EBP 2 You are caring for a 40-year-old man who recently had an AV sequential pacemaker inserted, with the rate set at 72 bpm. When taking his pulse, you note that his heart rate is 66 bpm. Describe the possible causes of this difference in heart rate and the nursing actions that are needed. The patient's wife tells you that her husband has informed her that now that he has a pacemaker, they must get rid of their microwave oven. What would you say to the wife and patient about this? What other education would you provide to them about safety in relation to the pacemaker? What is the evidence base that supports this education? Discuss the strength of the evidence and the criteria used to evaluate the strength of the evidence.

EBP 3 You are working as an occupational health nurse in a building that employs several people with significant cardiac risk factors. The organization's safety officer has asked you about purchasing and installing an AED. What other information would you need before you reply? Discuss the evidence that supports your answer.

4 Your patient is an 89-year-old man with atrial fibrillation. He is complaining about all the pills that he is taking and the time-consuming monitoring of them. He tells you that he wants to stop taking his antithrombotic medication. What are his options? How would you discuss this issue with him? How would you explore his issue about medications?

chapter 28

Management of Patients With Coronary Vascular Disorders

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

- 1 Describe the pathophysiology, clinical manifestations, and treatment of coronary atherosclerosis.
- 2 Describe the pathophysiology, clinical manifestations, and treatment of angina pectoris.
- 3 Use the nursing process as a framework for care of patients with angina pectoris.
- 4 Describe the pathophysiology, clinical manifestations, and treatment of myocardial infarction.
- 5 Use the nursing process as a framework for care of a patient with acute coronary syndrome.
- 6 Describe percutaneous coronary interventional and coronary artery revascularization procedures.
- 7 Describe the nursing care of a patient who has had a percutaneous coronary interventional procedure for treatment of coronary artery disease.
- 8 Describe the nursing care of a patient who has undergone cardiac surgery.

GLOSSARY

acute coronary syndrome (ACS): signs and symptoms that indicate unstable angina or acute myocardial infarction

angina pectoris: chest pain brought about by myocardial ischemia

atheroma: fibrous cap composed of smooth muscle cells that forms over lipid deposits within arterial vessels and protrudes into the lumen of the vessel, narrowing the lumen and obstructing blood flow; also called plaque

atherosclerosis: abnormal accumulation of lipid deposits and fibrous tissue within arterial walls and the lumen

contractility: ability of the cardiac muscle to shorten in response to an electrical impulse

coronary artery bypass graft (CABG): a surgical procedure in which a blood vessel from another part of the body is grafted onto the occluded coronary artery below the occlusion in such a way that blood flow bypasses the blockage

creatinine kinase (CK): an enzyme found in human tissues; one of the three types of CK is specific to heart muscle and may be used as an indicator of heart muscle injury

GLOSSARY (Continued)

high-density lipoprotein (HDL): a protein-bound lipid that transports cholesterol to the liver for excretion in the bile; composed of a higher proportion of protein to lipid than low-density lipoprotein; exerts a beneficial effect on the arterial wall

ischemia: insufficient tissue oxygenation

low-density lipoprotein (LDL): a protein-bound lipid that transports cholesterol to tissues in the body; composed of a lower proportion of protein to lipid than high-density lipoprotein; exerts a harmful effect on the arterial wall

metabolic syndrome: a cluster of metabolic abnormalities including insulin resistance, obesity, dyslipidemia, and hypertension that increase the risk of cardiovascular disease

myocardial infarction (MI): death of heart tissue caused by lack of oxygenated blood flow

percutaneous coronary intervention (PCI): an invasive procedure in which a catheter is placed in a coronary artery, and one of several methods is employed to remove or reduce a blockage within the artery

percutaneous transluminal coronary angioplasty (PTCA): a type of percutaneous coronary intervention in which a balloon is inflated within a coronary artery to break an atheroma and open the vessel lumen, improving coronary artery blood flow

stent: a woven mesh that provides structural support to a coronary vessel, preventing its closure

sudden cardiac death: abrupt cessation of effective heart activity

thrombolytic: an agent or process that breaks down blood clots

troponin: myocardial protein; measurement is used to assess heart muscle injury

Cardiovascular disease is the leading cause of death in the United States for men and women of all racial and ethnic groups (American Heart Association [AHA], 2007). Research related to the identification and treatment of cardiovascular disease includes all segments of the population affected by cardiac conditions, including women, children, and people of diverse racial and ethnic backgrounds. This research aims to identify specific prevention and treatment strategies in these populations.

CORONARY ARTERY DISEASE

Coronary artery disease (CAD) is the most prevalent type of cardiovascular disease in adults. For this reason, it is important for nurses to become familiar with various manifestations of coronary artery conditions and methods for assessing, preventing, and treating these disorders.

Coronary Atherosclerosis

The most common cause of cardiovascular disease in the United States is **atherosclerosis**, an abnormal accumulation of lipid, or fatty substances, and fibrous tissue in the lining of arterial blood vessel walls. These substances block and narrow the coronary vessels in a way that reduces blood flow to the myocardium. Atherosclerosis involves a repetitious inflammatory response to injury of the artery wall and subsequent alteration in the structural and biochemical properties of the arterial walls. New information that relates to the development of atherosclerosis has increased the understanding of treatment and prevention of this progressive and potentially life-threatening process.

Pathophysiology

Atherosclerosis is thought to begin as fatty streaks of lipids that are deposited in the intima of the arterial wall. These lesions commonly begin early in life, perhaps even in childhood. Not all fatty streaks later develop into advanced lesions. Genetics and environmental factors are involved in the progression of these lesions. The development of atherosclerosis over many years involves an inflammatory response, which begins with injury to the vascular endothelium (Futerman & Lemberg, 2006). The injury may be initiated by smoking, hypertension, and other factors. The presence of inflammation has multiple effects on the arterial wall, including the attraction of inflammatory cells, such as monocytes (macrophages). The macrophages ingest lipids, becoming “foam cells” that transport the lipids into the arterial wall. Activated macrophages also release biochemical substances that can further damage the endothelium, attracting platelets and initiating clotting (Carreiro-Lewandowski, 2006).

Smooth muscle cells within the vessel wall subsequently proliferate and form a fibrous cap over a core filled with lipid and inflammatory infiltrate. These deposits, called **atheromas** or plaques, protrude into the lumen of the vessel, narrowing it and obstructing blood flow (Fig. 28-1). Plaque may be stable or unstable, depending on the degree of inflammation and thickness of the fibrous cap. If the fibrous cap over the plaque is thick and the lipid pool remains

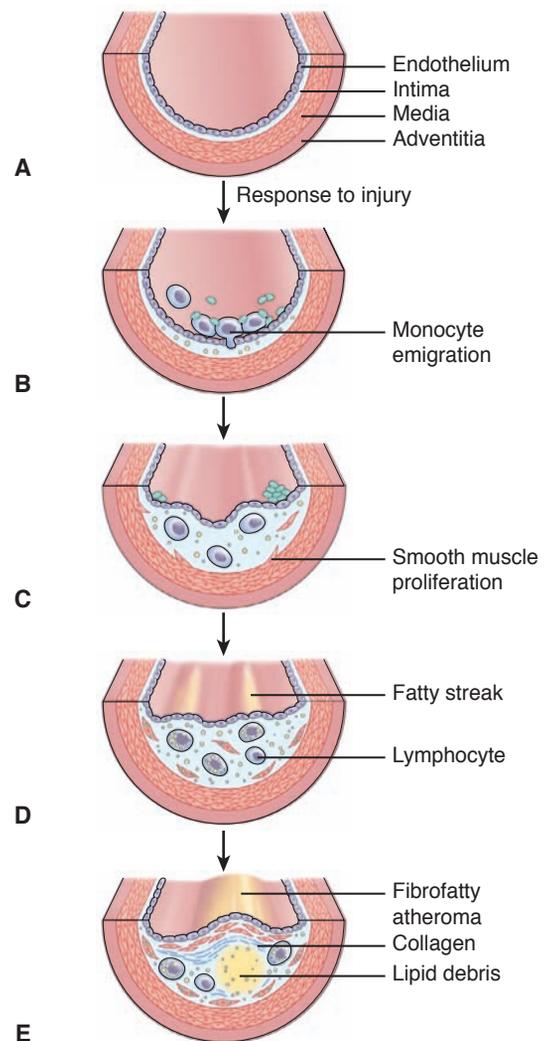

Figure 28-1 A, B, Atherosclerosis begins as monocytes and lipids enter the intima of an injured vessel. Smooth muscle cells proliferate within the vessel wall, C, contributing to the development of fatty accumulations and atheroma, D. As the plaque enlarges, the vessel narrows and blood flow decreases, E. The plaque may rupture and a thrombus might form, obstructing blood flow.

relatively stable, it can resist the stress of blood flow and vessel movement. If the cap is thin and inflammation is ongoing, the lesion becomes what is called vulnerable plaque. At this point, the lipid core may grow, causing it to rupture and hemorrhage into the plaque. A ruptured plaque is a focus for thrombus formation. The thrombus may then obstruct blood flow, leading to **acute coronary syndrome (ACS)**, which may result in an **acute myocardial infarction (MI)** if quick, decisive action is not taken. When an MI occurs, a portion of the heart muscle becomes necrotic.

The anatomic structure of the coronary arteries makes them particularly susceptible to the mechanisms of atherosclerosis. As Figure 28-2 shows, the three major coronary arteries have multiple branches. Atherosclerotic lesions most often form where the vessels branch, suggesting a hemodynamic component that favors their formation (Porth & Matfin, 2009). Although heart disease is most often caused by atherosclerosis of the coronary arteries, other phenomena

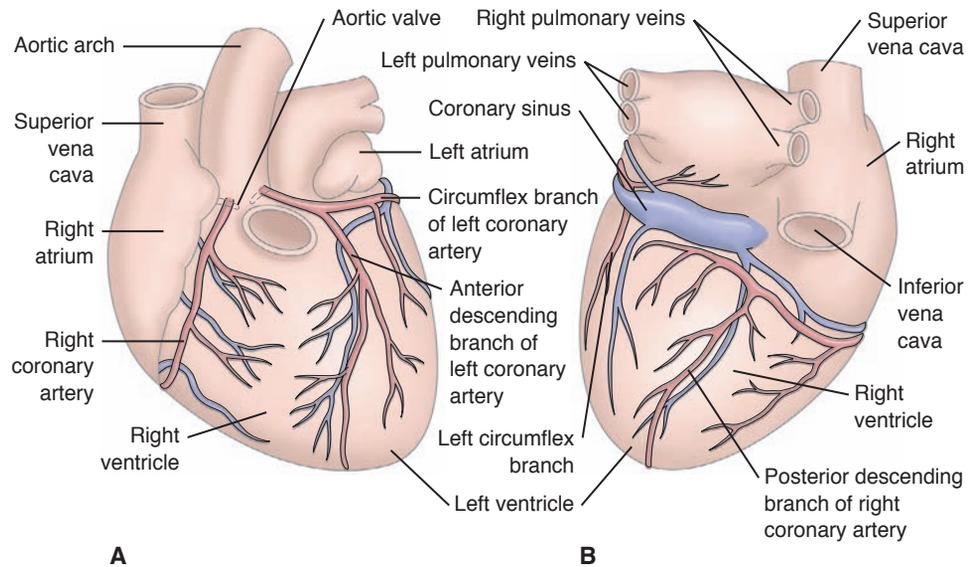

Figure 28-2 The coronary arteries supply the heart muscle with oxygenated blood, adjusting the flow according to metabolic needs. **A**, Anterior view and, **B**, posterior view of heart.

may also decrease blood flow to the heart. Examples include vasospasm (sudden constriction or narrowing) of a coronary artery, myocardial trauma from internal or external forces, structural disease, congenital anomalies, decreased oxygen supply (eg, from acute blood loss, anemia, or low blood pressure), and increased oxygen demand (eg, from rapid heart rate, thyrotoxicosis, or use of cocaine).

Clinical Manifestations

CAD produces symptoms and complications according to the location and degree of narrowing of the arterial lumen, thrombus formation, and obstruction of blood flow to the myocardium. This impediment to blood flow is usually progressive, causing an inadequate blood supply that deprives the cardiac muscle cells of oxygen needed for their survival. The condition is known as **ischemia**. **Angina pectoris** refers to chest pain that is brought about by myocardial ischemia. Angina pectoris usually is caused by significant coronary atherosclerosis. If the decrease in blood supply is great enough, of long enough duration, or both, irreversible damage and death of myocardial cells may result. Over time, irreversibly damaged myocardium undergoes degeneration and is replaced by scar tissue, causing various degrees of myocardial dysfunction. Significant myocardial damage may result in persistently low cardiac output and heart failure where the heart cannot support the body's needs for blood. A decrease in blood supply from CAD may even cause the heart to abruptly stop beating (**sudden cardiac death**).

The most common manifestation of myocardial ischemia is the onset of chest pain. However, the classic epidemiologic study of the people in Framingham, Massachusetts, showed that nearly 15% of men and women who had coronary events, which included unstable angina, MIs, or sudden cardiac death events, were totally asymptomatic prior to the coronary event (Kannel, 1986). Patients with myocardial ischemia may present to an emergency department or clinic with a variety of symptoms other than chest pain. Patients who are older or have a history of diabetes or heart failure may report symptoms such as shortness of breath. Many women have been found to have atypical symptoms, including dyspnea, nausea,

and weakness (Canto, Goldberg, Hand, et al., 2007). Prodromal symptoms may occur (ie, angina a few hours to days before the acute episode), or a major cardiac event may be the first indication of coronary atherosclerosis.

Risk Factors

Epidemiologic studies point to several factors that increase the probability that a person will develop heart disease. Major risk factors are listed in Chart 28-1. Some people do not have classic risk factors. Elevated **low-density lipoprotein (LDL)** cholesterol, also known as bad cholesterol, is the primary target of cholesterol-lowering therapy. People at highest risk for having a cardiac event within 10 years are those with known CAD or those with diabetes, peripheral arterial disease, abdominal aortic aneurysm, or carotid artery disease. The latter diseases are called CAD risk equivalents, because patients with these diseases have the same risk for a cardiac event as patients with CAD. The likelihood of having a cardiac event within 10 years is also affected by factors such as age, systolic blood pressure, smoking history, level of total cholesterol, level of LDL, and level of **high-density lipoprotein (HDL)**, also known as good cholesterol.

In addition, a cluster of metabolic abnormalities known as **metabolic syndrome** has emerged as a major risk factor for cardiovascular disease (Porth & Matfin, 2009; Xu & Whitmer, 2006; Zacho, Tyboerg-Hanson, Jensen, et al., 2008). A diagnosis of this syndrome includes three of the following conditions:

- Insulin resistance (fasting plasma glucose more than 100 mg/dL or abnormal glucose tolerance test)
- Central obesity (waist circumference more than 35 inches in women, more than 40 inches in men)
- Dyslipidemia (triglycerides more than 150 mg/dL, HDL less than 50 mg/dL in women, less than 40 mg/dL in men)
- Blood pressure persistently greater than 130/85 mm Hg
- Proinflammatory state (high levels of C-reactive protein)
- Prothrombotic state (high fibrinogen level)

CHART
28-1

Risk Factors for Coronary Artery Disease

A modifiable risk factor is one over which a person may exercise control, such as by changing a lifestyle or personal habit or by using medication. A nonmodifiable risk factor is a circumstance over which a person has no control. A risk factor may operate independently or in tandem with other risk factors. The more risk factors a person has, the greater the likelihood of coronary artery disease (CAD). Those at risk are advised to seek regular medical examinations and to engage in “heart-healthy” behavior (a deliberate effort to reduce the number and extent of risks).

Nonmodifiable Risk Factors

Family history of CAD (first-degree relative with cardiovascular disease at 55 years of age or younger for men and at 65 years of age or younger for women)

Increasing age (more than 45 years for men; more than 55 years for women)

Gender (men develop CAD at an earlier age than women)

Race (higher incidence of heart disease in African Americans than in Caucasians)

Modifiable Risk Factors

Hyperlipidemia

Cigarette smoking, tobacco use

Hypertension

Diabetes mellitus

Metabolic syndrome

Obesity

Physical inactivity

Many people with type 2 diabetes mellitus fit this clinical picture. It is theorized that in obese patients, excessive adipose tissue may secrete mediators that lead to metabolic changes. Adipokines (adipose tissue cytokines), free fatty acids, and other substances are known to modify insulin action and contribute to atherogenic changes in the cardiovascular system (Fig. 28-3).

C-reactive protein (CRP) is known to be an inflammatory marker for cardiovascular risk, including acute coronary events and stroke. The liver produces CRP in response to a stimulus such as tissue injury, and high levels of this protein may occur in people with diabetes and those who are likely to have an acute coronary event (Xu & Whitmer, 2006; Zacho, et al., 2008). To determine overall cardiovascular risk, clinicians view high sensitivity (hs-CRP) test results together with other screening tools such as measurements of lipid levels.

Prevention

Four modifiable risk factors—cholesterol abnormalities, tobacco use, hypertension, and diabetes mellitus—have been cited as major risk factors for CAD and its complications. As a result, they receive much attention in health promotion programs.

Controlling Cholesterol Abnormalities

The Third Report of the Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults (ATP III), published in 2001 and updated in 2006, lists the clinical guidelines for cholesterol testing and management

Physiology ■ Pathophysiology

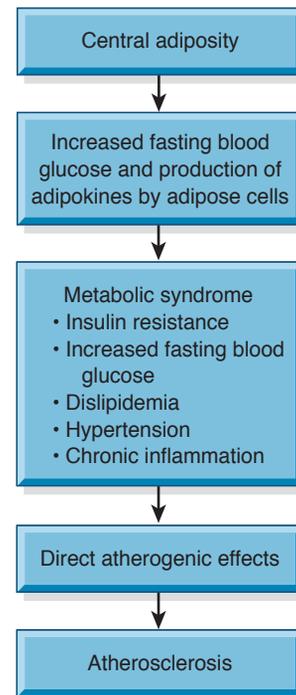

Figure 28-3 Pathophysiology of cardiovascular disease in metabolic syndrome. Central adiposity plays a major role in the development of metabolic syndrome. Adipokines (such as leptin) and other hormones and metabolites are thought to contribute to the development of metabolic abnormalities. The eventual effect of these processes is the promotion of atherosclerosis.

(Institute for Clinical Systems Improvement [ICSI], 2006b). These guidelines address primary prevention (preventing the occurrence of CAD) and secondary prevention (preventing the progression of CAD). The association of a high blood cholesterol level with heart disease is well established. The metabolism of fats is an important contributor to the development of heart disease. Fats, which are insoluble in water, are encased in water-soluble lipoproteins that allow them to be transported within the circulatory system. The various lipoproteins are categorized by their protein content, which is measured in density. The density increases when more protein is present. Four elements of fat metabolism—total cholesterol, LDL, HDL, and triglycerides—are known to affect the development of heart disease. Cholesterol is processed by the gastrointestinal tract into lipoprotein globules called chylomicrons. These are reprocessed by the liver as lipoproteins (Fig. 28-4). This is a physiologic process necessary for the formation of lipoprotein-based cell membranes and other important metabolic processes. When an excess of LDL is produced, LDL particles adhere to vulnerable points in the arterial endothelium. Here macrophages ingest them, contributing to plaque formation.

All adults 20 years of age or older should have a fasting lipid profile (total cholesterol, LDL, HDL, and triglyceride) performed at least once every 5 years and more often if the profile is abnormal. Patients who have had an

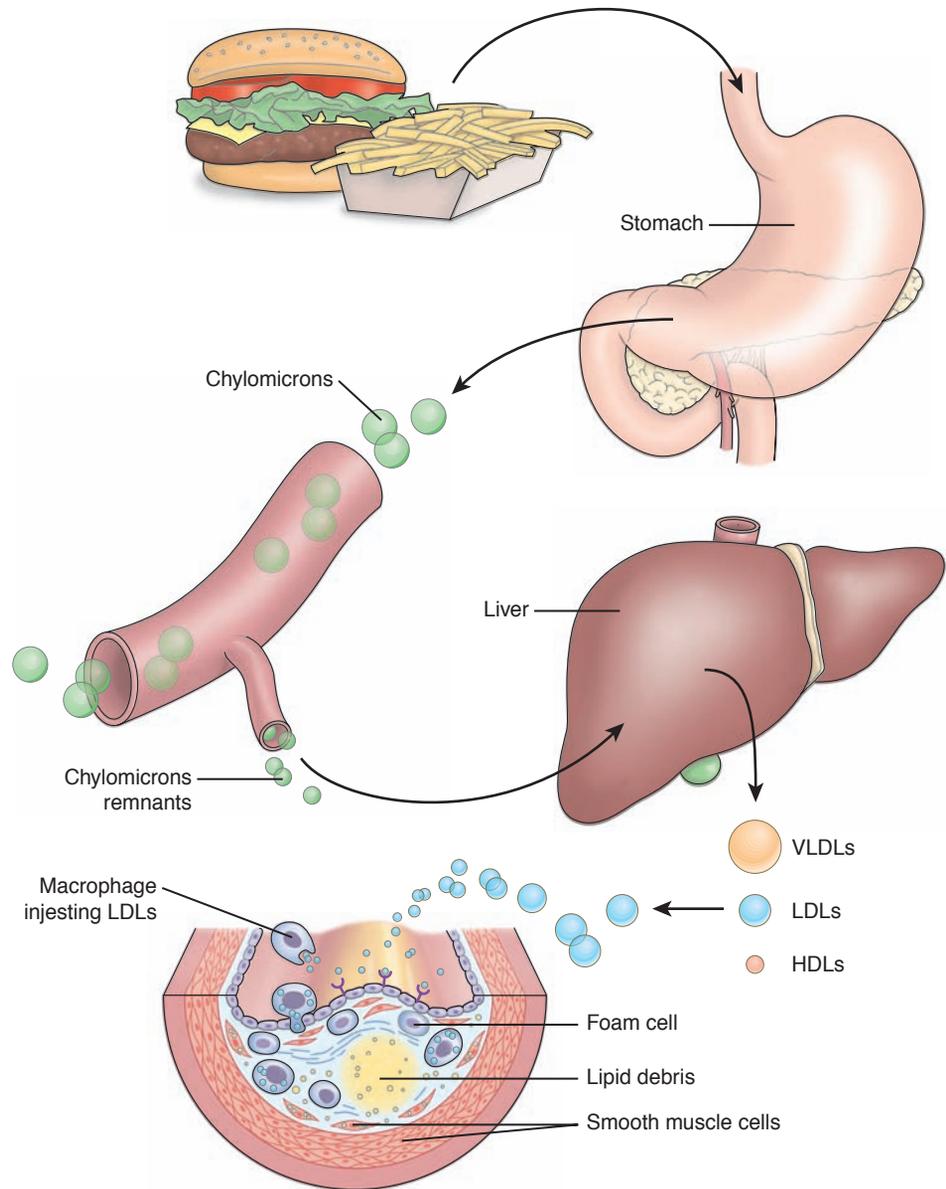

Figure 28-4 Lipoproteins and the development of atherosclerosis. As dietary cholesterol and saturated fat are processed by the gastrointestinal tract, chylomicrons enter the blood. They are broken down into chylomicron remnants in the capillaries. The liver processes them into lipoproteins. When these are released into the circulation, excess low-density lipoproteins (LDLs) adhere to receptors on the intimal wall. Macrophages also ingest LDLs and transport them into the vessel wall, beginning the process of plaque formation. HDLs, high-density lipoproteins; VLDL, very low-density lipoprotein.

acute event (eg, MI), a **percutaneous coronary intervention (PCI)**, or a **coronary artery bypass graft (CABG)** require assessment of their LDL cholesterol level within a few months of the event or procedure because LDL levels may be low immediately after the acute event or procedure. Subsequently, lipids should be monitored every 6 weeks until the desired level is achieved and then every 4 to 6 months. A fasting lipid profile should demonstrate the following values (Grundy, Cleeman, Daniels, et al., 2005):

- LDL cholesterol less than 100 mg/dL (less than 70 mg/dL for very high-risk patients)
- Total cholesterol less than 200 mg/dL
- HDL cholesterol greater than 60 mg/dL
- Triglyceride less than 150 mg/dL

LDL is the target of current therapy because of the known association with advancing CAD. The total cholesterol level is also a clear predictor of coronary events. HDL,

as previously stated, is known as good cholesterol because it transports other lipoproteins such as LDL to the liver, where they can be degraded and excreted. Because of this, a high HDL level is a strong negative risk factor for heart disease (ie, it protects against heart disease).

