional episodes of

emotional lability. The patient may laugh or cry easily and may be irritable and demanding or depressed and confused. The nurse can explain to the family that the patient's laughter does not necessarily connote happiness, nor does crying reflect sadness, and that emotional lability usually improves with time.

Helping the Patient Cope With Sexual Dysfunction

Sexual functioning can be profoundly altered by stroke. Although research in this area of stroke management is limited, it appears that patients who have had a stroke consider sexual function important, and many have sexual dysfunction. Sexual dysfunction after stroke is multifactorial. There may be medical reasons for the dysfunction (neurologic and cognitive deficits, previous diseases, medications), as well as various psychosocial factors, including depression. A stroke is such a catastrophic illness that the patient experiences loss of self-esteem and value as a sexual being. These psychosocial factors play an important role in determining sexual drive, activity, and satisfaction after a stroke.

Nurses in the rehabilitation setting play a crucial role in beginning a dialogue between the patient and his or her partner about sexuality after a stroke. In-depth assessments to determine sexual history before and after the stroke should be followed by appropriate interventions. Interventions for the patient and partner focus on providing relevant information, education, reassurance, adjustment of medications, counseling regarding coping skills, suggestions for alternative sexual positions, and a means of sexual expression and satisfaction (Kautz, 2007).

Promoting Home and Community-Based Care

TEACHING PATIENTS SELF-CARE. Patient and family education is a fundamental component of rehabilitation. The nurse provides teaching about stroke, its causes and prevention, and the rehabilitation process. In both acute care and rehabilitation facilities, the focus is on teaching the patient to resume as much self-care as possible. This may entail using assistive devices or modifying the home environment to help the patient live with a disability.

An occupational therapist may be helpful in assessing the home environment and recommending modifications to help the patient become more independent. For example, a shower is more convenient than a tub for the patient with hemiplegia because most patients do not gain sufficient strength to get up and down from a tub. Sitting on a stool of medium height with rubber suction tips allows the patient to wash with greater ease. A long-handled bath brush with a soap container is helpful to the patient who has only one functional hand. If a shower is not available, a stool may be placed in the tub and a portable shower hose attached to the faucet. Handrails may be attached alongside the bathtub and the toilet. Other assistive devices include special utensils for eating, grooming, dressing, and writing (see Chart 62-3).

A program of physical therapy can be beneficial, whether it takes place in the home or in an outpatient program. Recent research has focused on techniques using robotics and constraint-induced movement therapy. Constraint-induced movement therapy involves constraint of the less affected upper limb with a mitt and intensely training the more

affected limb. This technique has shown improved arm function in patients who had a stroke 3 to 9 months prior to receiving the treatment (Wolf, Winstein, Miller, et al., 2006). Robot-assisted therapy uses sensorimotor training of the upper limb. This method allows patients to train without the presence of a therapist.

CONTINUING CARE. The recovery and rehabilitation process after stroke may be prolonged and requires patience and perseverance on the part of both the patient and the family. Depending on the specific neurologic deficits resulting from the stroke, the patient at home may require the services of a number of health care professionals. The nurse often coordinates the care of the patient at home and considers the many educational needs of caregivers and patients. The family (often the spouse) requires education as well as assistance in planning and providing care.

The family is advised that the patient may tire easily, may become irritable and upset by small events, and may be less interested in events than expected. Emotional problems associated with stroke are often related to speech dysfunction and the frustrations of being unable to communicate. A speech therapist allows the family to be involved and gives the family practical instructions to help the patient between therapy sessions.

Depression is a common and serious problem in the patient who has had a stroke. Incidence of depression in patients who have had a stroke ranges from less than 10% to more than 50%. Risk factors include increased severity of stroke, a history of depression, and cognitive or physical impairment (Johnson, Minarik, Nyström, et al., 2006). Nurses should identify patients who may be at risk while they are in the hospital. In the home or in the rehabilitation setting, nurses may be involved in coordinating care and referring patients and family to appropriate resources. The family can help by continuing to support the patient and by giving positive reinforcement for the progress that is being made. Antidepressant therapy may help if depression dominates the patient's life.

Community-based stroke support groups may allow the patient and family to learn from others with similar problems and to share their experiences. Support groups take the form of in-person meetings as well as Internet-based support programs. The patient is encouraged to continue hobbies and recreational and leisure interests and to maintain contact with friends to prevent social isolation. All nurses coming in contact with the patient should encourage the patient to keep active, adhere to the exercise program, and remain as self-sufficient as possible.

The nurse should recognize the potential effects of caregiving on the family. Not all families have the adaptive coping skills and adequate psychological functioning necessary for the long-term care of another person. The patient's spouse may be elderly, with his or her own health concerns; in some instances, the patient may have been the provider of care to the spouse. A spouse may have to take on new roles and responsibilities in the relationship and around the home. He or she may also feel a sense of loss (of freedom and leisure time as well as of the marital relationship) (Chart 62-5).