Triglyceride is another fatty substance, made up of fatty acids, that is transported through the blood by a lipoprotein. Although an elevated triglyceride level (more than 200 mg/dL) may be genetic in origin, it also can be caused by obesity, physical inactivity, excessive alcohol intake, high-carbohydrate diets, diabetes mellitus, kidney disease, and certain medications, such as oral contraceptives and corticosteroids.

Dietary Measures

Table 28-1 provides recommendations of the Therapeutic Lifestyle Changes (TLC) diet (Lichtenstein, Appel, Brands, et al., 2006). These general recommendations may need to

Table 28-1 NUTRIENT CONTENT OF THE THERAPEUTIC LIFESTYLE CHANGES (TLC) DIET

Nutrient	Recommended Intake
Total calories*	Balance intake and expenditure to maintain desirable weight
Total fat	25%–35% of total calories
Saturated fat [†]	Less than 7% of total calories
Polyunsaturated fat	Up to 10% of total calories
Monounsaturated fat	Up to 20% of total calories
Carbohydrate [‡]	50%–60% of total calories
Dietary fiber	20–30 g/day
Protein	Approximately 15% of total calories
Cholesterol	Less than 200 mg/day

*Daily energy expenditure should include at least moderate physical activity (contributing approximately 200 kcal per day).

[†]Trans-fatty acids are formed from the processing (manufacturing, hydrogenation) of vegetable oils into a more solid form. The effects of trans-fatty acids are similar to saturated fats (ie, raising low-density lipoprotein and lowering high-density lipoprotein). Intake of trans-fatty acids should be minimized.

[‡]Carbohydrates should be derived predominately from foods rich in complex carbohydrates, including grains, especially whole grains, fruits, and vegetables.

From Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults. (ATP III). *Circulation*, 106(25), 3143–3421.

be adjusted for the individual patient who has other nutritional needs, such as the patient who has diabetes. To assist in following the appropriate TLC diet, the patient should be referred to a registered dietitian. Other TLC recommendations include weight loss, cessation of tobacco use, and increased physical activity.

The Mediterranean diet, another diet that promotes the ingestion of vegetables and fish and restricts red meat, is also reported to reduce mortality from cardiovascular disease (Mitrou, Kipnis, Thiebaut, et al., 2007). People who adopt strict vegetarian diets can significantly reduce blood lipids, blood glucose, body mass index, and blood pressure. However, very intensive dietary programs such as these may not be acceptable to all patients who need to modify risk factors.

In addition, soluble dietary fiber may help reduce cholesterol levels. Soluble fibers, which are found in fresh fruit, cereal grains, vegetables, and legumes, enhance the excretion of metabolized cholesterol. Intake of at least 25 g of fiber each day is recommended (Grundy, Cleeman, Merz, et al., 2004).

Many resources are available to assist people in controlling their cholesterol levels. The National Heart, Lung, and Blood Institute (NHLBI) and its National Cholesterol Education Program (NCEP), the AHA, and the American Diabetes Association (ADA), as well as CAD support groups and reliable Internet sources are a few examples of the available resources. Cookbooks and recipes that include the nutritional contents of foods can be included as resources for patients. Dietary control has been made easier because food manufacturers are required to provide nutritional data on product labels. The label information of interest to a person attempting to eat a heart-healthy diet is as follows: serving size (expressed in household measures), amount of total fat per serving, amount of saturated fat and trans fat per serving, amount of cholesterol per serving, and amount of fiber per serving.

Physical Activity

Management of an elevated triglyceride level focuses on weight reduction and increased physical activity. Regular, moderate physical activity increases HDL levels and reduces

triglyceride levels, decreasing the incidence of coronary events and reducing overall mortality risk. The goal for most people is a total of 30 minutes of moderate exercise (such as brisk walking) on most days (Leitzmann, Park, Blair, et al., 2007). The nurse helps patients set realistic goals for physical activity. For example, inactive patients can start with activity that lasts 3 minutes, such as parking farther from a building to increase daily walking time. For sustained activity, patients should begin with a 5-minute warm-up period to stretch and prepare the body for exercise. They should end the exercise with a 5-minute cool-down period in which they gradually reduce the intensity of the activity to prevent a sudden decrease in cardiac output. Patients should be instructed to engage in an activity or variety of activities that interest them to maintain motivation. They should also be taught to exercise to an intensity that does not preclude their ability to talk; if they cannot have a conversation while exercising, they should slow down or switch to a less intensive activity. When the weather is hot and humid, patients should exercise during the early morning, or indoors, and wear loose-fitting clothing. When the weather is cold, they should layer clothing and wear a hat. The nurse can also suggest walking in large stores or shopping malls in inclement weather. Patients should stop any activity if chest pain, unusual shortness of breath, dizziness, lightheadedness, or nausea occurs.

Medications

If diet alone cannot normalize serum cholesterol levels, medications can have a synergistic effect with the prescribed diet and control cholesterol levels (Table 28-2). Lipid-lowering medications can reduce CAD mortality in patients with elevated lipid levels and in at-risk patients with normal lipid levels (ICSI, 2006b). The lipid-lowering agents affect the lipid components somewhat differently and can be grouped into six types: 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) (or statins), nicotinic acids, fibric acids (or fibrates), bile acid sequestrants (or resins), cholesterol absorption inhibitor, and omega-3 acid-ethyl esters.

Promoting Cessation of Tobacco Use

Cigarette smoking contributes to the development and severity of CAD in the following three ways:

- The inhalation of smoke increases the blood carbon monoxide level. Hemoglobin, the oxygen-carrying component of blood, combines more readily with carbon monoxide than with oxygen. A decreased amount of available oxygen may decrease the heart's ability to pump.
- The nicotinic acid in tobacco triggers the release of catecholamines, which raise the heart rate and blood pressure. Nicotinic acid can also cause the coronary arteries to constrict. Smokers have an increased risk of CAD and sudden cardiac death (Porth & Matfin, 2009). The increase in catecholamines may be a factor in sudden cardiac death.
- Use of tobacco adversely affects the vascular endothelium, resulting in increased platelet adhesion and leading to a higher probability of thrombus formation.

A person at increased risk for heart disease is encouraged to stop tobacco use through any means possible: educational programs, counseling, consistent motivation and

Table 28-2  **MEDICATIONS AFFECTING LIPOPROTEIN METABOLISM**

Medications	Therapeutic Effects	Considerations
HMG-CoA Reductase Inhibitors (statins) Atorvastatin (Lipitor) Fluvastatin (Lescol) Lovastatin (Mevacor) Pravastatin (Pravachol) Rosuvastatin (Crestor) Simvastatin (Zocor)	↓ LDL ↑ HDL ↓ TG Block cholesterol synthesis Favorable effects on vascular endothelium, including anti-inflammatory and anti-thrombotic effects	Frequently given as initial therapy for significantly elevated cholesterol and LDL levels Myopathy is an adverse effect Monitor hepatic function Contraindicated in liver disease Check for drug interactions Indication for use now includes ACS
Nicotinic Acids Niacin-extended release (Niaspan) Niacin-intermediate release (Niacor) Niacin-sustained release (Slo-Niacin)	↓ LDL ↑ HDL ↓ TG ↓ Lipoprotein synthesis	May be used for minimally elevated cholesterol and LDL levels or as an adjunct to a statin when the lipid goal has not been achieved and TG levels are elevated Side effects include flushing, hyperglycemia, hyperuricemia (gout), upper GI distress, and hepatotoxicity Monitor hepatic function Contraindicated in gout and liver failure Dose needs to be titrated weekly to achieve therapeutic dosage
Fibric Acids (fibrates) Fenofibrate (TriCor) Gemfibrozil (Lopid)	↑ HDL ↓ TG ↓ Cholesterol synthesis	Adverse effects include dyspepsia, gallstones, and myopathy Contraindicated in severe renal and liver disease Have potential to ↑ LDL and may be used in patients with TG levels above 400 mg/dL Use with caution in patients who are also taking a statin
Bile Acid Sequestrants Cholestyramine (Questran) Colestipol (Colestid)	↓ LDL Slight ↑ HDL Bind cholesterol and ↑ its breakdown	Most often used as adjunct therapy when statins alone have not been effective in controlling lipid levels and TG levels less than 200 mg/dL Side effects include GI distress, constipation, and decreased absorption of other drugs
Cholesterol Absorption Inhibitor Ezetimibe (Zetia)	↓ LDL ↑ HDL ↓ TG	Better tolerated than bile acid sequestrants May be used in combination with other agents, such as statins Side effects include back pain, arthralgia, and abdominal pain
Omega-3-Acid-Ethyl Esters Fish oil capsules	↓ TG	May be used alone or in combination with other agents Side effects include GI distress, taste perversion, rash, flu syndrome, and back pain

ACS, acute coronary syndrome; GI, gastrointestinal; HDL, high-density lipoprotein; HMG-CoA, 3-hydroxy-3-methylglutaryl coenzyme A; LDL, low-density lipoprotein; TG, triglycerides; ↓ decrease, ↑ increase.

From Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults. (ATP III) (2002). *Circulation*, 106(25), 3143–3421.

reinforcement messages, support groups, and medications. Some people have found complementary therapies (eg, acupuncture, guided imagery, hypnosis) to be helpful. People who stop smoking reduce their risk of heart disease within the first year, and the risk continues to decline as long as they refrain from smoking (Lichtenstein, et al., 2006).

Use of medications such as the nicotine patch (NicoDerm CQ, Habitrol) or the antidepressant bupropion (Zyban) may assist with stopping use of tobacco (Fraker, Fihn, Gibbons, et al., 2007). Products containing nicotine have some of the same effects as smoking: catecholamine release (increasing heart rate and blood pressure) and increased platelet adhesion. These medications should be used for a short time and at the lowest effective doses.

Exposure to other smokers' smoke (passive or second-hand smoke) is believed to cause heart disease in nonsmokers (Office of the U.S. Surgeon General, 2006). Oral contraceptive use by women who smoke is inadvisable because these medications significantly increase the risk for CAD and sudden cardiac death.

Managing Hypertension

Hypertension is defined as blood pressure measurements that repeatedly exceed 140/90 mm Hg. The risk of cardiovascular disease increases as blood pressure increases, and people with a blood pressure greater than 120/80 mm Hg are considered prehypertensive and at risk (Rosendorff, Black, Cannon, et al., 2007). Long-standing elevated blood pressure may result in increased stiffness of the vessel walls,

leading to vessel injury and a resulting inflammatory response within the intima. Inflammatory mediators then lead to the release of growth-promoting factors that cause vessel hypertrophy and hyperresponsiveness. These changes result in acceleration and aggravation of atherosclerosis. Hypertension also increases the work of the left ventricle, which must pump harder to eject blood into the arteries. Over time, the increased workload causes the heart to enlarge and thicken (ie, hypertrophy) and may eventually lead to heart failure.

Early detection of high blood pressure and adherence to a therapeutic regimen can prevent the serious consequences associated with untreated elevated blood pressure. Hypertension is discussed in detail in Chapter 32.

Controlling Diabetes Mellitus

Diabetes mellitus is known to accelerate the development of heart disease, and for 65% to 75% of patients with diabetes, cardiovascular disease is identified as the cause of death (Zipes, Libby, Bonow, et al., 2005). Hyperglycemia fosters dyslipidemia, increased platelet aggregation, and altered red blood cell function, which can lead to thrombus formation. It has been suggested that these metabolic alterations impair endothelial cell–dependent vasodilation and smooth muscle function, promoting the development of atherosclerosis. Treatment with insulin (eg, Humulin, Novolin) and metformin (Glucophage) and other therapeutic interventions that lower plasma glucose levels can lead to improved endothelial function and patient outcomes. Diabetes is discussed in detail in Chapter 41.

Gender

Heart disease has long been recognized as a cause of morbidity and mortality in men, but it has not been as readily recognized and treated in women until recent years. Cardiovascular events in women occur an average of 10 years later in life than they do in men; in women older than 55 years of age, the incidence of CAD is approximately equal to that in men (AHA, 2007). Women also tend to have a higher incidence of complications from cardiovascular disease and a higher mortality. In addition, women tend to not recognize the symptoms of CAD as early as men, and they wait longer to report their symptoms and seek medical assistance. More likely to experience unstable angina than an MI, women may present with symptoms other than chest pain (Canto, et al., 2007).

The age difference between women and men newly diagnosed with CAD was traditionally thought to be related to estrogen. It is now recognized that menopause is a milestone in the aging process during which risk factors tend to accumulate. Cardiovascular disease may be well developed by the time of menopause, despite the supposed protective effects of estrogen (Mosca, Banka, Benjamin, et al., 2007). Although hormone therapy (HT) (formerly referred to as hormone replacement therapy) for menopausal women was once promoted as preventive therapy for CAD, research studies do not support HT as an effective means of prevention. HT decreases menopausal symptoms and the risk of osteoporosis-related bone fractures, but it also has been associated with an increased incidence of CAD, breast cancer, deep vein thrombosis, stroke, and pulmonary embolism. Current

guidelines do not recommend HT for primary or secondary prevention of CAD. However, women do respond well to other preventive measures such as management of serum lipids (Mosca, et al., 2007).

In the past, women who possibly had coronary vascular events were less likely than men to be referred for coronary artery diagnostic procedures such as heart catheterization or treatment with invasive interventions (eg, PCI). However, as a result of better education of health care professionals and the general public, gender differences now have less influence on diagnosis and treatment. When compared with men, women continue to have poorer outcomes, with increased morbidity and mortality after MI, CABG, and PCI. They also have poorer results related to symptom relief. These differences may be due to older age, more comorbid conditions, smaller coronary arteries, and the distribution of plaque in the coronary arteries (Eastwood & Doering, 2005).

Angina Pectoris

Angina pectoris is a clinical syndrome usually characterized by episodes or paroxysms of pain or pressure in the anterior chest. The cause is insufficient coronary blood flow, resulting in a decreased oxygen supply when there is increased myocardial demand for oxygen in response to physical exertion or emotional stress. In other words, the need for oxygen exceeds the supply. In general, the severity of the symptoms of angina is based on the magnitude of the precipitating activity and its effect on activities of daily living.

Pathophysiology

Angina is usually caused by atherosclerotic disease. Almost invariably, angina is associated with a significant obstruction of at least one major coronary artery. Normally, the myocardium extracts a large amount of oxygen from the coronary circulation to meet its continuous demands. When there is an increase in demand, flow through the coronary arteries needs to be increased. When there is blockage in a coronary artery, flow cannot be increased, and ischemia results. The types of angina are listed in Chart 28-2. Several factors are associated with typical anginal pain:

Chart 28-2 • Types of Angina

- **Stable angina:** predictable and consistent pain that occurs on exertion and is relieved by rest and/or nitroglycerin
- **Unstable angina** (also called preinfarction angina or crescendo angina): symptoms increase in frequency and severity; may not be relieved with rest or nitroglycerin
- **Intractable or refractory angina:** severe incapacitating chest pain
- **Variant angina** (also called Prinzmetal's angina): pain at rest with reversible ST-segment elevation; thought to be caused by coronary artery vasospasm
- **Silent ischemia:** objective evidence of ischemia (such as electrocardiographic changes with a stress test), but patient reports no pain

- Physical exertion, which can precipitate an attack by increasing myocardial oxygen demand
- Exposure to cold, which can cause vasoconstriction and elevated blood pressure, with increased oxygen demand
- Eating a heavy meal, which increases the blood flow to the mesenteric area for digestion, thereby reducing the blood supply available to the heart muscle; in a severely compromised heart, shunting of blood for digestion can be sufficient to induce anginal pain
- Stress or any emotion-provoking situation, causing the release of catecholamines, which increases blood pressure, heart rate, and myocardial workload

Unstable angina is not associated with these listed factors. It may occur at rest. See the later discussion of unstable angina in the section discussing ACS and MI.

Clinical Manifestations

Ischemia of the heart muscle may produce pain or other symptoms, varying in severity from mild indigestion to a choking or heavy sensation in the upper chest that ranges from discomfort to agonizing pain accompanied by severe apprehension and a feeling of impending death. The pain is often felt deep in the chest behind the sternum (retrosternal area). Typically, the pain or discomfort is poorly localized and may radiate to the neck, jaw, shoulders, and inner aspects of the upper arms, usually the left arm. The patient often feels tightness or a heavy choking or strangling sensation that has a viselike, insistent quality. The patient with diabetes mellitus may not have severe pain with angina because diabetic neuropathy can blunt nociceptor transmission, dulling the perception of pain. Women may have different symptoms than men, possibly because coronary disease in women tends to be more diffuse and affects long segments of the artery rather than discrete segments.

A feeling of weakness or numbness in the arms, wrists, and hands, as well as shortness of breath, pallor, diaphoresis, dizziness or lightheadedness, and nausea and vomiting may accompany the pain. Anxiety may occur with angina. An important characteristic of angina is that it subsides with rest or administering nitroglycerin. In many patients, anginal symptoms follow a stable, predictable pattern.

Unstable angina is characterized by attacks that increase in frequency and severity and are not relieved by rest and administering nitroglycerin. Patients with unstable angina require medical intervention.

Gerontologic Considerations

The elderly person with angina may not exhibit the typical pain profile because of the diminished responses of neurotransmitters that occur with aging. Often, the presenting symptom in the elderly is dyspnea. Sometimes there are no symptoms (“silent” CAD), making recognition and diagnosis a clinical challenge. Elderly patients should be encouraged to recognize their chest pain–like symptom (eg, weakness) as an indication that they should rest or take prescribed medications. Pharmacologic stress testing and cardiac catheterization may be used to diagnose CAD in elderly patients. Medications used to manage angina are administered cautiously in the elderly because they are associated with an increase risk of adverse reactions (Futterman & Lemberg, 2007). Invasive

procedures (eg, PCI) that were once considered too risky in the elderly may be considered; the elderly can benefit from symptom relief and longer survival.

Assessment and Diagnostic Findings

The diagnosis of angina begins with the patient’s history related to the clinical manifestations of ischemia. A 12-lead electrocardiogram (ECG) may show changes indicative of ischemia such as T-wave inversion. Laboratory studies are performed; these may include CRP and cardiac biomarker values to rule out an ACS (refer to later discussion on ACS). The patient may undergo an exercise or pharmacologic stress test in which the heart is monitored by an ECG, echocardiogram, or both. The patient may also be referred for a nuclear scan or invasive procedure (eg, cardiac catheterization, coronary angiography).

Medical Management

The objectives of the medical management of angina are to decrease the oxygen demand of the myocardium and to increase the oxygen supply. Medically, these objectives are met through pharmacologic therapy and control of risk factors. Alternatively, reperfusion procedures may be used to restore the blood supply to the myocardium. These include PCI procedures (eg, **percutaneous transluminal coronary angioplasty [PTCA]**, intracoronary stents, and atherectomy) and CABG.

Pharmacologic Therapy

Table 28-3 summarizes drug therapy.

Nitroglycerin

Nitrates are an important treatment for angina pectoris. A vasoactive agent, nitroglycerin is administered to reduce myocardial oxygen consumption, which decreases ischemia and relieves pain. Nitroglycerin dilates primarily the veins and, in higher doses, the arteries. Dilation of the veins causes venous pooling of blood throughout the body. As a result, less blood returns to the heart, and filling pressure (preload) is reduced. If the patient is hypovolemic (does not have adequate circulating blood volume), the decrease in filling pressure can cause a significant decrease in cardiac output and blood pressure.

Nitrates in higher doses also relax the systemic arteriolar bed, lowering blood pressure and decreasing afterload. These effects decrease myocardial oxygen requirements and increase oxygen supply, bringing about a more favorable balance between supply and demand.

Nitroglycerin may be given by several routes: sublingual tablet or spray, oral capsule, topical agent, and intravenous (IV) administration. Sublingual nitroglycerin is generally placed under the tongue or in the cheek (buccal pouch) and ideally alleviates the pain of ischemia within 3 minutes. Chart 28-3 provides more information on self-administration of sublingual nitroglycerin. Oral preparations and topical patches are used to provide sustained effects. The patches are often applied in the morning and removed at bedtime. This regimen allows for a nitrate-free period to prevent the development of tolerance.

A continuous or intermittent IV infusion of nitroglycerin may be administered to the hospitalized patient with

Table 28-3 SUMMARY OF MEDICATIONS USED TO TREAT ANGINA

Medications	Major Indications
Nitrates Nitroglycerin (Nitrostat, Nitro-Bid)	Short-term and long-term reduction of myocardial oxygen consumption through selective vasodilation
Beta-Adrenergic Blocking Agents (beta-blockers) Metoprolol (Lopressor, Toprol) Atenolol (Tenormin)	Reduction of myocardial oxygen consumption by blocking beta-adrenergic stimulation of the heart
Calcium Ion Antagonists (calcium channel blockers) Amlodipine (Norvasc) Diltiazem (Cardizem, Tiazac) Felodipine (Plendil)	Negative inotropic effects; indicated in patients not responsive to beta-blockers; used as primary treatment for vasospasm
Antiplatelet Medications Aspirin Clopidogrel (Plavix) Glycoprotein IIb/IIIa agents: Abciximab (ReoPro) Tirofiban (Aggrastat) Eptifibatid (Integrilin)	Prevention of platelet aggregation
Anticoagulants Heparin (unfractionated) Low-molecular-weight heparins (LMWHs): Enoxaparin (Lovenox) Dalteparin (Fragmin)	Prevention of thrombus formation

recurring signs and symptoms of ischemia or after a revascularization procedure. The dose of nitroglycerin administered is based on the patient's symptoms while avoiding side effects such as hypotension. It usually is not administered if the systolic blood pressure is 90 mm Hg or less. Generally, after the patient is symptom-free, the nitroglycerin may be switched to an oral or topical preparation within 24 hours.

Beta-Adrenergic Blocking Agents

Beta-blockers such as metoprolol (Lopressor, Toprol) and atenolol (Tenormin) reduce myocardial oxygen consumption by blocking beta-adrenergic sympathetic stimulation to the heart. The result is a reduction in heart rate, slowed conduction of impulses through the conduction system,

decreased blood pressure, and reduced myocardial **contractility** (force of contraction) to balance the myocardial oxygen needs (demands) and the amount of oxygen available (supply). This helps control chest pain and delays the onset of ischemia during work or exercise. Beta-blockers reduce the incidence of recurrent angina, infarction, and cardiac mortality. The dose can be titrated to achieve a resting heart rate of 50 to 60 bpm (beats per minute).

Cardiac side effects and possible contraindications include hypotension, bradycardia, advanced atrioventricular block, and acute heart failure. If a beta-blocker is given intravenously for an acute cardiac event, the ECG, blood pressure, and heart rate are monitored closely after the medication has been administered. Side effects include depression, fatigue,

CHART 28-3

PHARMACOLOGY *Self-Administration of Nitroglycerin*

Most patients with angina pectoris must self-administer nitroglycerin on an as-needed basis. A key nursing role in such cases is educating patients about the medication and how to take it. Sublingual nitroglycerin comes in tablet and spray forms.

- Instruct the patient to make sure the mouth is moist, the tongue is still, and saliva is not swallowed until the nitroglycerin tablet dissolves. If the pain is severe, the patient can crush the tablet between the teeth to hasten sublingual absorption.
- Advise the patient to carry the medication at all times as a precaution. However, because nitroglycerin is very unstable, it should be carried securely in its original container (eg, capped dark glass bottle); tablets should never be removed and stored in metal or plastic pillboxes.
- Explain that nitroglycerin is volatile and is inactivated by heat, moisture, air, light, and time. Instruct the patient to renew the nitroglycerin supply every 6 months.
- Inform the patient that the medication should be taken in anticipation of any activity that may produce pain. Because nitroglycerin increases tolerance for exercise and stress when taken prophylactically (ie, before angina-producing activity, such as exercise, stair-climbing, or sexual intercourse), it is best taken before pain develops.
- Recommend that the patient note how long it takes for the nitroglycerin to relieve the discomfort. Advise the patient that if pain persists after taking three sublingual tablets at 5-minute intervals, emergency medical services should be called.
- Discuss possible side effects of nitroglycerin, including flushing, throbbing headache, hypotension, and tachycardia.
- Advise the patient to sit down for a few minutes when taking nitroglycerin to avoid hypotension and syncope.

decreased libido, and masking of symptoms of hypoglycemia. Patients taking beta-blockers are cautioned not to stop taking them abruptly, because angina may worsen and MI may develop. Beta-blocker therapy should be decreased gradually over several days before being discontinued. Patients with diabetes who take beta-blockers are instructed to monitor their blood glucose levels often and to observe for signs and symptoms of hypoglycemia. Beta-blockers that are not cardioselective also affect the beta-adrenergic receptors in the bronchioles, causing bronchoconstriction, and therefore are contraindicated in patients with significant chronic pulmonary disorders, such as asthma.

Calcium Channel Blocking Agents

Calcium channel blockers (calcium ion antagonists) have a variety of effects. These agents decrease sinoatrial node automaticity and atrioventricular node conduction, resulting in a slower heart rate and a decrease in the strength of myocardial contraction (negative inotropic effect). These effects decrease the workload of the heart. Calcium channel blockers also relax the blood vessels, causing a decrease in blood pressure and an increase in coronary artery perfusion. Calcium channel blockers increase myocardial oxygen supply by dilating the smooth muscle wall of the coronary arterioles; they decrease myocardial oxygen demand by reducing systemic arterial pressure and the workload of the left ventricle.

The calcium channel blockers most commonly used are amlodipine (Norvasc) and diltiazem (Cardizem, Tiazac). They may be used by patients who cannot take beta-blockers, who develop significant side effects from beta-blockers or nitrates, or who still have pain despite beta-blocker and nitroglycerin therapy. Calcium channel blockers are also used to prevent and treat vasospasm, which may occur after a PCI.

First-generation calcium channel blockers such as nifedipine (Procardia) should be avoided or used with caution in people with heart failure because they decrease myocardial contractility. Amlodipine and felodipine (Plendil) are the calcium channel blockers of choice for patients with heart failure. Hypotension may occur after the IV administration of any of the calcium channel blockers. Other side effects may include atrioventricular block, bradycardia, constipation, and gastric distress.

Antiplatelet and Anticoagulant Medications

Antiplatelet medications are administered to prevent platelet aggregation and subsequent thrombosis, which impedes blood flow.

Aspirin. Aspirin prevents platelet aggregation and reduces the incidence of MI and death in patients with CAD. A 160- to 325-mg dose of aspirin should be given to the patient with angina as soon as the diagnosis is made (eg, in the emergency department or physician's office) and then continued with 81 to 325 mg daily. Patients should be advised to continue aspirin even if they concurrently take other analgesics such as acetaminophen (Tylenol). Because aspirin may cause gastrointestinal upset and bleeding, the use of H₂-blockers (eg, famotidine [Pepcid]) or proton pump inhibitors (eg, omeprazole [Prilosec]) should be considered to allow continued aspirin therapy.

Clopidogrel. Clopidogrel (Plavix) is given in addition to aspirin in patients at high risk for MI. Patients are given more than one platelet inhibitor because the medications act on different pathways to block platelet activation (Housholder-Hughes, 2006). Unlike aspirin, this medication takes a few days to achieve antiplatelet effects.

Heparin. IV unfractionated heparin prevents the formation of new blood clots. Treating patients with unstable angina with heparin reduces the occurrence of MI. If the patient's signs and symptoms indicate a significant risk for a cardiac event, the patient is hospitalized and may be given an IV bolus of heparin and started on a continuous infusion. The amount of heparin administered is based on the results of the activated partial thromboplastin time (aPTT). Heparin therapy is usually considered therapeutic when the aPTT is 2 to 2.5 times the normal aPTT value.

A subcutaneous injection of low-molecular-weight heparin (LMWH; enoxaparin [Lovenox] or dalteparin [Fragmin]) may be used instead of IV unfractionated heparin to treat patients with unstable angina or non-ST-segment elevation MIs (Antman, Hand, Armstrong, et al., 2007). LMWHs provide effective and stable anticoagulation, potentially reducing the risk of rebound ischemic events, and eliminate the need to monitor aPTT results. LMWHs may be beneficial before and during PCIs and for ST-segment elevation MIs.

Because unfractionated heparin and LMWH increase the risk of bleeding, the patient is monitored for signs and symptoms of external and internal bleeding, such as low blood pressure, increased heart rate, and decreased serum hemoglobin and hematocrit. The patient receiving heparin is placed on bleeding precautions, which include:

- Applying pressure to the site of any needle puncture for a longer time than usual
- Avoiding intramuscular (IM) injections
- Avoiding tissue injury and bruising from trauma or use of constrictive devices (eg, continuous use of an automatic blood pressure cuff)

A decrease in platelet count or evidence of thrombosis may indicate heparin-induced thrombocytopenia (HIT), an antibody-mediated reaction to heparin that may result in thrombosis (Cooney, 2006). Patients who have received heparin within the past 3 months and those who have been receiving unfractionated heparin for 5 to 15 days are at high risk for HIT (see Chapter 33 for further discussion of HIT).

Glycoprotein IIb/IIIa Agents. IV administration of glycoprotein (GP) IIb/IIIa agents (abciximab [ReoPro], tirofiban [Aggrastat], eptifibatid [Integrilin]) is indicated for hospitalized patients with unstable angina and as adjunct therapy for PCI. These agents prevent platelet aggregation by blocking the GP IIb/IIIa receptors on the platelets, preventing adhesion of fibrinogen and other factors that crosslink platelets to each other and thus form platelet clots. As with heparin, bleeding is the major side effect, and bleeding precautions should be initiated.

Oxygen Administration

Oxygen therapy is usually initiated at the onset of chest pain in an attempt to increase the amount of oxygen delivered to the myocardium and to decrease pain. The therapeutic effectiveness of oxygen is determined by observing the rate

and rhythm of respirations. Blood oxygen saturation is monitored by pulse oximetry; the normal oxygen saturation (SpO₂) level is greater than 93%.

NURSING PROCESS

THE PATIENT WITH ANGINA PECTORIS

Assessment

The nurse gathers information about the patient's symptoms and activities, especially those that precede and precipitate attacks of angina pectoris. Appropriate questions are listed in Chart 28-4. The answers to these questions form the basis for designing an effective program of treatment and prevention. In addition to assessing angina pectoris or its equivalent, the nurse also assesses the patient's risk factors for CAD, the patient's response to angina, the patient's and family's understanding of the diagnosis, and adherence to the current treatment plan.

Diagnosis

Nursing Diagnoses

Based on the assessment data, major nursing diagnoses may include:

- Ineffective cardiac tissue perfusion secondary to CAD as evidenced by chest pain or other prodromal symptoms
- Death anxiety related to cardiac symptoms
- Deficient knowledge about the underlying disease and methods for avoiding complications
- Noncompliance, ineffective management of therapeutic regimen related to failure to accept necessary lifestyle changes

Collaborative Problems/Potential Complications

Potential complications that may develop include the following, which are discussed in the chapters indicated:

- ACS and/or MI (described later in this chapter)
- Dysrhythmias and cardiac arrest (see Chapters 27 and 30)
- Heart failure (see Chapter 30)
- Cardiogenic shock (see Chapter 15)

CHART
28-4

Assessing Angina

Ask the following:

- "Where is the pain (or prodromal symptoms)? Can you point to it?"
- "Can you feel the pain anywhere else?"
- "How would you describe the pain?"
- "Is it like the pain you had before?"
- "Can you rate the pain on a 0 to 10 scale, with 10 being the most pain?"
- "When did the pain begin?"
- "How long does it last?"
- "What brings on the pain?"
- "What helps the pain to go away?"
- "Do you have any other symptoms with the pain?"

Planning and Goals

Major patient goals include immediate and appropriate treatment when angina occurs, prevention of angina, reduction of anxiety, awareness of the disease process and understanding of the prescribed care, adherence to the self-care program, and absence of complications.

Nursing Interventions

Treating Angina

If the patient reports pain (or the person's prodromal symptoms suggest anginal ischemia, which may include sensations of indigestion or nausea, choking, heaviness, weakness or numbness in the upper extremities, dyspnea, or dizziness), the nurse takes immediate action. When a patient experiences angina, the patient is directed to stop all activities and sit or rest in bed in a semi-Fowler's position to reduce the oxygen requirements of the ischemic myocardium. The nurse assesses the patient's angina, asking questions to determine whether the angina is the same as the patient typically experiences. A change may indicate a worsening of the disease or a different cause. The nurse then continues to assess the patient, measuring vital signs and observing for signs of respiratory distress. If the patient is in the hospital, a 12-lead ECG is usually obtained and scrutinized for ST-segment and T-wave changes. If the patient has been placed on cardiac monitoring with continuous ST-segment monitoring, the ST segment is assessed for changes.

Nitroglycerin is administered sublingually, and the patient's response is assessed (relief of chest pain and effect on blood pressure and heart rate). If the chest pain is unchanged or is lessened but still present, nitroglycerin administration is repeated up to three doses. Each time blood pressure, heart rate, and the ST segment (if the patient is on a monitor with ST-segment monitoring capability) are assessed. The nurse administers oxygen therapy if the patient's respiratory rate is increased or if the oxygen saturation level is decreased. Oxygen is usually administered at 2 L/min by nasal cannula, even without evidence of respiratory distress, although there is no documentation of its effect on outcome. If the pain is significant and continues after these interventions, the patient is further evaluated for acute MI and may be transferred to a higher-acuity nursing unit.

Reducing Anxiety

Patients with angina often fear loss of their roles within society and the family. They may also fear that the pain (or the prodromal symptoms) may lead to an MI or death. Exploring the implications that the diagnosis has for the patient and providing information about the illness, its treatment, and methods of preventing its progression are important nursing interventions. Various stress reduction methods, such as guided imagery or music therapy, should be explored with the patient. Addressing the spiritual needs of the patient and family may also assist in allaying anxieties and fears.

Preventing Pain

The nurse reviews the assessment findings, identifies the level of activity that causes the patient's pain or prodromal symptoms, and plans the patient's activities accordingly. If the patient has pain frequently or with minimal activity, the

nurse alternates the patient's activities with rest periods. Balancing activity and rest is an important aspect of the educational plan for the patient and family.

Promoting Home and Community-Based Care

TEACHING PATIENTS SELF-CARE. The teaching program for the patient with angina is designed so that the patient and family understand the illness, identify the symptoms of myocardial ischemia, state the actions to take when symptoms develop, and discuss methods to prevent chest pain and the advancement of CAD. The goals of education are to reduce the frequency and severity of anginal attacks, to delay the progress of the underlying disease if possible, and to prevent complications. The factors outlined in Chart 28-5 are important in educating the patient with angina pectoris.

The self-care program is prepared in collaboration with the patient and family or friends. Activities should be planned to minimize the occurrence of angina episodes. The patient needs to understand that any pain unrelieved within 15 minutes by the usual methods, including nitroglycerin (see Chart 28-3), should be treated at the closest emergency center; the patient should call 911 for assistance.

CONTINUING CARE. Arrangements are made for a home care nurse when appropriate. The home care nurse assists the patient with scheduling and keeping follow-up appointments. The patient may need reminders about follow-up monitoring, including periodic blood laboratory testing and ECGs. In addition, the home care nurse may monitor the

patient's adherence to dietary restrictions and to prescribed antianginal medications, including nitroglycerin. If the patient has severe anginal symptoms, the nurse may assess the home environment and recommend modifications that diminish the occurrence of anginal episodes. For instance, if a patient cannot climb stairs without experiencing ischemia, the home care nurse may help the patient plan daily activities that minimize stair climbing. Some patients may benefit from moving the bedroom to a lower level in the home.

Evaluation

Expected Patient Outcomes

1. Reports that pain is relieved promptly
 - a. Recognizes symptoms
 - b. Takes immediate action
 - c. Seeks medical assistance if pain persists or changes in quality
2. Reports decreased anxiety
 - a. Expresses acceptance of diagnosis
 - b. Expresses control over choices within medical regimen
 - c. Does not exhibit signs and symptoms that indicate a high level of anxiety
3. Understands ways to avoid complications and is free of complications
 - a. Describes the process of angina
 - b. Explains reasons for measures to prevent complications

CHART
28-5

HOME CARE CHECKLIST Managing Angina Pectoris

At the completion of home care instructions, the patient and significant other will be able to:	PATIENT	CAREGIVER
• Reduce the probability of an episode of anginal pain by balancing rest with activity.		
• Participate in a regular daily program of activities that do not produce chest discomfort, shortness of breath, or undue fatigue.	✓	
• Follow the prescribed exercise regimen.	✓	
• Recognize that temperature extremes (particularly cold) may induce anginal pain; therefore, avoid exercise in temperature extremes.	✓	
• Alternate activity with periods of rest.	✓	
• Use appropriate resources for support during emotionally stressful times (eg, counselor, nurse, clergy, physician).	✓	✓
• Avoid using medications or any over-the-counter substances (eg, diet pills, nasal decongestants) that can increase the heart rate and blood pressure without first discussing with a health care provider.	✓	✓
• Stop smoking and other forms of tobacco, and avoid secondhand smoke (because smoking increases the heart rate, blood pressure, and blood carbon monoxide levels).	✓	✓
• Follow a diet low in saturated fat, high in fiber, and if indicated, lower in calories.	✓	✓
• Achieve and maintain normal blood pressure.	✓	
• Achieve and maintain normal blood glucose levels.	✓	
• Take medications, especially aspirin and beta-blockers, as prescribed.	✓	
• Carry nitroglycerin at all times; state when and how to use it; identify its side effects.	✓	✓
• Make and keep follow-up appointments.	✓	✓
• Report increase in symptoms to health care provider.	✓	✓

- c. Exhibits normal ECG and cardiac biomarkers
 - d. Experiences no signs and symptoms of acute MI
4. Adheres to self-care program
 - a. Takes medications as prescribed
 - b. Keeps health care appointments
 - c. Implements plan to reduce risk factors

Acute Coronary Syndrome and Myocardial Infarction

ACS is an emergent situation characterized by an acute onset of myocardial ischemia that results in myocardial death (ie, MI) if definitive interventions do not occur promptly. (Although the terms coronary occlusion, heart attack, and MI are used synonymously, the preferred term is MI.) The spectrum of ACS includes unstable angina, non-ST-segment elevation MI (NSTEMI), and ST-segment elevation MI (STEMI).

Pathophysiology

In unstable angina, there is reduced blood flow in a coronary artery, often due to rupture of an atherosclerotic plaque, but the artery is not completely occluded. This is an acute situation that is sometimes referred to as preinfarction angina because the patient will likely have an MI if prompt interventions do not occur.

In an MI, an area of the myocardium is permanently destroyed, typically because plaque rupture and subsequent thrombus formation result in complete occlusion of the artery. Vasospasm (sudden constriction or narrowing) of a coronary artery, decreased oxygen supply (eg, from acute blood loss, anemia, or low blood pressure), and increased demand for oxygen (eg, from a rapid heart rate, thyrotoxicosis, or ingestion of cocaine) are other causes of MI. In each case, a profound imbalance exists between myocardial oxygen supply and demand.

The area of infarction develops over minutes to hours. As the cells are deprived of oxygen, ischemia develops, cellular injury occurs, and the lack of oxygen results in infarction, or the death of cells. The expression “time is muscle” reflects the urgency of appropriate treatment to improve patient outcomes. Each year in the United States, nearly 1 million people have acute MIs; one fourth of these people die as a result (AHA, 2007). Half of those who die never reach a hospital.

Various descriptions are used to further identify an MI: the type (NSTEMI, STEMI), the location of the injury to the ventricular wall (anterior, inferior, posterior, or lateral wall), and the point in time within the process of infarction (acute, evolving, or old). The differences between NSTEMI and STEMI are diagnostic and are explained later in this chapter.

The ECG usually identifies the type and location of the MI, and other ECG indicators such as a Q wave and patient history identify the timing. Regardless of the location, the goals of medical therapy are to prevent or minimize myocardial tissue death and prevent complications. The pathophysiology of CAD and the risk factors involved were discussed earlier in this chapter.

Clinical Manifestations

Chest pain that occurs suddenly and continues despite rest and medication is the presenting symptom in most patients with ACS. Some of these patients have prodromal symptoms or a previous diagnosis of CAD, but about half report no previous symptoms (AHA, 2007). Patients may present with a combination of symptoms, including chest pain, shortness of breath, indigestion, nausea, and anxiety. They may have cool, pale, and moist skin. Their heart rate and respiratory rate may be faster than normal. These signs and symptoms, which are caused by stimulation of the sympathetic nervous system, may be present for only a short time or may persist. In many cases, the signs and symptoms of MI cannot be distinguished from those of unstable angina; hence, the evolution of the term ACS.

Assessment and Diagnostic Findings

The diagnosis of ACS is generally based on the presenting symptoms (Chart 28-6); the 12-lead ECG and laboratory tests (eg, serial cardiac biomarkers) are performed to clarify whether the patient has unstable angina, NSTEMI, or STEMI. The prognosis depends on the severity of coronary artery obstruction and the presence and extent of myocardial damage. Physical examination is always conducted, but the examination alone does not confirm the diagnosis.

Patient History

The patient history includes the description of the presenting symptom (eg, pain), the history of previous cardiac and other illnesses, and the family history of heart disease. The history should also include information about the patient’s risk factors for heart disease.

Electrocardiogram

The 12-lead ECG provides information that assists in ruling out or diagnosing an acute MI. It should be obtained within 10 minutes from the time a patient reports pain or arrives in the emergency department. By monitoring serial ECG changes over time, the location, evolution, and resolution of an MI can be identified and monitored.

The ECG changes that occur with an MI are seen in the leads that view the involved surface of the heart. The classic ECG changes are T-wave inversion, ST-segment elevation, and development of an abnormal Q wave (Fig. 28-5). Because infarction evolves over time, the ECG also changes over time. The first ECG signs of an acute MI occur as a result of myocardial ischemia and injury. Myocardial injury causes the T wave to become enlarged and symmetric. As the area of injury becomes ischemic, myocardial repolarization is altered and delayed, causing the T wave to invert. The ischemic region may remain depolarized while adjacent areas of the myocardium return to the resting state. Myocardial injury also causes ST-segment changes. The injured myocardial cells depolarize normally but repolarize more rapidly than normal cells, causing the ST segment to rise at least 1 mm above the isoelectric line (the area between the T wave and the next P wave is used as the reference for the isoelectric line) when measured 0.06 to 0.08 seconds after the end of the QRS, a point called the J point (Fig. 28-6). This elevation in the ST segment in two contiguous leads is a key diagnostic indicator for MI (ie, STEMI).

CHART
28-6

Assessing for Acute Coronary Syndrome (ACS) or Acute Myocardial Infarction (MI)

Be alert for the following signs and symptoms:

Cardiovascular

- Chest pain or discomfort not relieved by rest or nitroglycerin palpitations. Heart sounds may include S_3 , S_4 , and new onset of a murmur.
- Increased jugular venous distention may be seen if the MI has caused heart failure.
- Blood pressure may be elevated because of sympathetic stimulation or decreased because of decreased contractility, impending cardiogenic shock, or medications.
- Irregular pulse may indicate atrial fibrillation.
- In addition to ST-segment and T-wave changes, ECG may show tachycardia, bradycardia, or other dysrhythmias.