Depression is common in caregivers of stroke survivors, and it may last 18 months or more (Berg, Palomäki,

CHART
62-5 **NURSING RESEARCH PROFILE**
Spouses Caring for Stroke Survivors

Coombs, U. (2007). Spousal caregiving for stroke survivors. *Journal of Neuroscience Nursing*, 39(2), 112–119.

Purpose

Survivors of a stroke may be discharged to an acute rehabilitation facility or skilled nursing facility. The ultimate goal after a stroke is to have survivors return home. A spouse plays an important role in caring for stroke survivors and also provides much-needed emotional support. The purpose of this study was to explore the phenomenon of spousal caregiving from the perspective of the spousal caregivers (the lived experience of spousal caregivers).

Design

This phenomenologic study was guided by the research question: What is it like for older caregivers to care for a spouse who has survived a stroke? This study used eight interviews from adults who were at least 50 years of age and were caring for a stroke survivor who was at least 1 year poststroke. Data were collected through taped interviews. Each participant had two separate interviews lasting 60 to 120 minutes using an interview guide containing five to six questions. Participants were asked to describe their caregiv-

ing experience, and the interview guide questions were used as prompts if needed.

Findings

Five females and three males participated, the mean age was 65 years, and all were married. The number of years caring for their spouses ranged from 1.5 to 5 years. The mean age of the stroke survivors was 68 years. Six themes emerged for this study: experiencing a profound sense of loss, adjusting to a new relationship with the spouse, taking on a new responsibility, feeling the demands of caregiving, having to depend on others, and maintaining hope and optimism.

Nursing Implications

The findings of this study may help nurses working in hospital, rehabilitation, community, or home health care settings understand the impact of caregiving on spouses. More attention should be given to the spouse in the acute care setting, and support resources should be provided. By being aware of the particular concerns of caregivers, nurses may anticipate problems and stresses that caregivers may encounter.

Lönnqvist, et al., 2005). Nurses should assess caregivers for signs of depression (Lightbody, Auton, Baldwin, et al., 2007). Caregivers who are depressed may be more likely to resort to physical or emotional abuse of the patient and to place the patient in a nursing home.

Caregivers may require reminders to attend to their own health concerns and well-being. Even healthy caregivers may find it difficult to maintain a schedule that includes being available around the clock. The nurse encourages the family to arrange for respite care services (planned short-term care to relieve the family from having to provide continuous 24-hour care), which may be available from an adult day care center. Some hospitals also offer weekend respite care that can provide caregivers with needed time for themselves. The nurse involved in home and continuing care also needs to remind the patient and family of the need for respite care as well as continuing health promotion and screening practices.

Evaluation

Expected Patient Outcomes

Expected patient outcomes may include the following:

1. Achieves improved mobility
 - a. Avoids deformities (contractures and footdrop)
 - b. Participates in prescribed exercise program
 - c. Achieves sitting balance
 - d. Uses unaffected side to compensate for loss of function of hemiplegic side
2. Reports absence of shoulder pain
 - a. Demonstrates shoulder mobility; exercises shoulder
 - b. Elevates arm and hand at intervals
3. Achieves self-care; performs hygiene care; uses adaptive equipment

4. Demonstrates techniques to compensate for altered sensory reception, such as turning the head to see people or objects
5. Demonstrates safe swallowing
6. Achieves normal bowel and bladder elimination
7. Participates in cognitive improvement program
8. Demonstrates improved communication
9. Maintains intact skin without breakdown
 - a. Demonstrates normal skin turgor
 - b. Participates in turning and positioning activities
10. Family members demonstrate a positive attitude and coping mechanisms
 - a. Encourage patient in exercise program
 - b. Take an active part in rehabilitation process
 - c. Contact respite care programs or arrange for other family members to assume some responsibilities for care
11. Develops alternative approaches to sexual expression

Hemorrhagic Stroke

Hemorrhagic strokes account for 15% to 20% of cerebrovascular disorders and are primarily caused by intracranial or subarachnoid hemorrhage. Hemorrhagic strokes are caused by bleeding into the brain tissue, the ventricles, or the subarachnoid space. Primary intracerebral hemorrhage from a spontaneous rupture of small vessels accounts for approximately 80% of hemorrhagic strokes and is caused chiefly by uncontrolled hypertension. Subarachnoid hemorrhage results from a ruptured intracranial **aneurysm** (a weakening in the arterial wall) in about half the cases (Hickey, 2009).