Respiratory

Shortness of breath, dyspnea, tachypnea, and crackles if MI has caused pulmonary congestion. Pulmonary edema may be present.

Gastrointestinal

Nausea and vomiting.

Genitourinary

Decreased urinary output may indicate cardiogenic shock.

Skin

Cool, clammy, diaphoretic, and pale appearance due to sympathetic stimulation may indicate cardiogenic shock.

Neurologic

Anxiety, restlessness, and lightheadedness may indicate increased sympathetic stimulation or a decrease in contractility and cerebral oxygenation. The same symptoms may also herald cardiogenic shock.

Psychological

Fear with feeling of impending doom, or denial that anything is wrong.

The appearance of abnormal Q waves is another indication of MI. Q waves develop within 1 to 3 days because there is no depolarization current conducted from necrotic tissue. The lead system then views the flow of current from other parts of the heart. A new and significant Q wave is 0.04 seconds or longer and 25% of the R-wave depth (provided the R wave exceeds a depth of 5 mm). An acute MI may also cause a significant decrease in the height of the R wave. During an acute MI, injury and ischemic changes are usually present. An abnormal Q wave may be present without ST-

segment and T-wave changes, which indicates an old, not acute, MI. For some patients, there are no persistent ECG changes, and the MI is diagnosed by blood levels of cardiac biomarkers.

Using the above information, patients are diagnosed with one of the following forms of ACS:

- Unstable angina: The patient has clinical manifestations of coronary ischemia, but ECG and cardiac biomarkers show no evidence of acute MI.
- STEMI: The patient has ECG evidence of acute MI with characteristic changes in two contiguous leads on a 12-lead ECG. In this type of MI, there is significant damage to the myocardium.
- NSTEMI: The patient has elevated cardiac biomarkers but no definite ECG evidence of acute MI.

During recovery from an MI, the ST segment often is the first ECG indicator to return to normal (1 to 6 weeks). The T

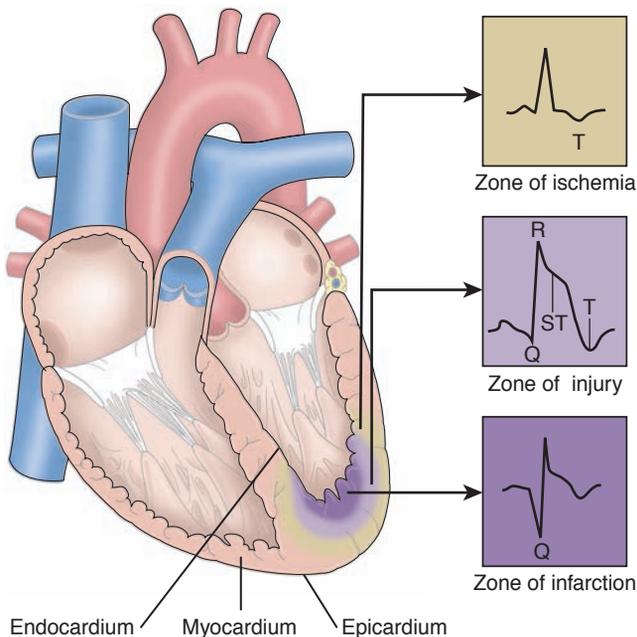

Figure 28-5 Effects of ischemia, injury, and infarction on an electrocardiogram (ECG) recording. Ischemia causes inversion of the T wave because of altered repolarization. Cardiac muscle injury causes elevation of the ST segment. Later, Q waves develop because of the absence of depolarization current from the necrotic tissue and opposing currents from other parts of the heart.

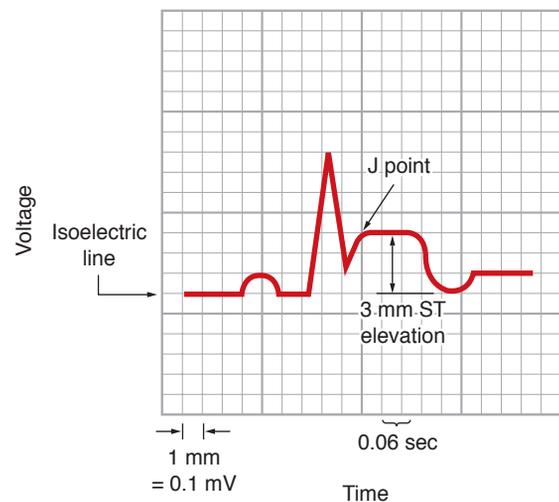

Figure 28-6 Using the electrocardiogram (ECG) to diagnose acute myocardial infarction (MI). (ST-segment elevation is measured 0.06 to 0.08 seconds after the J point. An elevation of more than 1 mm in contiguous leads is indicative of acute MI.)

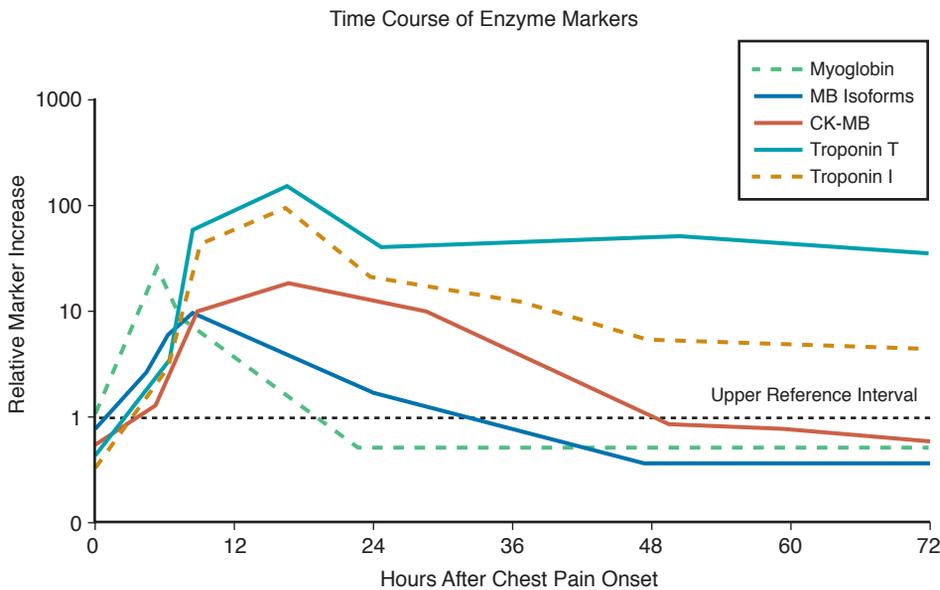

Figure 28-7 Peak elevation and duration of serum enzymes and biomarkers after acute myocardial infarction. Illustration from Morton, P. G. & Fontaine, D. K. (2009). *Critical care nursing* (9th ed.). Philadelphia: Lippincott Williams & Wilkins.

wave becomes large and symmetric for 24 hours, and it then inverts within 1 to 3 days for 1 to 2 weeks. Q-wave alterations are usually permanent. An old STEMI is usually indicated by an abnormal Q wave or decreased height of the R wave without ST-segment and T-wave changes.

Echocardiogram

The echocardiogram is used to evaluate ventricular function. It may be used to assist in diagnosing an MI, especially when the ECG is nondiagnostic. The echocardiogram can detect hypokinetic and akinetic wall motion and can determine the ejection fraction (see Chapter 26).

Laboratory Tests

Cardiac enzymes and biomarkers are used to diagnose an acute MI. Cardiac biomarkers, which include myoglobin and troponin, can be analyzed rapidly, expediting an accurate diagnosis. These tests are based on the release of cellular contents into the circulation when myocardial cells die. Figure 28-7 shows the time courses of cardiac enzymes and biomarkers.

Creatine Kinase and Its Isoenzymes

There are three **creatinine kinase (CK)** isoenzymes: CK-MM (skeletal muscle), CK-MB (heart muscle), and CK-BB (brain tissue). CK-MB is the cardiac-specific isoenzyme; it is found mainly in cardiac cells and therefore increases only when there has been damage to these cells. Elevated CK-MB assessed by mass assay is an indicator of acute MI; the level begins to increase within a few hours and peaks within 24 hours of an MI. If the area is reperfused (eg, due to thrombolytic therapy or PCI), it peaks earlier.

Myoglobin

Myoglobin is a heme protein that helps transport oxygen. Like CK-MB enzyme, myoglobin is found in cardiac and skeletal muscle. The myoglobin level starts to increase within 1 to 3 hours and peaks within 12 hours after the onset of symptoms. An increase in myoglobin is not very specific in indicating an acute cardiac event; however, negative results are an excellent parameter for ruling out an acute MI.

Troponin

Troponin, a protein found in the myocardium, regulates the myocardial contractile process. There are three isomers of troponin: C, I, and T. Troponins I and T are specific for cardiac muscle, and these biomarkers are currently recognized as reliable and critical markers of myocardial injury (Carreiro-Lewandowski, 2006). An increase in the level of troponin in the serum can be detected within a few hours during acute MI. It remains elevated for a long period, often as long as 3 weeks, and it therefore can be used to detect recent myocardial damage.

Medical Management

The goals of medical management are to minimize myocardial damage, preserve myocardial function, and prevent complications. These goals are facilitated by the use of guidelines developed by the American College of Cardiology (ACC) and the AHA (Chart 28-7). These goals may be achieved by reperfusing the area with the emergency use of thrombolytic medications or by PCI. Minimizing myocardial damage is also accomplished by reducing myocardial oxygen demand and increasing oxygen supply with medications, oxygen administration, and bed rest. The resolution of pain and ECG changes indicate that demand and supply are in equilibrium; they may also indicate reperfusion. Visualization of blood flow through an open vessel in the catheterization laboratory is evidence of reperfusion.

Pharmacologic Therapy

The patient with suspected MI is given aspirin, nitroglycerin, morphine, an IV beta-blocker, and other medications as indicated while the diagnosis is being confirmed. Patients should continue the beta-blocker throughout hospitalization and after discharge because long-term therapy with beta-blockers can decrease the incidence of future cardiac events. Unfractionated heparin or an LMWH is prescribed along with platelet-inhibiting agents to prevent further clot formation. Nonsteroidal anti-inflammatory drugs (NSAIDs)

Chart 28-7 • Treatment Guidelines for Acute Myocardial Infarction

- Use rapid transit to the hospital.
- Obtain 12-lead electrocardiogram (ECG) to be read within 10 minutes.
- Obtain laboratory blood specimens of cardiac biomarkers, including troponin.
- Obtain other diagnostics to clarify the diagnosis.
- Begin routine medical interventions:
 - Supplemental oxygen
 - Nitroglycerin
 - Morphine
 - Aspirin 162 to 325 mg
 - Beta-blocker
 - Angiotensin-converting enzyme inhibitor within 24 hours
 - Anticoagulation with heparin and platelet inhibitors
- Evaluate for indications for reperfusion therapy:
 - Percutaneous coronary intervention
 - Thrombolytic therapy
- Continue therapy as indicated:
 - Intravenous heparin, low-molecular-weight heparin, bivalirudin, or fondaparinux
 - Clopidogrel (Plavix)
 - Glycoprotein IIb/IIIa inhibitor
 - Bed rest for a minimum of 12 to 24 hours

Antman, E. M., Hand, M, Armstrong, P. W., et al. (2007). 2007 Focused update of the ACC/AHA guidelines for the management of patients with ST-elevation myocardial infarction. *Circulation*, 117, 296–329. <http://circ.ahajournals.org>

may be discontinued because of their association with adverse cardiac events (Antman, et al., 2007).

Analgesics

The analgesic of choice for acute MI is morphine administered in IV boluses to reduce pain and anxiety. It also reduces preload and afterload, which decreases the workload of the heart and relaxes bronchioles to enhance oxygenation. The cardiovascular response to morphine is monitored

carefully, particularly the blood pressure, which can decrease, and the respiratory rate, which can be depressed. Because morphine decreases the sensation of pain, ST-segment changes may be a better indicator of subsequent ischemia than reported pain.

Angiotensin-Converting Enzyme Inhibitors

Angiotensin-converting enzyme (ACE) inhibitors prevent the conversion of angiotensin I to angiotensin II. In the absence of angiotensin II, the blood pressure decreases and the kidneys excrete sodium and fluid (diuresis), decreasing the oxygen demand of the heart. Use of ACE inhibitors in patients after MI decreases mortality rates and prevents remodeling of myocardial cells that is associated with the onset of heart failure. It is important to ensure that a patient is not hypotensive, hyponatremic, hypovolemic, or hyperkalemic before administering ACE inhibitors. Blood pressure, urine output, and serum sodium, potassium, and creatinine levels need to be monitored closely.

Thrombolytics

Thrombolytics are used to treat some patients with acute MI. These agents are administered IV according to a specific protocol (Chart 28-8). The purpose of thrombolytics is to dissolve (ie, lyse) the thrombus in a coronary artery (thrombolysis), allowing blood to flow through the coronary artery again (reperfusion), minimizing the size of the infarction and preserving ventricular function. Thrombolytics can be used as first-line therapy in facilities that lack the resources to perform PCIs (Boden, Eagle & Granger, 2007). However, although thrombolytics may dissolve the thrombus, they do not affect the underlying atherosclerotic lesion. The patient may be referred for a cardiac catheterization and other invasive interventions.

Thrombolytics dissolve all clots, not just the one in the coronary artery. Thus, they should not be used if the patient has formed a protective clot elsewhere, such as after major surgery or hemorrhagic stroke. Because thrombolytics reduce the patient's ability to form a clot, the patient is at risk

CHART
28-8

PHARMACOLOGY

Administration of Thrombolytic Therapy

Indications

- Chest pain for longer than 20 minutes, unrelieved by nitroglycerin
- ST-segment elevation in at least two leads that face the same area of the heart
- Less than 6 hours from onset of pain

Absolute Contraindications

- Active bleeding
- Known bleeding disorder
- History of hemorrhagic stroke
- History of intracranial vessel malformation
- Recent major surgery or trauma
- Uncontrolled hypertension
- Pregnancy

Nursing Considerations

- Minimize the number of times the patient's skin is punctured

- Avoid intramuscular injections
- Draw blood for laboratory tests when starting the IV line
- Start IV lines before thrombolytic therapy; designate one line to use for blood draws
- Avoid continual use of noninvasive blood pressure cuff
- Monitor for acute dysrhythmias and hypotension
- Monitor for reperfusion: resolution of angina or acute ST-segment changes
- Check for signs and symptoms of bleeding: decrease in hematocrit and hemoglobin values, decrease in blood pressure, increase in heart rate, oozing or bulging at invasive procedure sites, back pain, muscle weakness, changes in level of consciousness, complaints of headache
- Treat major bleeding by discontinuing thrombolytic therapy and any anticoagulants; apply direct pressure and notify the physician immediately
- Treat minor bleeding by applying direct pressure if accessible and appropriate; continue to monitor

for bleeding. Thrombolytics should not be used if the patient is bleeding or has a bleeding disorder. All patients who receive thrombolytic therapy are placed on bleeding precautions to minimize the risk for bleeding. This means minimizing the number of punctures for inserting IV lines, avoiding IM injections, preventing tissue trauma, and applying pressure for longer than usual after any puncture.

To be effective, thrombolytics must be administered as early as possible after the onset of symptoms that indicate an acute MI, generally within 3 to 6 hours. They are given to patients with ECG evidence of acute MI. The selected thrombolytic agent should be initiated within 30 minutes of presentation to the hospital (ISCI, 2006a). This is called door-to-needle time, and hospitals monitor their ability to administer the thrombolytic agent within the recommended time period as an indicator of quality of care.

The thrombolytic agents used most often are alteplase (Activase) and reteplase (r-PA, TNKase). Alteplase is a tissue plasminogen activator (t-PA) that activates the plasminogen present on a blood clot. An IV bolus dose is given and followed by an infusion. Aspirin and unfractionated heparin or LMWH may be used with t-PA to prevent another clot from forming at the site of the lesion. Reteplase, a newer recombinant thrombolytic, is similar to alteplase and has similar effects. It is administered in two bolus doses, followed by a heparin infusion.

Emergent Percutaneous Coronary Intervention

The patient with STEMI may be taken directly to the cardiac catheterization laboratory for an immediate PCI. The procedure is used to open the occluded coronary artery and promote reperfusion to the area that has been deprived of oxygen. Superior outcomes have been reported with use of PCI compared to thrombolytics (Antman, et al., 2007). Early PCI has been shown to be effective in patients of all ages, including those older than 75 years (Chart 28-9). PCI may also be indicated in patients with unstable angina and NSTEMI who are at high risk due to persistent ischemia (King, Smith, Hirshfeld, et al., 2007). The procedure treats the underlying atherosclerotic lesion. Because the duration of oxygen deprivation is directly related to the number of myocardial cells that die, the time from the patient's arrival in the emergency department to the time PCI is performed should be less than 60 minutes. This is frequently referred to as door-to-balloon time. A cardiac catheterization laboratory and staff must be available if an emergent PCI is to be performed within this short time. The nursing care related to PCI is presented later in this chapter.

Cardiac Rehabilitation

After the patient with an MI is free of symptoms, an active rehabilitation program is initiated. Cardiac rehabilitation is an important continuing care program for patients with CAD that targets risk reduction by means of education, individual and group support, and physical activity. It is considered to be an important part of continuing care for patients with CAD (Thomas, King, Lui, et al., 2007). Most insurance programs, including Medicare, cover the cost of cardiac rehabilitation, although not all patients who are candidates for cardiac rehabilitation services participate in these programs.

CHART
28-9

Ethics and Related Issues

Should Aggressive Treatment Be Recommended for the Elderly With Acute Coronary Syndrome (ACS)?

Situation

Many patients who present with acute coronary events are elderly. They often have chronic conditions such as diabetes or arthritis. Elderly patients have traditionally been managed conservatively with medications, but currently interventions such as cardiac catheterization may be recommended. These patients look to their family members for help with treatment decisions.

Dilemma

An 80-year-old woman is hospitalized with unstable angina. When discussing the situation with her two adult sons, the cardiologist recommends cardiac catheterization with possible percutaneous transluminal coronary angioplasty (PTCA) and stent placement. The patient is oriented but lethargic. She defers to her sons regarding treatment decisions. One son worries that she will be subjected to an invasive procedure that is potentially high risk, painful, expensive, and possibly futile. The second son feels that if there is hope of success, she should have the procedure.

Discussion

Research on the risks and benefits of treatment for ACS now includes the elderly as a subgroup. Studies suggest that elderly patients may benefit as much, if not more, than younger patients from coronary reperfusion procedures in terms of reduction of death or myocardial infarction (Futterman & Lemberg, 2007).

1. What information would you provide that supports or discourages aggressive treatment for ACS in the elderly?
2. What assistance can you offer to enhance the patient's and family's autonomy regarding decision making as well as their sense of justice regarding the allocation of resources?

The goals of rehabilitation for the patient who has had an MI are to extend life and improve the quality of life. The immediate objectives are to limit the effects and progression of atherosclerosis, return the patient to work and preillness lifestyle, enhance the psychosocial and vocational status of the patient, and prevent another cardiac event. These objectives are accomplished by encouraging physical activity and physical conditioning, educating the patient and family, and providing counseling and behavioral interventions.

Throughout all phases of rehabilitation, the goals of activity and exercise tolerance are achieved through gradual physical conditioning. Cardiac efficiency is achieved when work and activities of daily living can be performed at a lower heart rate and lower blood pressure, thereby reducing the heart's oxygen requirements and reducing cardiac workload. Physical conditioning is achieved gradually over time. It is not unusual for patients to "overdo it" in an attempt to achieve their goals too rapidly. Patients are observed for chest pain, dyspnea, weakness, fatigue, and palpitations and instructed to stop exercise if any of these occur. In a monitored program, they are also monitored for an increase in

heart rate above the target heart rate, an increase in systolic or diastolic blood pressure of more than 20 mm Hg, a decrease in systolic blood pressure, onset or worsening of dysrhythmias, or ST-segment changes on the ECG.

The target heart rate during hospitalization is an increase of less than 10% from the resting heart rate, or 120 bpm. Following discharge, the target heart rate is based on the patient's stress test results, medications, and overall condition. Oxygen saturation may also be assessed through pulse oximetry to ensure that it remains higher than 93%. If signs or symptoms occur, the patient is instructed to slow down or stop exercising. If the patient is exercising in an unmonitored program, he or she is cautioned to cease activity immediately if signs or symptoms occur and to seek appropriate medical attention.

Patients who are able to walk at 3 to 4 miles/h can usually resume sexual activities. They should be well rested and in a familiar setting, wait at least 1 hour after eating or drinking alcohol, and use a comfortable position. Sexual dysfunction or cardiac symptoms should be reported to the health care provider.

Phases of Cardiac Rehabilitation

Cardiac rehabilitation programs are categorized in three phases.

Phase I begins with the diagnosis of atherosclerosis, which may occur when the patient is admitted to the hospital for ACS (eg, unstable angina or acute MI). Because of today's brief hospital stays, mobilization occurs earlier and patient teaching focuses on the essentials of self-care, rather than instituting behavioral changes for risk reduction. Research has shown that the low-level activities and initial education for the patient and family improve patient outcomes (Flynn, Cafarelli, Petrakos, et al., 2007). Priorities for in-hospital teaching include the signs and symptoms that indicate the need to call 911 (seek emergency assistance), the medication regimen, rest-activity balance, and follow-up appointments with the physician. The patient is reassured that although CAD is a lifelong disease and must be treated as such, most patients can resume a normal life after an MI. This positive approach while in the hospital helps motivate and teach the patient to continue the education and lifestyle changes that are usually needed after discharge. The amount of activity recommended at discharge depends on the age of the patient, his or her condition before the cardiac event, the extent of the disease, the course of the hospital stay, and the development of any complications.

Phase II occurs after the patient has been discharged. The patient attends sessions three times a week for 4 to 6 weeks but may continue for as long as 6 months. This outpatient program consists of supervised, often ECG-monitored, exercise training that is individualized based on the results of an exercise stress test. Support and guidance related to the treatment of the disease and teaching and counseling related to lifestyle modification for risk factor reduction are a part of this phase. Short-term and long-range goals are collaboratively determined based on the patient's needs. At each session, the patient is assessed for the effectiveness of and adherence to the treatment. To prevent complications and another hospitalization, the cardiac rehabilitation staff alerts the referring physician to any problems.

Outpatient cardiac rehabilitation programs are designed to encourage patients and families to support each other. Programs may offer support sessions for spouses and significant others while the patients exercise. The programs involve group educational sessions for both patients and families that are given by cardiologists, exercise physiologists, dietitians, nurses, and other health care professionals. These sessions may take place outside a traditional classroom setting. For instance, a dietitian may take a group of patients to a grocery store to examine labels and meat selections or to a restaurant to discuss menu offerings for a "heart-healthy" diet.

Phase III is a long-term outpatient program that focuses on maintaining cardiovascular stability and long-term conditioning. The patient is usually self-directed during this phase and does not require a supervised program, although it may be offered. The goals of each phase build on the accomplishments of the previous phase.

NURSING PROCESS

THE PATIENT WITH ACUTE CORONARY SYNDROME

Assessment

One of the most important aspects of care of the patient with ACS is the assessment. It establishes the baseline for the patient so that any deviations may be identified, systematically identifies the patient's needs, and helps determine the priority of those needs. Systematic assessment includes a careful history, particularly as it relates to symptoms: chest pain or discomfort, difficulty breathing (dyspnea), palpitations, unusual fatigue, faintness (syncope), or sweating (diaphoresis). Each symptom must be evaluated with regard to time, duration, and the factors that precipitate the symptom and relieve it and in comparison with previous symptoms. A precise and complete physical assessment is critical to detect complications and any change in patient status. Chart 28-6 identifies important assessments and possible findings.

IV sites are examined frequently. Two IV lines are typically placed for any patient with ACS to ensure that access is available for administering emergency medications. Medications are administered IV to achieve rapid onset and to allow for timely adjustment. After the patient's condition stabilizes, IV lines may be changed to a saline lock to maintain IV access.

Diagnosis

Nursing Diagnoses

Based on the clinical manifestations, history, and diagnostic assessment data, major nursing diagnoses may include:

- Ineffective cardiac tissue perfusion related to reduced coronary blood flow
- Risk for imbalanced fluid volume
- Risk for ineffective peripheral tissue perfusion related to decreased cardiac output from left ventricular dysfunction
- Death anxiety related to cardiac event
- Deficient knowledge about post-ACS self-care

Collaborative Problems/Potential Complications

Based on the assessment data, potential complications that may develop include the following:

- Acute pulmonary edema (see Chapter 30)
- Heart failure (see Chapter 30)
- Cardiogenic shock (see Chapter 15)
- Dysrhythmias and cardiac arrest (see Chapters 27 and 30)
- Pericardial effusion and cardiac tamponade (see Chapter 30)

Planning and Goals

The major goals for the patient include relief of pain or ischemic signs (eg, ST-segment changes) and symptoms, prevention of myocardial damage, absence of respiratory dysfunction, maintenance or attainment of adequate tissue perfusion, reduced anxiety, adherence to the self-care program, and absence or early recognition of complications. Care of the patient with ACS who has an uncomplicated MI is summarized in the Plan of Nursing Care (Chart 28-10).

Nursing Interventions

Relieving Pain and Other Signs and Symptoms of Ischemia

Balancing myocardial oxygen supply with demand (eg, as evidenced by the relief of chest pain) is the top priority in the care of the patient with an ACS. Although administering medications as previously described is required to accomplish this goal, nursing interventions are also important. Collaboration among the patient, nurse, and physician is critical in assessing the patient's response to therapy and in altering the interventions accordingly.

Oxygen should be administered along with medication therapy to assist with relief of symptoms. Administration of oxygen, even in low doses, raises the circulating level of oxygen to reduce pain associated with low levels of myocardial oxygen. The route of administration, usually by nasal cannula, and the oxygen flow rate are documented. A flow rate of 2 to 4 L/min is usually adequate to maintain oxygen saturation levels of 96% to 100% unless chronic pulmonary disease is present.

Vital signs are assessed frequently as long as the patient is experiencing pain and other signs or symptoms of acute ischemia. Physical rest in bed with the backrest elevated or in a supportive chair helps decrease chest discomfort and dyspnea. Elevation of the head and torso is beneficial for the following reasons:

- Tidal volume improves because of reduced pressure from abdominal contents on the diaphragm and better lung expansion.
- Drainage of the upper lung lobes improves.
- Venous return to the heart (preload) decreases, reducing the work of the heart.

Improving Respiratory Function

Regular and careful assessment of respiratory function detects early signs of pulmonary complications. The nurse monitors fluid volume status to prevent overloading the heart and lungs and encourages the patient to breathe

deeply and change position frequently to help keep fluid from pooling in the bases of the lungs. Pulse oximetry guides the use of oxygen therapy.

Promoting Adequate Tissue Perfusion

Bed or chair rest during the initial phase of treatment helps reduce myocardial oxygen consumption. This limitation on mobility should remain until the patient is pain free and hemodynamically stable. It is important to check skin temperature and peripheral pulses frequently to monitor tissue perfusion.

Reducing Anxiety

Alleviating anxiety and decreasing fear are important nursing functions that reduce the sympathetic stress response. Decreased sympathetic stimulation decreases the workload of the heart, which may relieve pain and other signs and symptoms of ischemia.

The development of a trusting and caring relationship with the patient is critical in reducing anxiety. Providing information to the patient and family in an honest and supportive manner encourages the patient to be a partner in care and greatly assists in developing a positive relationship. Other interventions that can be used to reduce anxiety include ensuring a quiet environment, preventing interruptions that disturb sleep, using a caring and appropriate touch, teaching relaxation techniques, using humor, and providing spiritual support consistent with the patient's beliefs. The nurse provides frequent opportunities for the patient to privately share concerns and fears. An atmosphere of acceptance helps the patient know that these concerns and fears are both realistic and normal. Music therapy and pet therapy can also relax the patient and reduce anxiety (Cole, 2007). Hospitals may have developed infection control and safety procedures pertaining to the animals, their handlers, and the patients eligible for pet therapy.

Monitoring and Managing Potential Complications

Complications that can occur after acute MI may be caused by the damage that occurs to the myocardium and to the conduction system from reduced coronary blood flow. Because these complications can be life-threatening, close monitoring for and early identification of their signs and symptoms are critical (see the Plan of Nursing Care in Chart 28-10).

The nurse monitors the patient closely for changes in cardiac rate and rhythm, heart sounds, blood pressure, chest pain, respiratory status, urinary output, skin color and temperature, sensorium, ECG changes, and laboratory values. It is necessary to report promptly any changes in the patient's condition to the physician and institute emergency measures when necessary.

Promoting Home and Community-Based Care

TEACHING PATIENTS SELF-CARE. The most effective way to increase the probability that the patient will implement a self-care regimen after discharge is to identify the patient's priorities, provide adequate education about heart-healthy living, and facilitate the patient's involvement in a cardiac rehabilitation program (Decker, Garavelia, Chen, et al., 2007). Patient participation in the development of an individualized

CHART

PLAN OF NURSING CARE

Care of the Patient With an Uncomplicated Myocardial Infarction

NURSING DIAGNOSIS: Ineffective cardiac tissue perfusion related to reduced coronary blood flow**GOAL:** Relief of chest pain/discomfort**Nursing Interventions**

1. Initially assess, document, and report to the physician the following:
 - a. The patient's description of chest discomfort, including location, intensity, radiation, duration, and factors that affect it. Other symptoms such as nausea, diaphoresis, or complaints of unusual fatigue.
 - b. The effect of coronary ischemia on perfusion to the heart (eg, change in blood pressure, heart rhythm), to the brain (eg, changes in LOC), to the kidneys (eg, decrease in urine output), and to the skin (eg, color, temperature).
2. Obtain a 12-lead ECG recording during symptomatic events, as prescribed, to assess for ongoing ischemia.
3. Administer oxygen as prescribed.
4. Administer medication therapy as prescribed and evaluate the patient's response continuously.
5. Ensure physical rest: backrest elevated to promote comfort; diet as tolerated; use of bedside commode; use of stool softener to prevent straining at stool. Provide a restful environment, and allay fears and anxiety by being calm and supportive. Individualize visitation, based on patient response.

Rationale

1. These data assist in determining the cause and effect of the chest discomfort and provide a baseline with which posttherapy symptoms can be compared.
 - a. There are many conditions associated with chest discomfort. There are characteristic clinical findings of ischemic pain and symptoms.
 - b. MI decreases myocardial contractility and ventricular compliance and may produce dysrhythmias. Cardiac output is reduced, resulting in reduced blood pressure and decreased organ perfusion.
2. An ECG during symptoms may be useful in the diagnosis of ongoing ischemia.
3. Oxygen therapy increases the oxygen supply to the myocardium.
4. Medication therapy (nitroglycerin, morphine, beta-blocker, aspirin) is the first line of defense in preserving myocardial tissue.
5. Physical rest reduces myocardial oxygen consumption. Fear and anxiety precipitate the stress response; this results in increased levels of endogenous catecholamines, which increase myocardial oxygen consumption.

Expected Outcomes

- Reports beginning relief of chest discomfort and symptoms.
- Appears comfortable and is free of pain and other signs or symptoms.
- Respiratory rate, cardiac rate, and blood pressure return to prediscomfort level.
- Skin warm and dry.
- Adequate cardiac output as evidenced by:
 - Stable/improving ECG
 - Heart rate and rhythm
 - Blood pressure
 - Mentation
 - Urine output
 - Serum BUN and creatinine
 - Skin color and temperature
- No adverse effects from medications.

NURSING DIAGNOSIS: Risk for impaired gas exchange related to left ventricular failure**GOAL:** Absence of respiratory distress**Nursing Interventions**

1. Initially, every 4 hours, and with chest discomfort or symptoms, assess, document, and report to the physician abnormal heart sounds (S_3 and S_4 gallop or new murmur), abnormal breath sounds (particularly crackles), decreased oxygenation, and activity intolerance.

Rationale

1. These data are useful in diagnosing left ventricular failure. Diastolic filling sounds (S_3 and S_4) result from decreased left ventricular compliance associated with MI. Papillary muscle dysfunction (from infarction of the papillary muscle) can result in mitral regurgitation and a reduction in stroke volume. The presence of crackles (usually at the lung bases) may indicate pulmonary congestion from increased left heart pressures. The association of symptoms and activity can be used as a guide for activity prescription and a basis for patient teaching.

Expected Outcomes

- No shortness of breath, dyspnea on exertion, orthopnea, or paroxysmal nocturnal dyspnea.
- Respiratory rate less than 20 breaths/min with physical activity and 16 breaths/min with rest.
- Skin color and temperature normal.
- SpO_2 , PaO_2 , and $PaCO_2$ within normal limits.
- Heart rate less than 100 bpm and greater than 60 bpm, with blood pressure within patient's normal limits.
- Chest x-ray unchanged.
- Appears comfortable and rested.

 CHART
28-10

PLAN OF NURSING CARE
Care of the Patient With an Uncomplicated Myocardial Infarction (Continued)

NURSING DIAGNOSIS: Risk for ineffective peripheral tissue perfusion related to decreased cardiac output GOAL: Maintenance/attainment of adequate tissue perfusion		
Nursing Interventions <ol style="list-style-type: none"> 1. Initially, every 4 hours, and with chest discomfort, assess, document, and report to the physician the following: <ol style="list-style-type: none"> a. Hypotension b. Tachycardia and other dysrhythmia c. Activity intolerance d. Mentation changes (use family input) e. Reduced urine output (less than 30 mL/h) f. Cool, moist, cyanotic extremities, decreased peripheral pulses, prolonged capillary refill 	Rationale <ol style="list-style-type: none"> 1. These data are useful in determining a low cardiac output state. 	Expected Outcomes <ul style="list-style-type: none"> • Blood pressure within the patient's normal range. • Ideally, normal sinus rhythm without dysrhythmia is maintained, or patient's baseline rhythm is maintained between 60 and 100 bpm without further dysrhythmia. • Prescribed activity is well tolerated. • Remains alert and oriented and without cognitive or behavioral change. • Appears comfortable. • Urine output greater than 30 mL/h. • Extremities warm and dry with normal color.
NURSING DIAGNOSIS: Anxiety related to cardiac event GOAL: Reduction of anxiety		
Nursing Interventions <ol style="list-style-type: none"> 1. Assess, document, and report to the physician the patient's and family's level of anxiety and coping mechanisms. 2. Assess the need for spiritual counseling and refer as appropriate. 3. Assess the need for social service referral. 	Rationale <ol style="list-style-type: none"> 1. These data provide information about psychological well-being. Causes of anxiety are variable and individual, and may include acute illness, hospitalization, pain, disruption of activities of daily living at home and at work, changes in role and self-image due to illness, and financial concerns. Because anxious family members can transmit anxiety to the patient, the nurse must also identify strategies to reduce the family's fear and anxiety. 2. If a patient finds support in a religion, spiritual counseling may assist in reducing anxiety and fear. 3. Social services can assist with post-hospital care and financial concerns. 	Expected Outcomes <ul style="list-style-type: none"> • Reports less anxiety. • Patient and family discuss their anxieties and fears about illness and death. • Patient and family appear less anxious. • Appears restful, respiratory rate less than 16 breaths/min, heart rate less than 100 bpm without ectopic beats, blood pressure within patient's normal limits, skin warm and dry. • Participates actively in a progressive rehabilitation program. • Practices stress reduction techniques.
NURSING DIAGNOSIS: Deficient knowledge about post-MI self-care GOAL: Adheres to the home health care program; chooses lifestyle consistent with heart-healthy recommendations (See Chart 28-11: Promoting Health After Myocardial Infarction and Other Acute Coronary Syndromes)		

program enhances the potential for an effective treatment plan (Chart 28-11).

CONTINUING CARE. Depending on the patient's condition and the availability of family assistance, a home care referral may be indicated. The home care nurse assists the patient with scheduling and keeping follow-up appointments and with adhering to the prescribed cardiac rehabilitation regimen. The patient may need reminders about follow-up monitoring, including periodic laboratory testing and ECGs, as well as general health screening. In addition, the home care nurse monitors the patient's adherence to dietary restrictions and to prescribed medications. If the patient is receiving home oxygen, the nurse ensures that the patient

is using the oxygen as prescribed and that appropriate home safety measures are maintained. If the patient has evidence of heart failure secondary to an MI, appropriate home care guidelines for the patient with heart failure are followed (see Chapter 30).

Evaluation

Expected Patient Outcomes

Expected patient outcomes may include the following:

1. Experiences relief of angina
2. Has stable cardiac and respiratory status
3. Maintains adequate tissue perfusion

CHART
28-11**HEALTH PROMOTION****Promoting Health After Myocardial Infarction and Other Acute Coronary Syndromes**

To extend and improve the quality of life, a patient who has had an MI must adjust his or her lifestyle to promote heart-healthy living. With this in mind, the nurse and patient develop a program to help the patient achieve desired outcomes.

Lifestyle Recommendations During Convalescence and Healing

Adaptation to an MI is an ongoing process and usually requires some modification of lifestyle. Instruct patients to make the following specific modifications:

- Avoid any activity that produces chest pain, extreme dyspnea, or undue fatigue
- Avoid extremes of heat and cold and walking against the wind
- Lose weight, if indicated
- Stop smoking and use of tobacco; avoid secondhand smoke
- Develop heart-healthy eating patterns and avoid large meals and hurrying while eating
- Modify meals to align with the Therapeutic Lifestyle Changes (TLC) or other recommended diet
- Adhere to medical regimen, especially in taking medications
- Follow recommendations that ensure blood pressure and blood glucose are in control
- Pursue activities that relieve and reduce stress

4. Exhibits decreased anxiety
5. Adheres to a self-care program
6. Has no complications

INVASIVE CORONARY ARTERY PROCEDURES**Percutaneous Coronary Interventions****Types of Procedures**

Invasive interventional procedures to treat CAD include PTCA, intracoronary stent implantation, atherectomy, and brachytherapy. All of these procedures are classified as PCIs.

Percutaneous Transluminal Coronary Angioplasty

In PTCA, a balloon-tipped catheter is used to open blocked coronary vessels and resolve ischemia. It is used in patients with angina and as an intervention for ACS. Catheter-based interventions can also be used to open blocked CABGs. The purpose of PTCA is to improve blood flow within a coronary artery by compressing and “cracking” the atheroma. The procedure is attempted when the interventional cardiologist believes that PTCA can improve blood flow to the myocardium.

PTCA is carried out in the cardiac catheterization laboratory. Hollow catheters called sheaths are inserted, usually in the femoral artery (and sometimes femoral vein), providing a conduit for other catheters. Catheters are then threaded through the femoral artery, up through the aorta, and into the

Adoption of an Activity Program

Additionally, the patient needs to undertake a structured program of activity and exercise for long-term rehabilitation. Advise patients to:

- Engage in a regimen of physical conditioning with a gradual increase in activity duration and then a gradual increase in activity intensity
- Walk daily, increasing distance and time as prescribed
- Monitor pulse rate during physical activity
- Avoid physical exercise immediately after a meal
- Alternate activity with rest periods (some fatigue is normal and expected during convalescence)
- Participate in a daily program of exercise that develops into a program of regular exercise for a lifetime

Managing Symptoms

The patient must learn to recognize and take appropriate action for recurrent symptoms. Make sure that patients know to do the following:

- Call 911 if chest pressure or pain (or prodromal symptoms) is not relieved in 15 minutes by nitroglycerin
- Contact the physician if any of the following occur: shortness of breath, fainting, slow or rapid heartbeat, swelling of feet and ankles

coronary arteries. Angiography is performed using injected radiopaque contrast agents (commonly called dye) to identify the location and extent of the blockage. A balloon-tipped dilation catheter is passed through the sheath and positioned over the lesion. The physician determines the catheter position by examining markers on the balloon that can be seen with fluoroscopy. When the catheter is properly positioned, the balloon is inflated with high pressure for several seconds and then deflated. The pressure compresses and often “cracks” the atheroma (Fig. 28-8). The media and adventitia of the coronary artery are also stretched.

Several inflations and several balloon sizes may be required to achieve the goal, usually defined as an improvement in blood flow and a residual stenosis of less than 20% (Urden, Stacy & Lough, 2006). Other measures of the success of a PTCA are an increase in the artery’s lumen and no clinically obvious arterial trauma. Because the blood supply to the coronary artery decreases while the balloon is inflated, the patient may complain of chest pain and the ECG may display ST-segment changes. Intracoronary stents are usually positioned in the intima of the vessel to maintain patency after the balloon is withdrawn.

Coronary Artery Stent

After PTCA, the area that has been treated may close off partially or completely, a process called restenosis. The intima of the coronary artery has been injured and responds by initiating an acute inflammatory process. This process may include release of mediators that leads to vasoconstriction, clotting, and scar tissue formation. A coronary artery stent may be placed to overcome these risks. A **stent** is a metal

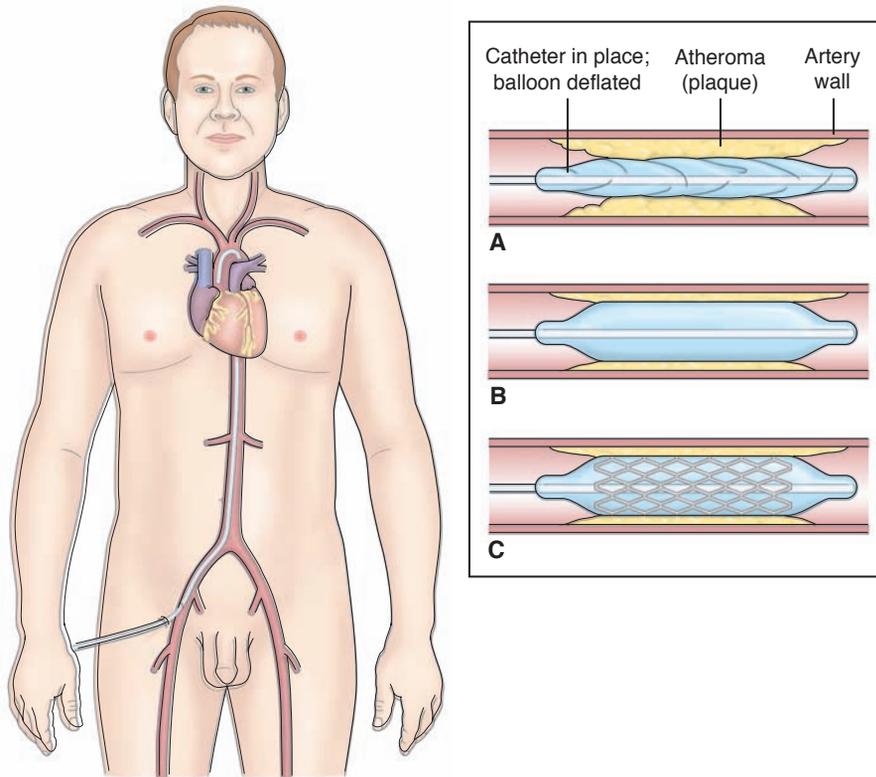

Figure 28-8 Percutaneous transluminal coronary angioplasty. **A**, A balloon-tipped catheter is passed into the affected coronary artery and placed across the area of the atheroma (plaque). **B**, The balloon is then rapidly inflated and deflated with controlled pressure. **C**, A stent is placed to maintain patency of the artery, and the balloon is removed.

mesh that provides structural support to a vessel at risk of acute closure. The stent is positioned over the angioplasty balloon. When the balloon is inflated, the mesh expands and presses against the vessel wall, holding the artery open. The balloon is withdrawn, but the stent is left permanently in place within the artery (see Fig. 28-8). Eventually, endothelium covers the stent and it is incorporated into the vessel wall. Some stents are coated with medications, such as sirolimus (Rapamune) or paclitaxel (Taxol), which may minimize the formation of thrombi or scar tissue within the stent. These drug-eluting stents have increased the success of PCI (Fennessy & Borden, 2006). Because of the risk of thrombus formation within the stent, the patient receives antiplatelet medications, usually aspirin and clopidogrel. The clopidogrel is continued for at least a month following placement of a bare metal stent and for a year following drug-eluting stents (King, et al., 2007).

Atherectomy

Atherectomy is an invasive interventional procedure that involves the removal of the atheroma, or plaque, from a coronary artery by cutting, shaving, or grinding (Urden, et al., 2006). It may be used in conjunction with PTCA. Directional coronary atherectomy and transluminal extraction catheter procedures involve the use of a catheter that removes the lesion and its fragments. Another procedure called rotational atherectomy uses a catheter with diamond chips impregnated on the tip (called a bur) that rotates like a dentist's drill at 130,000 to 180,000 rpm, pulverizing the lesion. Usually, several passes of these catheters are needed to achieve satisfactory results. Postprocedural patient care is the same as for a patient after PTCA.

Brachytherapy

PTCA and stent implantation cause a cellular reaction in the coronary artery that promotes proliferation of the intima of the artery, increasing the possibility of arterial obstruction. Brachytherapy reduces the recurrence of obstruction, preventing vessel restenosis by inhibiting smooth muscle cell proliferation. Brachytherapy involves the delivery of gamma or beta radiation by placing a radioisotope close to the lesion. The radioisotope may be delivered by a catheter or implanted with the stent. However, drug-eluting stents are used more commonly to prevent restenosis, because they are typically more effective and less expensive than brachytherapy (Reynolds, et al., 2007).