Another common cause of intracerebral hemorrhage in the elderly is cerebral amyloid angiopathy, which involves damage caused by the deposit of beta-amyloid protein in the small and medium-sized blood vessels of the brain. Secondary intracerebral hemorrhage is associated with arteriovenous malformations (AVMs), intracranial aneurysms, intracranial neoplasms, or certain medications (eg, anticoagulants, amphetamines). The mortality rate has been reported to be as high as 48% at 30 days after an intracranial hemorrhage (Flaherty, Haverbusch, Sekar, et al., 2006). Patients who survive the acute phase of care usually have more severe deficits and a longer recovery phase compared to those with ischemic stroke.

Pathophysiology

The pathophysiology of hemorrhagic stroke depends on the cause and type of cerebrovascular disorder. Symptoms are produced when a primary hemorrhage, aneurysm, or AVM presses on nearby cranial nerves or brain tissue or, more dramatically, when an aneurysm or AVM ruptures, causing subarachnoid hemorrhage (hemorrhage into the cranial subarachnoid space). Normal brain metabolism is disrupted by the brain's exposure to blood; by an increase in ICP resulting from the sudden entry of blood into the subarachnoid space, which compresses and injures brain tissue; or by secondary ischemia of the brain resulting from the reduced perfusion pressure and vasospasm that frequently accompany subarachnoid hemorrhage.

Intracerebral Hemorrhage

An intracerebral hemorrhage, or bleeding into the brain tissue, is most common in patients with hypertension and cerebral atherosclerosis, because degenerative changes from these diseases cause rupture of the blood vessel. An intracerebral hemorrhage may also result from certain types of arterial pathology, brain tumors, and the use of medications (eg, oral anticoagulants, amphetamines, and illicit drug use).

Bleeding occurs most commonly in the cerebral lobes, basal ganglia, thalamus, brain stem (mostly the pons), and cerebellum (Hickey, 2009). Occasionally, the bleeding ruptures the wall of the lateral ventricle and causes intraventricular hemorrhage, which is frequently fatal.

Intracranial (Cerebral) Aneurysm

An intracranial (cerebral) aneurysm is a dilation of the walls of a cerebral artery that develops as a result of weakness in the arterial wall. The cause of aneurysms is unknown, although research is ongoing. An aneurysm may be due to atherosclerosis, which results in a defect in the vessel wall with subsequent weakness of the wall; a congenital defect of the vessel wall; hypertensive vascular disease; head trauma; or advancing age.

Any artery within the brain can be the site of a cerebral aneurysm, but these lesions usually occur at the bifurcations of the large arteries at the circle of Willis (Fig. 62-5). The cerebral arteries most commonly affected by an aneurysm are the internal carotid artery (ICA), anterior cerebral artery (ACA), anterior communicating artery (ACoA), posterior communicating artery (PCoA), posterior cerebral artery (PCA), and middle cerebral artery (MCA). Multiple cerebral aneurysms are not uncommon.

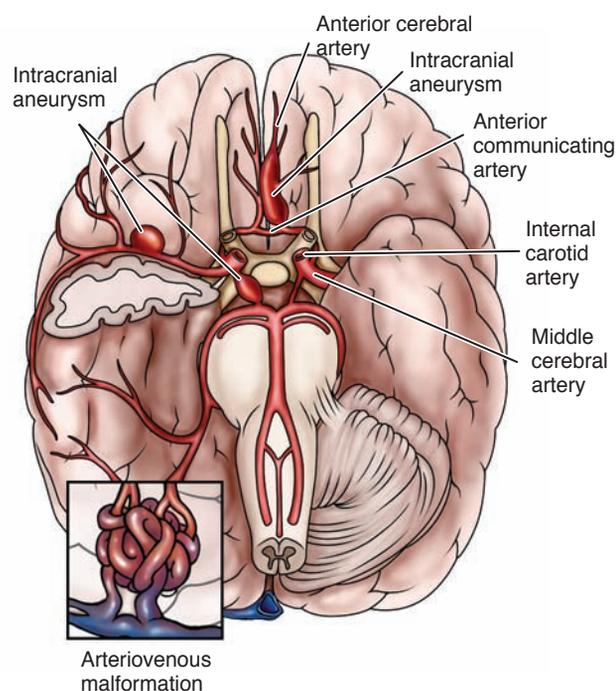

Figure 62-5 Common sites of intracranial aneurysms and an arteriovenous malformation.

Arteriovenous Malformations

Most AVMs are caused by an abnormality in embryonal development that leads to a tangle of arteries and veins in the brain that lacks a capillary bed (see Fig. 62-5). The absence of a capillary bed leads to dilation of the arteries and veins and eventual rupture. AVM is a common cause of hemorrhagic stroke in young people.

Subarachnoid Hemorrhage

A subarachnoid hemorrhage (hemorrhage into the subarachnoid space) may occur as a result of an AVM, intracranial aneurysm, trauma, or hypertension. The most common causes are a leaking aneurysm in the area of the circle of Willis and a congenital AVM of the brain.

Clinical Manifestations

The patient with a hemorrhagic stroke can present with a wide variety of neurologic deficits, similar to the patient with ischemic stroke. The conscious patient most commonly reports a severe headache. A comprehensive assessment reveals the extent of the neurologic deficits. Many of the same motor, sensory, cranial nerve, cognitive, and other functions that are disrupted after ischemic stroke are also altered after a hemorrhagic stroke. Table 62-2 reviews the neurologic deficits frequently seen in stroke patients. Table 62-3 compares the symptoms seen in right hemispheric stroke with those seen in left hemispheric stroke. Other symptoms that may be observed more frequently in patients with acute intracerebral hemorrhage (compared with ischemic stroke) are vomiting, an early sudden change in level of consciousness, and possibly focal seizures due to frequent brain stem involvement (Hickey, 2009).

In addition to the neurologic deficits (similar to those of ischemic stroke), the patient with an intracranial aneurysm or AVM may have some unique clinical manifestations. Rupture of an aneurysm or AVM usually produces a sudden, unusually severe headache and often loss of consciousness for a variable period of time. There may be pain and rigidity of the back of the neck (nuchal rigidity) and spine due to meningeal irritation. Visual disturbances (visual loss, diplopia, ptosis) occur if the aneurysm is adjacent to the oculomotor nerve. Tinnitus, dizziness, and hemiparesis may also occur.

At times, an aneurysm or AVM leaks blood, leading to the formation of a clot that seals the site of rupture. In this instance, the patient may show little neurologic deficit. In other cases, severe bleeding occurs, resulting in cerebral damage, followed rapidly by coma and death.

Prognosis depends on the neurologic condition of the patient, the patient's age, associated diseases, and the extent and location of the hemorrhage or intracranial aneurysm. Subarachnoid hemorrhage from an aneurysm is a catastrophic event with significant morbidity and mortality. Chart 62-6 presents ethical issues related to the patient with a severe hemorrhagic stroke.

Assessment and Diagnostic Findings

Any patient with suspected stroke should undergo a CT scan or MRI to determine the type of stroke, the size and location of the hematoma, and the presence or absence of ventricular blood and hydrocephalus. Cerebral angiography confirms the diagnosis of an intracranial aneurysm or AVM. These tests show the location and size of the lesion and provide information about the affected arteries, veins, adjoin-

ing vessels, and vascular branches. Lumbar puncture is performed if there is no evidence of increased ICP, the CT scan results are negative, and subarachnoid hemorrhage must be confirmed. Lumbar puncture in the presence of increased ICP could result in brain stem herniation or rebleeding. When diagnosing a hemorrhagic stroke in a patient younger than 40 years of age, some clinicians obtain a toxicology screen for illicit drug use.

Prevention

Primary prevention of hemorrhagic stroke is the best approach and includes managing hypertension and ameliorating other significant risk factors. Control of hypertension, especially in people older than 55 years of age, reduces the risk of hemorrhagic stroke (Luders, 2007). Additional risk factors are increased age, male gender, and excessive alcohol intake. Stroke risk screenings provide an ideal opportunity to lower hemorrhagic stroke risk by identifying high-risk individuals or groups and educating patients and the community about recognition and prevention.

Complications

Potential complications of hemorrhagic stroke include rebleeding or hematoma expansion; cerebral vasospasm resulting in cerebral ischemia; acute hydrocephalus, which results when free blood obstructs the reabsorption of cerebrospinal fluid (CSF) by the arachnoid villi; and seizures.

Cerebral Hypoxia and Decreased Blood Flow

Immediate complications of a hemorrhagic stroke include cerebral hypoxia, decreased cerebral blood flow, and extension of the area of injury. Providing adequate oxygenation of blood to the brain minimizes cerebral hypoxia. Brain function depends on delivery of oxygen to the tissues. Administering supplemental oxygen and maintaining the hemoglobin and hematocrit at acceptable levels will assist in maintaining tissue oxygenation.

Cerebral blood flow is dependent on the blood pressure, cardiac output, and integrity of cerebral blood vessels. Adequate hydration (IV fluids) must be ensured to reduce blood viscosity and improve cerebral blood flow. Extremes of hypertension or hypotension need to be avoided to prevent changes in cerebral blood flow and the potential for extending the area of injury.

A seizure can also compromise cerebral blood flow, resulting in further injury to the brain. Observing for seizure activity and initiating appropriate treatment are important components of care after a hemorrhagic stroke.

Vasospasm