Complications

Complications that can occur during a PCI procedure include dissection, perforation, abrupt closure, or vasospasm of the coronary artery, acute MI, acute dysrhythmias (eg, ventricular tachycardia), and cardiac arrest. These may require emergency surgical treatment. Complications after the procedure may include abrupt closure of the coronary artery and vascular complications, such as bleeding at the insertion site, retroperitoneal bleeding, hematoma, and arterial occlusion, as well as acute renal failure (Table 28-4) (Lins, Guffey, VanRiper, et al., 2006).

Postprocedure Care

Patient care is similar to that for a diagnostic cardiac catheterization (see Chapter 26). Patients who are not already hospitalized are admitted the day of the PCI. Those with no complications go home the next day. When the

Table 28-4 COMPLICATIONS AFTER PERCUTANEOUS CORONARY INTERVENTIONS

Complication	Clinical Manifestations	Possible Causes	Nursing Actions
Myocardial ischemia	Chest pain Ischemic changes on ECG Dysrhythmias	Thrombosis Restenosis of coronary artery	Administer oxygen and nitroglycerin Obtain 12-lead ECG Notify cardiologist
Bleeding and hematoma formation	Continuation of bleeding from vascular access site Swelling at site Formation of hard lump Pain with leg movement Possible hypotension and tachycardia	Anticoagulant therapy Vascular trauma Inadequate hemostasis Leg movement	Keep patient on bedrest Apply manual pressure over sheath insertion site Outline hematoma with marking pen Notify physician if bleeding continues
Retroperitoneal hematoma	Back, flank, or abdominal pain Hypotension Tachycardia Restlessness, agitation	Arterial leak of blood into the retroperitoneal space	Notify physician Stop anticoagulants Administer IV fluids Anticipate diagnostic testing (eg, computed tomography scan) Prepare patient for intervention Notify physician Anticipate intervention
Arterial occlusion	Lost/weakened pulse distal to sheath insertion site Extremity cool, cyanotic, painful	Arterial thrombus or embolus	
Pseudoaneurysm formation	Swelling at vascular access site Pulsatile mass, bruit	Vessel trauma during the procedure	Notify physician Anticipate intervention
Arteriovenous fistula formation	Swelling at vascular access site Pulsatile mass, bruit	Vessel trauma during the procedure	Notify physician Anticipate intervention
Acute renal failure	Decreased urine output Elevated blood urea nitrogen, serum creatinine	Nephrotoxic contrast agent	Monitor urine output, blood urea nitrogen, creatinine, electrolytes Provide adequate hydration Administer renal protective agents (acetylcysteine) before and after procedure as prescribed

ECG, electrocardiogram; IV, intravenous.

PCI is performed emergently to treat ACS, patients usually go to a critical care unit and stay in the hospital for a few days. During the PCI, patients receive IV heparin or a thrombin inhibitor (eg, bivalirudin [Angiomax]) and are monitored closely for signs of bleeding (Levine, Berger, Cohen, et al., 2006). Patients may also receive a GP IIb/IIIa agent (eg, eptifibatide) for several hours following the PCI to prevent platelet aggregation and thrombus formation in the coronary artery. Hemostasis is achieved, and femoral sheaths may be removed at the end of the procedure by using a vascular closure device (eg, *Angio-Seal*, *VasoSeal*) or a device that sutures the vessels. Hemostasis after sheath removal may also be achieved by direct manual pressure, a mechanical compression device (eg, C-shaped clamp), or a pneumatic compression device (eg, *FemoStop*).

Patients may return to the nursing unit with the large peripheral vascular access sheaths in place. The sheaths are then removed after blood studies (eg, activated clotting time) indicate that the heparin is no longer active and the clotting time is within an acceptable range. This usually takes a few hours, depending on the amount of heparin given during the procedure. The patient must remain flat in bed and keep the affected leg straight until the sheaths are removed and then for a few hours afterward to maintain hemostasis. Because immobility and bed rest may cause discomfort, treatment may include analgesics and sedation. Sheath removal and the application of pressure on the vessel insertion site may cause the heart rate to slow and the blood pressure to decrease (vasovagal response). An IV bolus of atropine is usually given to treat this response.

Some patients with unstable lesions and at high risk for abrupt vessel closure are restarted on heparin after sheath removal, or they receive an IV infusion of a GP IIb/IIIa inhibitor. These patients are monitored closely and may have a delayed recovery period.

After hemostasis is achieved, a pressure dressing is applied to the site. Patients resume self-care and ambulate unassisted within a few hours of the procedure. The duration of immobilization depends on the size of the sheath inserted, the amount of anticoagulant administered, the method of hemostasis, the patient's underlying condition, and the physician's preference. On the day after the procedure, the site is inspected and the dressing removed. The patient is instructed to monitor the site for bleeding or development of a hard mass indicative of hematoma.

Surgical Procedures: Coronary Artery Revascularization

Advances in diagnostics, medical management, surgical and anesthesia techniques, as well as the care provided in critical care and surgical units, home care, and rehabilitation programs have continued to make surgery an effective treatment option for patients with CAD. CAD has been treated by myocardial revascularization since the 1960s, and the most common CABG techniques have been performed for more than 35 years. CABG is a surgical procedure in which a blood vessel is grafted to an occluded coronary artery so that blood can flow beyond the occlusion; it is also called a bypass graft.

The major indications for CABG are:

- Alleviation of angina that cannot be controlled with medication or PCI
- Treatment of left main coronary artery stenosis or multivessel CAD
- Prevention and treatment of MI, dysrhythmias, or heart failure
- Treatment for complications from an unsuccessful PCI

CABG is performed less frequently in women. Compared with men, women referred for this surgery tend to be older and have more comorbidities. In addition, they have a higher risk of surgical complications such as MIs and strokes (Puskas, Kilgo, Kutner, et al., 2007). Furthermore, women have smaller coronary arteries, which makes the surgical procedure technically more difficult. Although some women have good outcomes following CABG, men generally have a better rate of graft patency and symptom relief (Eastwood & Doering, 2005).

The recommendation for CABG is determined by a number of factors, including the number of diseased coronary vessels, the degree of left ventricular dysfunction, the presence of other health problems, the patient's symptoms, and any previous treatment. Studies have shown that CABG may be the preferred treatment for high-risk patients such as those with severe triple-vessel CAD, ventricular dysfunction, and diabetes (Bravata, Gienger, McDonald, et al., 2007). Studies continue to compare clinical outcomes of CABG and PCI in patients with CAD.

For a patient to be considered for CABG, the coronary arteries to be bypassed must have approximately a 70% occlusion (60% if in the left main coronary artery). If significant blockage is not present, flow through the artery will compete with flow through the bypass, and circulation to the ischemic area of myocardium may not improve. It is also necessary that the artery be patent beyond the area of blockage or the flow through the bypass will be impeded.

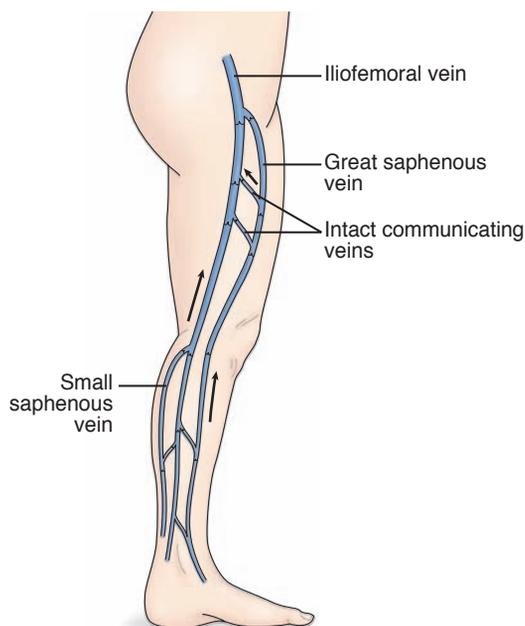

Figure 28-9 The greater and lesser saphenous veins are commonly used in bypass graft procedures.

A vessel commonly used for CABG is the greater saphenous vein, followed by the lesser saphenous vein (Fig. 28-9). Cephalic and basilic veins are also used. The vein is removed from the leg (or arm) and grafted to the ascending aorta and to the coronary artery distal to the lesion. Traditionally, a skin incision was made over the length of vein segment, but new techniques allow small incisions on the affected extremity. A common adverse effect of vein removal is edema in the extremity from which the vein was taken. The degree of edema varies and usually diminishes over time. Within 5 to 10 years, atherosclerotic changes often develop in saphenous vein grafts.

The right and left internal mammary arteries and occasionally the radial and gastroepiploic arteries are also used for CABG. Arterial grafts are preferred to venous grafts because they do not develop atherosclerotic changes as quickly and remain patent longer. The surgeon leaves the proximal end of the mammary artery intact and detaches the distal end of the artery from the chest wall. This end of the artery is then grafted to the coronary artery distal to the occlusion. The internal mammary arteries may not be long enough to use for multiple bypasses. Because of this, many CABG procedures are performed with a combination of venous and arterial grafts.

Traditional Coronary Artery Bypass Graft

CABG procedures are performed with the patient under general anesthesia. In the traditional CABG procedure, the surgeon performs a median sternotomy and connects the patient to the cardiopulmonary bypass (CPB) machine. Next, a blood vessel from another part of the patient's body (eg, saphenous vein, left internal mammary artery) is grafted distal to the coronary artery lesion, bypassing the obstruction (Fig. 28-10). CPB is then discontinued, chest tubes and epicardial pacing wires are placed,

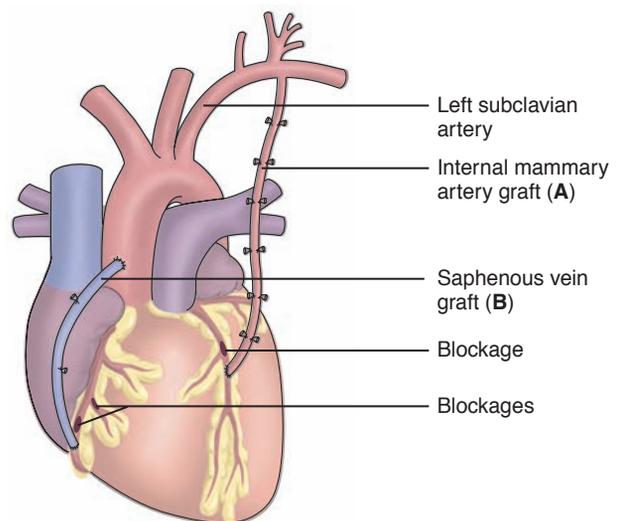

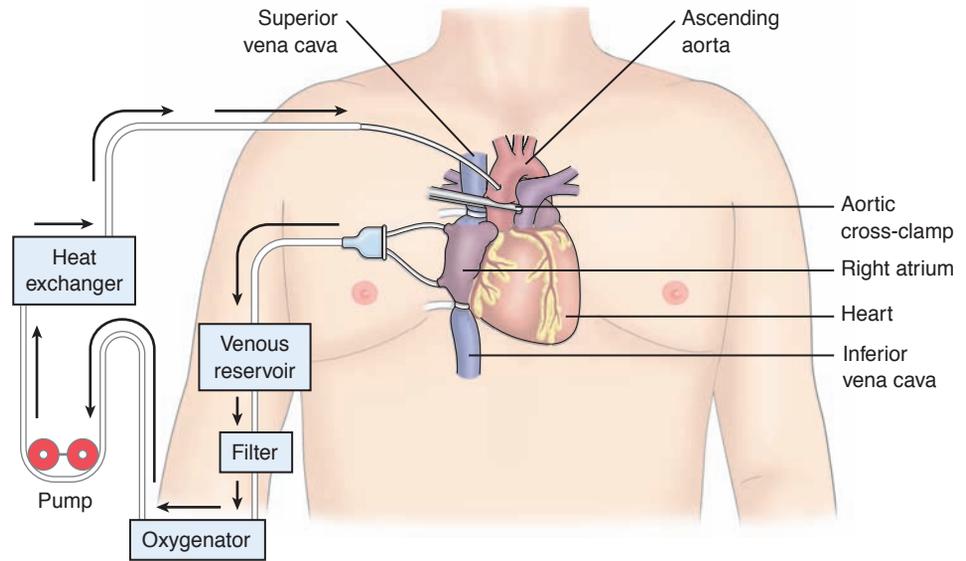

Figure 28-10 Coronary artery bypass grafts. One or more procedures may be performed using various veins and arteries. **A**, Left internal mammary artery, used frequently because of its functional longevity. **B**, Saphenous vein, also used as bypass graft.

Figure 28-11 The cardiopulmonary bypass (CPB) system in which cannulas are placed through the right atrium into the superior and inferior vena cava to divert blood from the body and into the bypass system. The pump system creates a vacuum, pulling blood into the venous reservoir. The blood is cleared of air bubbles, clots, and particulates by the filter and then is passed through the oxygenator, releasing carbon dioxide and obtaining oxygen. Next, the blood is pulled to the pump and pushed out to the heat exchanger, where its temperature is regulated. The blood is then returned to the body via the ascending aorta.

and the incision is closed. The patient is then admitted to a critical care unit.

Cardiopulmonary Bypass

Many cardiac surgical procedures are possible because of CPB (ie, extracorporeal circulation). The procedure mechanically circulates and oxygenates blood for the body while bypassing the heart and lungs. CPB maintains perfusion to body organs and tissues and allows the surgeon to complete the anastomoses in a motionless, bloodless surgical field.

CPB is accomplished by placing a cannula in the right atrium, vena cava, or femoral vein to withdraw blood from the body. The cannula is connected to tubing filled with an isotonic crystalloid solution. Venous blood removed from the body by the cannula is filtered, oxygenated, cooled or warmed by the machine, and then returned to the body. The cannula used to return the oxygenated blood is usually inserted in the ascending aorta, or it may be inserted in the femoral artery (Fig. 28-11). The heart is stopped by the injection of a potassium-rich cardioplegia solution into the coronary arteries. The patient receives heparin to prevent clotting and thrombus formation in the bypass circuit when blood comes in contact with the surfaces of the tubing. At the end of the procedure when the patient is disconnected from the bypass machine, protamine sulfate is administered to reverse the effects of heparin.

During the procedure, hypothermia is maintained, usually 28°C to 32°C (82.4°F to 89.6°F). The blood is cooled during CPB and returned to the body. The cooled blood slows the body's basal metabolic rate, thereby decreasing the demand for oxygen. Cooled blood usually has a higher viscosity, but the crystalloid solution used to prime the bypass tubing dilutes the blood. When the surgical procedure is completed, the blood is rewarmed as it passes through the CPB circuit. Urine output, arterial blood gases, electrolytes, and coagulation studies are monitored to assess the patient's status during CPB.

Alternative Coronary Artery Bypass Graft Techniques

A number of alternative CABG techniques have been developed that may have fewer complications for some groups of patients. Off-pump CABG (OPCAB) surgery has been used successfully in many patients since the 1990s. OPCAB involves a standard median sternotomy incision, but the surgery is performed without CPB. A beta-adrenergic blocker may be used to slow the heart rate. The surgeon also uses a myocardial stabilization device to hold the site still for the anastomosis of the bypass graft into the coronary artery while the heart continues to beat (Fig. 28-12). The

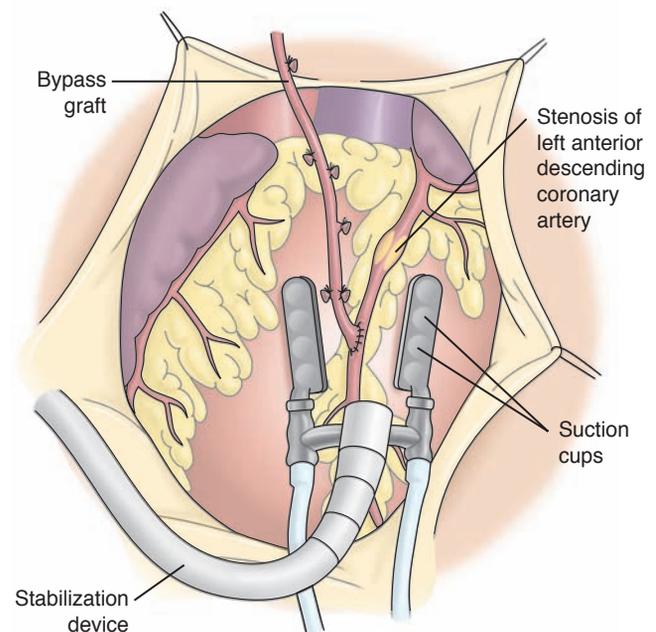

Figure 28-12 Stabilizer device for off-pump coronary artery bypass surgery.

potential benefits of OPCAB include a decrease in the incidence of stroke and other neurologic complications, renal failure, and other postoperative complications (Lattouf, Puskas, Thourani, et al., 2007). Comparison of this technique with traditional CABG has been found to be favorable in some patient groups.

Minimally invasive surgical techniques that eliminate median sternotomy have also been developed. These endoscopic techniques use smaller incisions and a robotic system to place bypass grafts (Katz & Bonatti, 2007). The patient is placed on CPB via the femoral vessels. Patients who require multiple bypass grafts or grafts to arteries on the dorsum of the heart may not be candidates for this technique.

Complications of Coronary Artery Bypass Graft

CABG may result in complications such as hemorrhage, dysrhythmias, and MI (Table 28-5). The patient may require interventions for more than one complication at a time. Collaboration among nurses, physicians, pharmacists, respiratory therapists, and dietitians is necessary to achieve the desired patient outcomes. Although most patients improve symptomatically following surgery, CABG is not a cure for CAD, and angina, exercise intolerance, or other symptoms experienced before CABG may recur. Medications required before surgery may need to be continued. Lifestyle modifications recommended before surgery remain important to treat the underlying CAD and for the continued viability of the newly implanted grafts.

Nursing Management

Cardiac surgery patients have many of the same needs and require the same perioperative care as other surgical patients (see Chapters 18 through 20), plus some special needs.

Preoperative Management

Preoperative teaching is important; patients and their families may be very anxious as the association of the heart with life and death intensifies their emotions. Before surgery, physical and psychological assessments establish a baseline for future reference. In addition, it is necessary to evaluate the patient's understanding of the surgical procedure, informed consent, and adherence to treatment protocols.

Assessing the Patient

Patients are frequently admitted to the hospital the day of the procedure. Therefore, most of the preoperative evaluation is completed in the physician's office and during preadmission testing.

Nursing and medical personnel perform a history and physical examination. Preoperative testing consists of a chest x-ray, ECG, laboratory tests, including coagulation studies, and blood typing and cross-matching. The health assessment focuses on obtaining baseline physiological, psychological, and social information. The patient's and family's learning needs are identified and addressed. Of particular importance are the patient's usual functional level, coping mechanisms, and available support systems. These affect the patient's postoperative course, discharge plans, and rehabilitation.

The preoperative history and health assessment should be thorough and well documented because they provide a basis for postoperative comparison. It is necessary to perform a systematic assessment of all systems, with emphasis on cardiovascular functioning. The nurse assesses the patient for disorders that could complicate or affect the postoperative course, such as diabetes, hypertension, and preexisting disabilities.

The status of the cardiovascular system is determined by reviewing the patient's symptoms, including past and present experiences with chest pain, palpitations, and breathing difficulty (dyspnea), leg pain that occurs with walking (intermittent claudication), and peripheral edema. The patient's history of major illnesses, previous surgeries, medication, use of illicit and over-the-counter drugs, herbal supplements, alcohol, and tobacco is also obtained. Particular attention is paid to blood glucose control in patients with diabetes because there is a higher incidence of postoperative complications when glycemic control is poor (Presutti & Millo, 2006).

A complete physical examination is performed, with a focused cardiovascular emphasis, as previously discussed in detail in Chapter 26.

The psychosocial assessment and the assessment of the patient's and family's learning needs are as important as the physical examination. Anticipation of cardiac surgery is a source of great stress to the patient and family, and patients with high anxiety levels have poorer outcomes (Gallagher & McKinley, 2007). However, some anxiety is expected, and the work of worrying can help patients identify priorities and find coping strategies that help them face the threat of surgery (Chart 28-12). Questions may be asked to obtain the following information:

- Knowledge and understanding of the surgical procedure, postoperative course, and recovery
- Meaning of the surgery to the patient and family
- Fears regarding the present and future
- Coping mechanisms that are being used
- Support systems in effect

Reducing Fear and Anxiety

The nurse gives the patient and family time and opportunity to express their fears. Topics of concern may be pain, changes in body image, fear of the unknown, and disability or death. It is often helpful to describe to the patient the sensations that he or she can expect. It is necessary to describe the preoperative sedation, the anesthetic, and the postoperative pain medications. The nurse reassures the patient that the fear of pain is normal, that some pain will be experienced, that medication to relieve pain will be provided, and that the patient will be closely monitored. In addition, the nurse suggests that the patient request analgesic medication before the pain becomes severe. If the patient has concerns about scarring from surgery, the nurse encourages him or her to discuss this issue and corrects any misconceptions. The patient and family may want to discuss their fear of the patient dying. After the fear is expressed, the nurse can assure the patient and family that this fear is normal and further explore their feelings.

For patients with extreme anxiety or fear and for whom emotional support and education are not successful, medication therapy may be helpful. The anxiolytic agents most

Table 28-5 POTENTIAL COMPLICATIONS OF CARDIAC SURGERY

Complication	Cause	Assessment and Management
Cardiac Complications		
Decreased Cardiac Output Hypovolemia (most common cause of decreased cardiac output after cardiac surgery)	<ul style="list-style-type: none"> • Net loss of blood and intravascular volume. • Surgical hypothermia (as the reduced body temperature rises after surgery, blood vessels dilate, and more volume is needed to fill the vessels). • Intravenous fluid loss to the interstitial spaces because surgery and anesthesia increase capillary permeability. 	<ul style="list-style-type: none"> • Arterial hypotension, tachycardia, low central venous pressure (CVP) and low pulmonary artery wedge pressure (PAWP) are often seen. • Fluid replacement may be prescribed. Replacement fluids include colloid (albumin, hetastarch), packed red blood cells, or crystalloid solution (normal saline, lactated Ringer's solution).
Persistent bleeding	<ul style="list-style-type: none"> • Cardiopulmonary bypass causes platelet dysfunction, and hypothermia alters clotting mechanisms. • Surgical trauma causes tissues and blood vessels to ooze bloody drainage. • Intraoperative anticoagulant (heparin) therapy. • Postoperative coagulopathy may also result from liver dysfunction and depletion of clotting components. 	<ul style="list-style-type: none"> • Accurate measurement of wound bleeding and chest tube blood is essential. Drainage should not exceed 200 mL/h for the first 4 to 6 hours. Drainage should decrease and stop within a few days, while progressing from sanguinous to serosanguineous to serous. • Serial hemoglobin, hematocrit, and coagulation studies are performed to guide therapy. • Administration of fluids, colloids, and blood products: packed red blood cells, fresh frozen plasma, platelet concentrate. • Protamine sulfate may be administered to neutralize unfractionated heparin. • Administration of desmopressin acetate (DDAVP) to enhance platelet function. • If bleeding persists, the patient may return to the operating room.
Cardiac tamponade	<ul style="list-style-type: none"> • Fluid and clots accumulate in the pericardial sac, which compress the heart, preventing blood from filling the ventricles. 	<ul style="list-style-type: none"> • Signs and symptoms include arterial hypotension, tachycardia, muffled heart sounds, decreased urine output, and ↑ CVP. Arterial pressure waveform may show pulsus paradoxus (decrease of more than 10 mm Hg systolic blood pressure during inspiration). • The chest drainage system is checked to eliminate possible kinks or obstructions in the tubing. • Chest x-ray may show a widening mediastinum. • Emergency medical management is required; may include return to surgery.
Fluid overload	<ul style="list-style-type: none"> • Intravenous (IV) fluids and blood products increase circulating volume. 	<ul style="list-style-type: none"> • High CVP and pulmonary artery pressures as well as crackles indicate fluid overload. • Diuretics are prescribed and the rate of IV fluid administration is reduced. • Alternative treatments include continuous renal replacement therapy and dialysis.
Hypothermia	<ul style="list-style-type: none"> • Low body temperature leads to vasoconstriction, shivering, and arterial hypertension. 	<ul style="list-style-type: none"> • Patient is rewarmed gradually after surgery, decreasing vasoconstriction.
Hypertension	<ul style="list-style-type: none"> • Results from postoperative vasoconstriction. It may stretch suture lines and cause postoperative bleeding. The condition is usually transient. 	<ul style="list-style-type: none"> • Vasodilators (nitroglycerin [Tridil], nitroprusside [Nipride]) may be used to treat hypertension. Administer cautiously to avoid hypotension.
Tachydysrhythmias	<ul style="list-style-type: none"> • Increased heart rate is common with perioperative volume changes. Uncontrolled atrial fibrillation commonly occurs during the first few days postoperatively. 	<ul style="list-style-type: none"> • If a tachydysrhythmia is the primary problem, the heart rhythm is assessed and medications (eg, amiodarone [Cordarone], diltiazem [Cardizem], may be prescribed. Antidysrhythmic agents may be given before coronary artery bypass graft (CABG) to minimize the risk of postoperative tachydysrhythmias. • Carotid massage may be performed by a physician to assist with diagnosing or treating the dysrhythmia. • Cardioversion and defibrillation are alternatives for symptomatic tachydysrhythmias.
Bradycardias	<ul style="list-style-type: none"> • Decreased heart rate due to surgical trauma and edema affecting the cardiac conduction system. 	<ul style="list-style-type: none"> • Many postoperative patients have temporary pacer wires that can be attached to a pulse generator (pacemaker) to stimulate the heart to beat faster. Less commonly, atropine or other medications may be used to increase heart rate.
Cardiac failure	<ul style="list-style-type: none"> • Myocardial contractility may be decreased perioperatively. 	<ul style="list-style-type: none"> • The nurse observes for and reports signs of heart failure including hypotension, ↑ CVP, ↑ PAWP, venous distention; labored respirations; and edema. • Medical management includes diuretics, digoxin, and IV inotropic agents.

Continued on following page

Table 28-5 POTENTIAL COMPLICATIONS OF CARDIAC SURGERY (Continued)		
Complication	Cause	Assessment and Management
Myocardial infarction (MI) (may occur intraoperatively or postoperatively)	<ul style="list-style-type: none"> Portion of the cardiac muscle dies; therefore, contractility decreases. Impaired ventricular wall motion further decreases cardiac output. Symptoms may be masked by the postoperative surgical discomfort or the anesthesia–analgesia regimen. 	<ul style="list-style-type: none"> Careful assessment to determine the type of pain the patient is experiencing; MI suspected if the mean blood pressure is low with normal preload. Serial electrocardiograms (ECGs) and cardiac biomarkers assist in making the diagnosis (alterations may be due to the surgical intervention).
Pulmonary Complications		
Impaired gas exchange	<ul style="list-style-type: none"> During and after anesthesia, patients require mechanical assistance to breathe. Anesthetic agents stimulate production of mucus and chest incision pain may decrease the effectiveness of ventilation. Potential for postoperative atelectasis. 	<ul style="list-style-type: none"> Pulmonary complications are detected during assessment of breath sounds, oxygen saturation levels, arterial blood gases, and ventilator readings. Extended periods of mechanical ventilation may be required while complications are treated.
Neurologic Complications		
Neurologic changes; stroke	<ul style="list-style-type: none"> Thrombi and emboli may cause cerebral infarction and neurological signs may be evident when patients recover from anesthesia. 	<ul style="list-style-type: none"> Inability to follow simple commands within 6 hours of recovery from anesthetic; weakness on one side of body or other neurological changes may indicate stroke. Patients who are elderly or who have renal or hepatic failure may take longer to recover from anesthesia.
Renal Failure and Electrolyte Imbalance		
Acute renal failure	<ul style="list-style-type: none"> May result from hypoperfusion of the kidneys or from injury to the renal tubules by nephrotoxic drugs. 	<ul style="list-style-type: none"> May respond to diuretics or may require continuous renal replacement therapy (CRRT) or dialysis. Fluids, electrolytes, and urine output are monitored frequently. Renal failure may become chronic and require ongoing dialysis.
Electrolyte imbalance	<ul style="list-style-type: none"> Postoperative imbalances in potassium, magnesium, sodium, calcium, and blood glucose are related to surgical losses, metabolic changes, and the administration of medications and IV fluids. 	<ul style="list-style-type: none"> Monitor electrolytes and basic metabolic studies frequently. Implement treatment to correct electrolyte imbalance promptly (see Chart 28-13).
Other Complications		
Hepatic failure	<ul style="list-style-type: none"> Surgery and anesthesia stress the liver. Most common in patients with cirrhosis, hepatitis, or prolonged right-sided heart failure. 	<ul style="list-style-type: none"> Use of medications metabolized by the liver must be minimized. Bilirubin, albumin, and amylase levels are monitored, and nutritional support is provided.
Infection	<ul style="list-style-type: none"> Surgery and anesthesia alter the patient's immune system. Multiple invasive devices used to monitor and support the patient's recovery may serve as a source of infection. 	<ul style="list-style-type: none"> Monitor for signs of possible infection: body temperature, white blood cell and differential counts, incision and puncture sites, urine (clarity, color, and odor), bilateral breath sounds, sputum (color, odor, amount). Antibiotic therapy may be instituted or modified as necessary. Invasive devices are discontinued as soon as they are no longer required. Institutional protocols for maintaining and replacing invasive lines and devices are followed to minimize the risk of infection.

commonly used before cardiac surgery are lorazepam (Ativan) and diazepam (Valium).

Monitoring and Managing Potential Complications

Angina may occur because of increased stress and anxiety related to the forthcoming surgery. The patient who develops angina usually responds to typical angina therapy, most commonly nitroglycerin. Some patients require oxygen and IV nitroglycerin infusions. Physiologically unstable patients may require management in a critical care unit preoperatively.

Providing Patient Teaching

Prior to surgery, patients and their families are given specific preoperative instructions. This includes information about the prescribed medications, including anticoagu-

lants, antihypertensives, and medications that control diabetes. The patient is instructed to shower with an antiseptic solution.

Teaching also includes information about the hospitalization and surgery. The nurse informs the patient and family about the equipment, tubes, and lines that will be present after surgery and their purposes. They should expect monitors, several IV lines, chest tubes, and a urinary catheter. Explaining the purpose and the approximate time that these devices will be in place helps reassure the patient. Most patients remain intubated and on mechanical ventilation for 2 to 24 hours after surgery. It is important that patients realize that this will prevent them from talking, and the nurse should reassure them that the staff will be able to assist them with other means of communication.

CHART
28-12

NURSING RESEARCH PROFILE

Anxiety in Patients Undergoing Coronary Artery Bypass Graft

Gallagher, R. & McKinley, S. (2007). Stressors and anxiety in patients undergoing coronary artery bypass surgery. *American Journal of Critical Care*, 162(3), 248–257.

Purpose

Although a coronary artery bypass graft (CABG) is a commonly performed surgical procedure, it is known to be a stressful event for patients. The anxiety associated with surgery persists throughout the postoperative course and is associated with increased pain, continuing cardiac symptoms, and readmission to the hospital. The aim of this study was to describe the specific stressors facing patients and identify those associated with high levels of anxiety.

Design

A convenience sample of adult, English-speaking patients scheduled for CABGs at two hospitals in Sydney, Australia, participated in this study. Investigators used parts of the Hospital Anxiety and Depression Scale and the Stressor Scale when they interviewed the participants. In addition to these instruments, open-ended questions about participants' most important concerns were also part of the evaluation. This as-

essment occurred at three times: before surgery (n = 172), before discharge (n = 143), and 10 days after discharge (n = 138).

Findings

Although many participants reported low levels of anxiety, 40% experienced borderline or clinically significant levels of anxiety before surgery and after discharge. Women were particularly likely to express anxiety, and participants who were anxious before surgery were likely to continue to experience anxiety throughout recovery. The highest ranking stressors were as follows: waiting for surgery (preoperative period), being away from home or work (before discharge), and being in pain or discomfort (following discharge).

Nursing Implications

Anxiety should be assessed before CABG in all patients. Interventions should address the stress of waiting for surgery, especially for patients who wait for a long period of time. Pain management protocols and resuming roles and lifestyle should also be addressed. Special efforts should be made to support patients with high anxiety levels.

The nurse takes care to answer the patient's questions about postoperative care and procedures. After the nurse explains deep breathing and coughing, use of the incentive spirometer, and foot exercises, the patient practices these procedures before surgery. It is important to discuss the benefit of early and frequent ambulation. The family's questions at this time usually focus on the length of the surgery, who will discuss the results of the procedure with them after surgery, where to wait during the surgery, the visiting procedures for the critical care unit, and how they can support the patient before surgery and in the critical care unit.

Intraoperative Management

The perioperative nurse performs assessments and prepares the patient as described previously in Chapters 18 and 19. In addition to assisting with the surgical procedure, perioperative nurses are responsible for the comfort and safety of the patient.

Before the chest incision is closed, chest tubes are inserted to evacuate air and drainage from the mediastinum and the thorax. Temporary epicardial pacemaker electrodes may be implanted on the surface of the right atrium and the right ventricle. These epicardial electrodes can be connected to an external pacemaker if the patient has persistent bradycardia perioperatively. Possible intraoperative complications include low cardiac output, dysrhythmias, hemorrhage, MI, stroke, embolization, and organ failure from shock, embolus, or adverse drug reactions. Astute intraoperative nursing assessment is critical to prevent, detect, and initiate prompt intervention for these complications.

Postoperative Nursing Management

Initial postoperative care focuses on achieving or maintaining hemodynamic stability and recovery from general anesthesia. Care may be provided in the postanesthesia care unit (PACU) or intensive care unit. The immediate postoperative

period for the patient who has undergone cardiac surgery presents many challenges to the health care team. All efforts are made to facilitate the transition from the operating room to the critical care unit or PACU with minimal risk. Specific information about the surgical procedure and important factors about postoperative management are communicated by the surgical team and anesthesia personnel to the critical care or PACU nurse, who then assumes responsibility for the patient's care. Figure 28-13 presents an overview of the many aspects of postoperative care of the cardiac surgical patient.

Once the patient's cardiac status and respiratory status are stable, the patient is transferred to a surgical progressive care unit with telemetry. Care focuses on monitoring of cardiopulmonary status, pain management, wound care, progressive activity, and nutrition. Education about medications and risk factor modification is emphasized.

A typical plan of postoperative nursing care is presented in Chart 28-13.

Assessing the Patient

When the patient is admitted to the critical care unit or PACU, and hourly for at least every 8 hours thereafter, nursing and medical personnel perform a complete assessment of all systems. It is necessary to assess the following parameters:

Neurologic status: level of responsiveness, pupil size and reaction to light, reflexes, facial symmetry, movement of the extremities, and hand grip strength

Cardiac status: heart rate and rhythm, heart sounds, pacemaker status, arterial blood pressure, central venous pressure (CVP), and in selected patients, hemodynamic parameters: pulmonary artery pressure, pulmonary artery wedge pressure (PAWP), cardiac output and index, systemic and pulmonary vascular resistance, mixed venous oxygen saturation (SvO₂) (see Chapter 26 for a detailed description of hemodynamic monitoring)

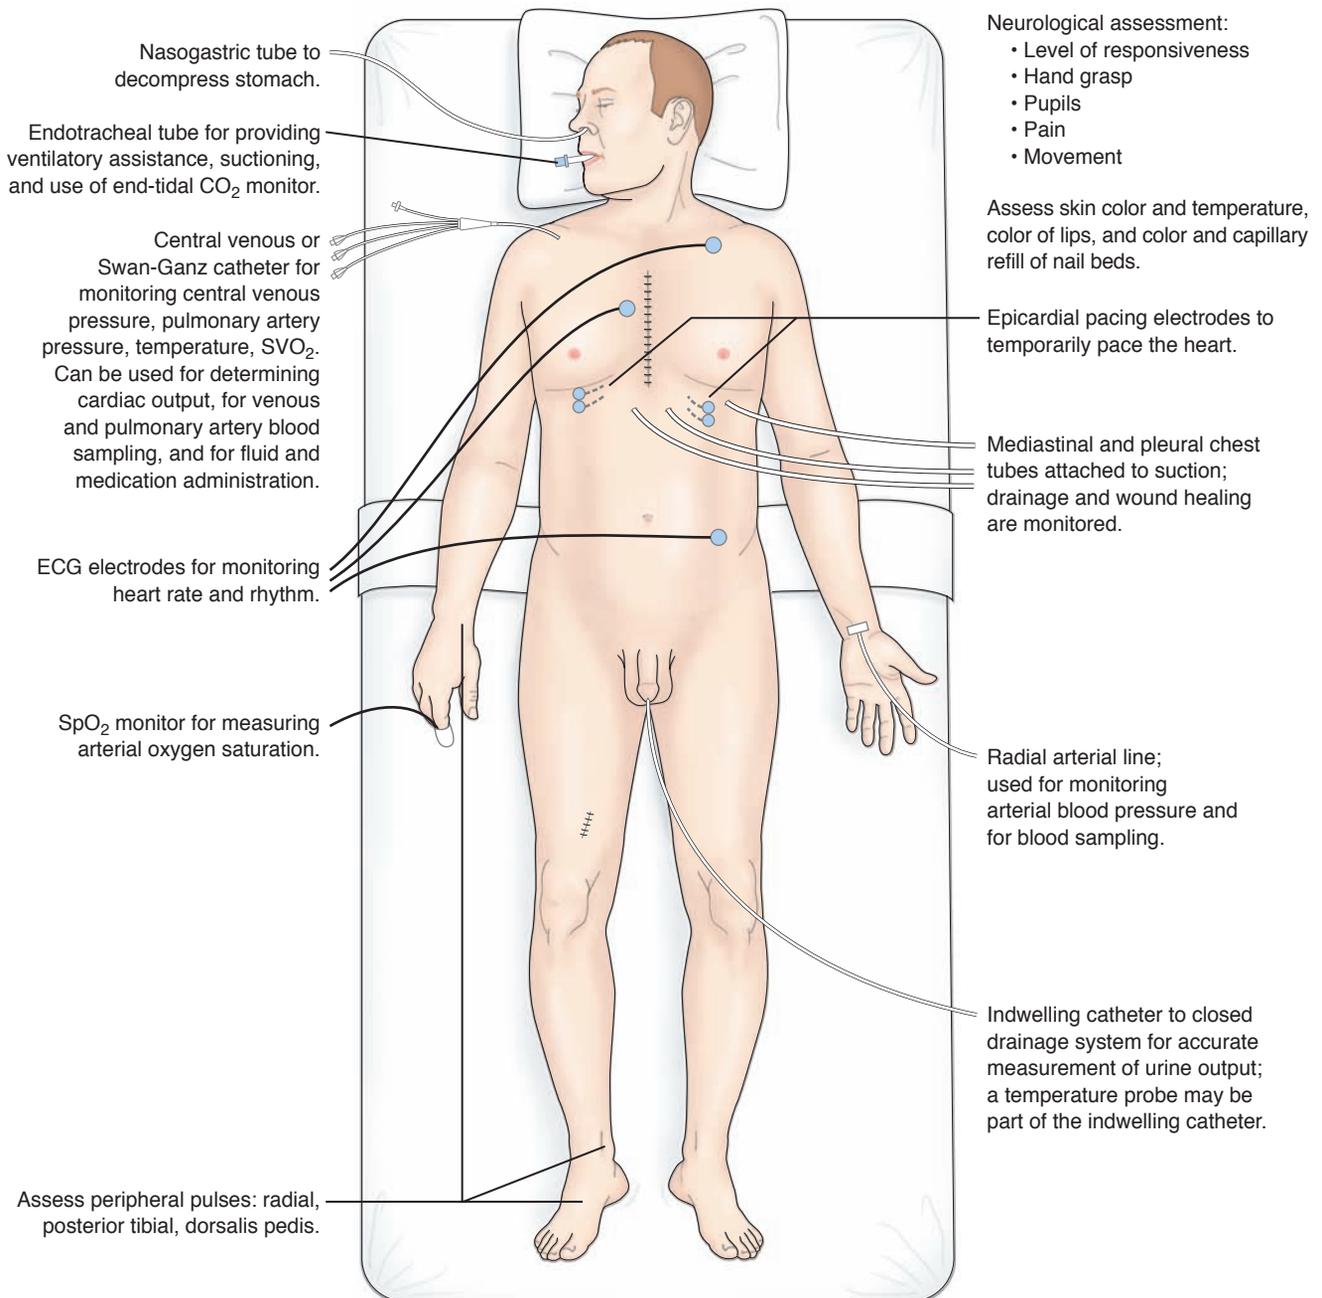

Figure 28-13 Postoperative care of the cardiac surgical patient requires the nurse to be proficient in interpreting hemodynamics, correlating physical assessments with laboratory results, sequencing interventions, and evaluating progress toward desired outcomes.

Respiratory status: chest movement, breath sounds, ventilator settings (eg, rate, tidal volume, oxygen concentration, mode such as synchronized intermittent mandatory ventilation, positive end-expiratory pressure, pressure support), respiratory rate, peak inspiratory pressure, arterial oxygen saturation (SaO_2), percutaneous oxygen saturation (SpO_2), end-tidal CO_2 , pleural chest tube drainage, arterial blood gases

Peripheral vascular status: peripheral pulses; color of skin, nail beds, mucosa, lips, and earlobes; skin temperature; edema; condition of dressings and invasive lines

Renal function: urinary output; urine specific gravity and osmolality

Fluid and electrolyte status: intake, output from all drainage tubes, all cardiac output parameters, and indications of electrolyte imbalance

Pain: nature, type, location, and duration; apprehension; response to analgesics

Assessment also includes checking all equipment and tubes to ensure that they are functioning properly: endotracheal tube, ventilator, end-tidal CO_2 monitor, SpO_2 monitor, pulmonary artery catheter, SvO_2 monitor, arterial and IV lines, IV infusion devices and tubing, cardiac monitor, pacemaker, chest tubes, and urinary drainage system.

As the patient regains consciousness and progresses through the postoperative period, the nurse also assesses

CHART
28-13

PLAN OF NURSING CARE

Care of the Patient After Cardiac Surgery

NURSING DIAGNOSIS: Decreased cardiac output related to blood loss and compromised myocardial function

GOAL: Restoration of cardiac output to maintain organ and tissue perfusion

Nursing Interventions

1. Monitor cardiovascular status. Serial readings of blood pressure, other hemodynamic parameters, and cardiac rhythm and rate are obtained, recorded, and correlated with the patient's overall condition.
 - a. Assess arterial blood pressure every 15 minutes until stable; then arterial or cuff blood pressure every 1 to 4 hours × 24 hours; then every 8 to 12 hours until hospital discharge.
 - b. Auscultate for heart sounds and rhythm.
 - c. Assess peripheral pulses (pedal, tibial, radial).
 - d. Monitor hemodynamic parameters to assess cardiac output, volume status, and vascular tone.
 - e. Watch for trends in hemodynamics and note that mechanical ventilation may alter hemodynamics.
 - f. Monitor ECG pattern for cardiac dysrhythmias and ischemic changes.
 - g. Assess cardiac biomarker results.
 - h. Measure urine output every half hour to 1 hour at first, then with vital signs.
 - i. Observe buccal mucosa, nail beds, lips, earlobes, and extremities.
 - j. Assess skin; note temperature and color.
2. Observe for persistent bleeding: excessive chest tube drainage of blood; hypotension; low CVP; tachycardia. Prepare to administer blood products, IV solutions.

Rationale

1. Effectiveness of cardiac output is determined by continuous monitoring.
 - a. Blood pressure is one of the most important physiologic parameters to monitor; vasoconstriction after cardiopulmonary bypass may require treatment with an IV vasodilator.
 - b. Auscultation provides evidence of cardiac tamponade (muffled distant heart sounds), pericarditis (precordial rub), dysrhythmias.
 - c. Presence or absence and quality of pulses provide data about cardiac output as well as obstructive lesions.
 - d. Rising CVP and PAWP may indicate congestive heart failure or pulmonary edema. Low pressures may indicate need for volume replacement.
 - e. Trends are more important than isolated readings. Mechanical ventilation increases intrathoracic pressure.
 - f. Dysrhythmias may occur with coronary ischemia, hypoxia, bleeding, acid-base or electrolyte disturbances, digitalis toxicity, or cardiac failure. ST-segment changes may indicate myocardial ischemia. Pacemaker capture and antiarrhythmic medications are used to maintain heart rate and rhythm and to support blood pressure.
 - g. Elevations may indicate myocardial infarction.
 - h. Urine output less than 30 mL/h indicates decreased renal perfusion and may reflect decreased cardiac output.
 - i. Dusky skin and cyanosis may indicate decreased cardiac output.
 - j. Cool moist skin indicates vasoconstriction and decreased cardiac output.
2. Bleeding can result from surgical trauma to tissues, anticoagulant medications, and clotting defects.

Expected Outcomes

- The following parameters are within the patient's normal ranges:
 - Arterial pressure
 - CVP
 - Pulmonary artery pressures
 - PAWP
 - Heart sounds
 - Pulmonary and systemic vascular resistance
 - Cardiac output and cardiac index
 - Peripheral pulses
 - Cardiac rate and rhythm
 - Cardiac biomarkers
 - Urine output
 - Skin and mucosal color
 - Skin temperature
- Less than 200 mL/h of drainage through chest tubes during first 4 to 6 hours.
- Vital signs stable.

Continued on following page

 CHART
28-13

PLAN OF NURSING CARE
Care of the Patient After Cardiac Surgery (Continued)

Nursing Interventions <ol style="list-style-type: none"> 3. Observe for cardiac tamponade: hypotension; rising CVP and PAWP, pulsus paradoxus; muffled heart sounds; weak, thready pulse; jugular vein distention; decreasing urinary output. Check for diminished amount of blood in chest drainage collection system. Prepare for reoperation. 4. Observe for signs of cardiac failure. Prepare to administer diuretics, digoxin, IV inotropic agents. 	Rationale <ol style="list-style-type: none"> 3. Cardiac tamponade results from bleeding into the pericardial sac or accumulation of fluid in the sac, which compresses the heart and prevents adequate filling of the ventricles. Decrease in chest drainage may indicate that fluid and clots are accumulating in the pericardial sac. 4. Cardiac failure results from decreased pumping action of the heart; can cause deficient perfusion to vital organs. 	Expected Outcomes <ul style="list-style-type: none"> • CVP and other hemodynamic parameters within normal limits. • Urinary output within normal limits. • Skin color normal. • Respirations unlabored, clear breath sounds. • Pain limited to incision.
NURSING DIAGNOSIS: Impaired gas exchange related to chest surgery GOAL: Adequate gas exchange		
Nursing Interventions <ol style="list-style-type: none"> 1. Maintain mechanical ventilation until the patient is able to breathe independently. 2. Monitor arterial blood gases, tidal volume, peak inspiratory pressure, and extubation parameters. 3. Auscultate chest for breath sounds. 4. Sedate patient adequately, as prescribed, and monitor respiratory rate and depth. 5. Suction tracheobronchial secretions as needed, using strict aseptic technique. 6. Assist in weaning and endotracheal tube removal. 7. After extubation, promote deep breathing, coughing, and turning. Encourage use of the incentive spirometer and compliance with breathing treatments. Teach incisional splinting with a "cough pillow" to decrease discomfort. 	Rationale <ol style="list-style-type: none"> 1. Ventilatory support is used to decrease work of the heart, to maintain effective ventilation, and to provide an airway in the event of complications. 2. ABGs and ventilator parameters indicate effectiveness of ventilator and changes that need to be made to improve gas exchange. 3. Crackles indicate pulmonary congestion; decreased or absent breath sounds may indicate pneumothorax, hemothorax, dislodgement of tube. 4. Sedation helps the patient to tolerate the endotracheal tube and to cope with ventilatory sensations. 5. Retention of secretions leads to hypoxia and possible infection. 6. Extubation decreases risk of pulmonary infections and enhances ability of patient to communicate. 7. Aids in keeping airway patent, preventing atelectasis, and facilitating lung expansion. 	Expected Outcomes <ul style="list-style-type: none"> • Airway patent. • ABGs within normal range. • Endotracheal tube correctly placed, as evidenced by x-ray. • Breath sounds clear bilaterally. • Ventilator synchronous with respirations. • Breath sounds clear after suctioning/coughing. • Nail beds and mucous membranes pink. • Mental acuity consistent with amount of sedatives and analgesics received. • Oriented to person; able to respond yes and no appropriately. • Able to be weaned successfully from ventilator.
NURSING DIAGNOSIS: Risk for imbalanced fluid volume and electrolyte imbalance related to alterations in blood volume GOAL: Fluid and electrolyte balance		
Nursing Interventions <ol style="list-style-type: none"> 1. Monitor fluid and electrolyte balance. <ol style="list-style-type: none"> a. Accurately document intake and output; record urine volume every half hour to 4 hours while in critical care unit; then every 8 to 12 hours while hospitalized. 	Rationale <ol style="list-style-type: none"> 1. Adequate circulating blood volume is necessary for optimal cellular activity; fluid and electrolyte imbalance can occur after surgery. <ol style="list-style-type: none"> a. Provides a method to determine positive or negative fluid balance and fluid requirements. 	Expected Outcomes <ul style="list-style-type: none"> • Fluid intake and output balanced. • Hemodynamic assessment parameters negative for fluid overload or hypovolemia.

 CHART
28-13

PLAN OF NURSING CARE
Care of the Patient After Cardiac Surgery (Continued)

NURSING DIAGNOSIS: Disturbed sensory perception related to excessive environmental stimulation, sleep deprivation, physiological imbalance

GOAL: Reduction of symptoms of sensory perceptual imbalance; prevention of postcardiotomy delirium

Nursing Interventions

1. Use measures to prevent postcardiotomy delirium:
 - a. Explain all procedures and the need for patient cooperation.
 - b. Plan nursing care to provide for periods of uninterrupted sleep with patient's normal day-night pattern.
 - c. Promote continuity of care.
 - d. Orient to time and place frequently. Encourage family to visit.
 - e. Assess for medications that may contribute to delirium.
2. Observe for perceptual distortions, hallucinations, disorientation, and paranoid delusions.

Rationale

1. Postcardiotomy delirium may result from anxiety, sleep deprivation, increased sensory input, disorientation to night and day. Normally, sleep cycles are at least 50 minutes long. The first cycle may be as long as 90 to 120 minutes and then shorten during successive cycles. Sleep deprivation results when the sleep cycles are interrupted or inadequate in number.
2. Delirium can indicate a serious medical condition such as hypoxia, acid-base imbalance, metabolic abnormalities, and cerebral infarction.

Expected Outcomes

- Cooperates with procedures.
- Sleeps for long, uninterrupted intervals.
- Oriented to person, place, time.
- Experiences no perceptual distortions, hallucinations, disorientation, delusions.

NURSING DIAGNOSIS: Acute pain related to surgical trauma and pleural irritation caused by chest tubes

GOAL: Relief of pain

Nursing Interventions

1. Record nature, type, location, intensity, and duration of pain.
2. Encourage routine pain medication dosing for the first 24 to 72 hours and observe for side effects of lethargy, hypotension, tachycardia, respiratory depression.

Rationale

1. Pain and anxiety increase pulse rate, oxygen consumption, and cardiac workload.
2. Analgesia promotes rest, decreases oxygen consumption caused by pain, and aids patient in performing deep-breathing and coughing exercises; pain medications is more effective when taken before pain is severe.

Expected Outcomes

- States pain is decreasing in severity.
- Reports absence of pain.
- Restlessness decreased.
- Vital signs stable.
- Participates in deep-breathing and coughing exercises.
- Verbalizes fewer complaints of pain each day.
- Positions self; participates in care activities.
- Gradually increases activity.

NURSING DIAGNOSIS: Ineffective renal tissue perfusion related to decreased cardiac output, hemolysis, or vasopressor drug therapy

GOAL: Maintenance of adequate renal perfusion

Nursing Interventions

1. Assess renal function:
 - a. Measure urine output every half hour to 4 hours in critical care then every 8 to 12 hours until hospital discharge.
 - b. Monitor and report lab results: BUN, serum creatinine, serum electrolytes.
2. Prepare to administer rapid-acting diuretics or inotropic drugs (eg, dobutamine).
3. Prepare patient for dialysis or continuous renal replacement therapy if indicated.

Rationale

1. Renal injury can be caused by deficient perfusion, hemolysis, low cardiac output, and use of vasopressor agents to increase blood pressure.
 - a. Less than 30 mL/h indicates decreased renal function.
 - b. Indicate kidneys' ability to excrete waste products.
2. Promote renal function and increase cardiac output and renal blood flow.
3. Provides patient with the opportunity to ask questions and prepare for the procedure.

Expected Outcomes

- Urine output consistent with fluid intake; greater than 30 mL/h.
- Urine specific gravity 1.003 to 1.030.
- BUN, creatinine, electrolytes within normal limits.

Continued

 CHART
28-13

PLAN OF NURSING CARE
Care of the Patient After Cardiac Surgery (Continued)
NURSING DIAGNOSIS: Ineffective thermoregulation related to infection or postpericardiotomy syndrome

GOAL: Maintenance of normal body temperature

Nursing Interventions

1. Assess temperature every hour.
2. Use aseptic technique when changing dressings, suctioning endotracheal tube; maintain closed systems for all intravenous and arterial lines and for indwelling urinary catheter.
3. Observe for symptoms of postpericardiotomy syndrome.
4. Obtain cultures and other lab work (CBC, ESR); administer antibiotics as prescribed.
5. Administer anti-inflammatory agents as directed.

Rationale

1. Fever can indicate infectious or inflammatory process.
2. Decreases risk of infection.
3. Occurs in approximately 10% of patients after cardiac surgery.
4. Antibiotics treat documented infection.
5. Relieve symptoms of inflammation.

Expected Outcomes

- Normal body temperature.
- Incisions are free of infection and are healing.
- Absence of symptoms of postpericardiotomy syndrome: fever, malaise, pericardial effusion, pericardial friction rub, arthralgia.

NURSING DIAGNOSIS: Deficient knowledge about self-care activities

GOAL: Ability to perform self-care activities

Nursing Interventions

1. Develop teaching plan for patient and family. Provide specific instructions for the following:
 - Diet and daily weights
 - Activity progression
 - Exercise
 - Deep breathing, coughing, lung expansion exercises
 - Temperature monitoring
 - Medication regimen
 - Pulse taking
 - Access to the emergency medical system
2. Provide verbal and written instructions; provide several teaching sessions for reinforcement and answering questions.
3. Involve family in teaching sessions.
4. Provide contact information for surgeon and cardiologist and instructions about follow-up visit with surgeon.
5. Make appropriate referrals: home care agency, cardiac rehabilitation program, community support groups.

Rationale

1. Each patient will have unique learning needs.
2. Repetition promotes learning by allowing for questions and clarification of misinformation.
3. Family members responsible for home care are usually anxious and require adequate time for learning.
4. Arrangements for contacts with health care personnel help to allay anxieties.
5. Learning, recovery and lifestyle changes continue after discharge from the hospital.

Expected Outcomes

- Patient and family members explain and comply with therapeutic regimen.
- Patient and family members identify necessary lifestyle changes.
- Has copy of discharge instructions (in the patient's primary language and at appropriate reading level; has an alternate format if indicated).
- Keeps follow-up appointments.

indicators of psychological and emotional status. The patient may exhibit behavior that reflects denial or depression or may experience postcardiotomy delirium. Characteristic signs of delirium include transient perceptual illusions, visual and auditory hallucinations, disorientation, and paranoid delusions (Pun, 2007).

It is also necessary to assess the family's needs. The nurse ascertains how family members are coping with the situation; determines their psychological, emotional, and spiritual needs; and finds out whether they are receiving adequate information about the patient's condition.

Monitoring for Complications

The patient is continuously assessed for impending complications (see Table 28-5). The nurse and the surgeon function collaboratively to prevent complications, to identify early signs and symptoms of complications, and to institute measures to reverse their progression.

Decreased Cardiac Output. A decrease in cardiac output is always a threat to the patient who has had cardiac surgery and it can have a variety of causes. Preload alterations occur when too little blood volume returns to the heart as a

result of hypovolemia, persistent bleeding, or cardiac tamponade. Excessive postoperative bleeding can lead to decreased intravascular volume, hypotension, and low cardiac output. Bleeding problems are common after cardiac surgery because of the effects of CPB, trauma from the surgery, and anticoagulation (Ferraris, Ferraris, Saha, et al., 2007). Preload can also be altered if too much volume returns to the heart, causing fluid overload.

Afterload alterations occur when the arteries are constricted as a result of postoperative hypertension or hypothermia, increasing the workload of the heart. Heart rate alterations from bradycardia, tachycardia, and dysrhythmias can lead to decreased cardiac output, and contractility can be altered in cardiac failure, MI, electrolyte imbalances, and hypoxia.

Fluid Volume and Electrolyte Imbalance. Fluid and electrolyte imbalance may occur after cardiac surgery. Nursing assessment for these complications includes monitoring of intake and output, weight, hemodynamic parameters, hematocrit levels, distention of neck veins, edema, liver size, breath sounds (eg, fine crackles, wheezing), and electrolyte levels. The nurse reports changes in serum electrolytes promptly so that treatment can be instituted. Especially important are dangerously high or dangerously low levels of potassium, magnesium, sodium, and calcium. Elevated blood glucose levels are common in the postoperative period. Administration of IV insulin may be required in patients both with and without diabetes to achieve the glycemic control necessary to promote wound healing and recovery (Presutti & Millo, 2006).

Impaired Gas Exchange. Impaired gas exchange is another possible complication after cardiac surgery. All body tissues require an adequate supply of oxygen for survival. To achieve this after surgery, an endotracheal tube with ventilator assistance may be used for 24 hours or more. The assisted ventilation is continued until the patient's blood gas values are acceptable and the patient demonstrates the ability to breathe independently. Patients who are stable after surgery may be extubated as early as 2 to 4 hours after surgery, which reduces their discomfort and anxiety and facilitates patient–nurse communication.

The patient is continuously assessed for signs of impaired gas exchange: restlessness, anxiety, cyanosis of mucous membranes and peripheral tissues, tachycardia, and fighting the ventilator. Breath sounds are assessed often to detect pulmonary congestion and monitor lung expansion. Arterial blood gases, SpO₂, and end-tidal CO₂ are assessed for decreased oxygen and increased carbon dioxide. Following extubation, aggressive pulmonary interventions, such as turning, coughing, deep breathing, and early ambulation are necessary to prevent atelectasis and pneumonia.

Impaired Cerebral Circulation. Brain function depends on a continuous supply of oxygenated blood. The brain does not have the capacity to store oxygen and must rely on adequate continuous perfusion by the heart. It is important to observe the patient for signs and symptoms of hypoxia: restlessness, confusion, dyspnea, hypotension, and cyanosis. An assessment of the patient's neurologic status includes level of consciousness, response to verbal commands and painful

stimuli, pupil size and reaction to light, facial symmetry, movement of the extremities, hand grip strength, presence of pedal and popliteal pulses, and temperature and color of extremities. The nurse documents any indication of a change in status and reports abnormal findings to the surgeon because they may signal the onset of a complication. Hypoperfusion or microemboli may produce central nervous system injury after cardiac surgery.

Restoring Cardiac Output

To evaluate the patient's cardiac status, the nurse primarily determines the effectiveness of cardiac output through clinical observations and routine measurements: serial readings of blood pressure, heart rate, CVP, arterial pressure, and pulmonary artery pressures.

Renal function is related to cardiac function, as blood pressure and cardiac output drive glomerular filtration; therefore, urinary output is measured and recorded. Urine output of less than 30 mL/h may indicate a decrease in cardiac output or inadequate fluid volume.

Body tissues depend on adequate cardiac output to provide a continuous supply of oxygenated blood to meet the changing demands of the organs and body systems. Because the buccal mucosa, nail beds, lips, and earlobes are sites with rich capillary beds, they are observed for cyanosis or dusky skin as possible signs of reduced cardiac output. Distention of the neck veins when the head of the bed is elevated to 30 degrees or more may signal right-sided heart failure. If cardiac output has decreased, the skin becomes cool, moist, and cyanotic or mottled.

Dysrhythmias may develop due to decreased perfusion to or irritation of the myocardium from surgery. The most common dysrhythmias encountered during the postoperative period are atrial fibrillation, bradycardias, tachycardias, and ectopic beats. Continuous observation of the cardiac monitor for dysrhythmias is essential.

The nurse reports any indications of decreased cardiac output promptly to the physician. The physician uses the assessment data to determine the cause of the problem. After a diagnosis has been made, the physician and the nurse work collaboratively to restore cardiac output and prevent further complications. When indicated, the physician prescribes blood components, fluids, antidysrhythmics, diuretics, vasodilators, or vasopressors. If additional surgery is necessary, the patient and family are prepared for the procedure.

Promoting Adequate Gas Exchange

To ensure adequate gas exchange, the patency of the endotracheal tube is assessed and maintained. It must be secured to prevent it from slipping out or down into the right mainstem bronchus. Suctioning is necessary when crackles or coughing are present. Routinely, 100% oxygen is delivered to the patient from the ventilator or by a manual resuscitation bag (eg, Ambu-Bag) before and after suctioning to minimize the risk of hypoxia that can result from the suctioning procedure. Arterial blood gas determinations are compared with baseline data, and changes are reported to the physician promptly.

When the patient's condition stabilizes, body position is changed every 1 to 2 hours. Frequent changes of patient position provide for optimal pulmonary ventilation and perfusion by allowing the lungs to expand more fully.

Physical assessment and arterial blood gas results guide the process of weaning the patient from the ventilator. Before being extubated, the patient should have cough and gag reflexes and stable vital signs; be able to lift the head off the bed or have a firm hand grasp; have adequate vital capacity, negative inspiratory force, and minute volume appropriate for body size; and have acceptable arterial blood gas levels while breathing warmed humidified oxygen without the assistance of the ventilator.

The nurse assists with the weaning process and eventually with removal of the endotracheal tube. After extubation, the nurse encourages deep breathing and coughing at least every 1 to 2 hours to clear secretions, open the alveolar sacs, and promote effective ventilation.

Maintaining Fluid and Electrolyte Balance

To promote fluid and electrolyte balance, the nurse carefully assesses intake and output, using flow sheets to determine positive or negative fluid balance. It is necessary to record all fluid intake, including IV, nasogastric tube, and oral fluids, as well as all output, including urine, nasogastric drainage, and chest drainage.

Hemodynamic parameters (ie, blood pressure, CVP, PAWP) are correlated with intake, output, and weight to determine the adequacy of hydration and cardiac output. Serum electrolytes are monitored, and the patient is observed for signs of potassium, magnesium, sodium, or calcium imbalance.

Any indications of dehydration, fluid overload, or electrolyte imbalance are reported promptly, and the physician and nurse work collaboratively to restore fluid and electrolyte balance and monitor the patient's response to therapies.

Minimizing Sensory-Perception Imbalance

Some patients exhibit abnormal perceptions and behaviors that occur with varying intensity and duration. Clinical manifestations of postoperative delirium include restlessness, agitation, visual and auditory hallucinations, and paranoia. The delirium typically appears after a 2- to 5-day stay in an intensive care environment. In the early years of cardiac surgery, this phenomenon occurred more frequently than it does today. Advances in surgical techniques and in the delivery of anesthetic agents have significantly decreased the incidence of postoperative delirium. Presumed causes of postoperative delirium include anxiety, sleep deprivation, increased sensory input, medications, and physiologic problems such as hypoxemia and metabolic imbalance (Pun, 2007). The delirium typically resolves after the patient is transferred from the unit.

Basic comfort measures are used in conjunction with prescribed analgesics and sedatives to promote rest. Invasive lines and tubes are discontinued as soon as possible to promote comfort and safety. Patient care is coordinated to provide undisturbed periods of rest. As the patient's condition stabilizes and the patient is disturbed less frequently for monitoring and therapeutic procedures, rest periods can be extended. Uninterrupted sleep is provided as much as possible, especially during the patient's normal hours of sleep.

Careful explanations of all procedures and of the need for cooperation help keep the patient oriented throughout the postoperative course. Continuity of care is desirable; a familiar face and a nursing staff with a consistent approach

help the patient feel safe. The patient's family should be welcomed at the bedside. A well-designed and individualized plan of nursing care can assist the nursing team in coordinating its efforts for the emotional well-being of the patient.

Relieving Pain

Patients who have had cardiac surgery may have pain in the peri-incisional area or throughout the chest, shoulders, and back. Pain is usually a result of trauma to the chest wall and irritation of the pleura by the chest tubes as well as incisional pain from peripheral vein or artery graft harvest sites.

The nurse assesses patients for verbal and nonverbal indicators of pain and accurately records the nature, type, location, and duration of the pain. To reduce the amount of pain, the nurse encourages the patient to use patient-controlled analgesia (PCA) or accept medication as often as it is prescribed. The addition of adjunctive pain relievers (anti-inflammatory agents, muscle relaxants) to opioids decreases the amount of opioids required for pain relief and increases patient comfort. Patients report the most pain during coughing, turning, and moving. Physical support of the incision with a folded bath blanket or small pillow during deep breathing and coughing helps minimize pain. The patient should then be able to participate in respiratory exercises and to progressively increase self-care. Patient comfort improves after removal of the chest tubes.

Pain produces tension, which may stimulate the central nervous system to release catecholamines, resulting in constriction of the arterioles and increased heart rate. This can cause increased afterload and decreased cardiac output. Opioids alleviate pain and induce sleep and feelings of euphoria, which reduces the metabolic rate and oxygen demands. After the administration of opioids, it is necessary to document observations indicating relief of apprehension and pain in the patient's record. The nurse observes the patient for any adverse effects of opioids, including respiratory depression, hypotension, constipation, ileus, or urinary retention. If serious side effects occur, an opioid antagonist (eg, naloxone [Narcan]) may be required.

Maintaining Adequate Tissue Perfusion

The nurse routinely palpates peripheral pulses (eg, pedal, tibial, femoral, radial, brachial) to assess for arterial obstruction. If a pulse is absent in any extremity, the cause may be prior catheterization of that extremity, chronic peripheral vascular disease, or a thromboembolic obstruction. The nurse immediately reports newly identified absence of any pulse to the physician.

Thromboembolic events can result from vascular injury, dislodgment of a clot from a damaged valve, loosening of mural thrombi, or coagulation problems. Air embolism can result from CPB or central venous cannulation. Symptoms of embolization vary according to site. The usual embolic sites are the lungs, coronary arteries, mesentery, spleen, extremities, kidneys, and brain. It is necessary to observe the patient for onset of the following:

- Chest pain and respiratory distress from pulmonary embolus or MI
- Abdominal or back pain from mesenteric emboli
- Pain, cessation of pulses, blanching, numbness, or coldness in an extremity

- One-sided weakness and pupillary changes, as occur in stroke

The nurse promptly reports any of these symptoms to the physician.

After surgery, it is important to prevent venous stasis, which can cause deep venous thrombosis and subsequent pulmonary embolism, by using the following measures:

- Apply sequential pneumatic compression wraps or anti-embolism stockings
- Discourage crossing of legs
- Avoid elevating the knees on the bed
- Omit pillows in the popliteal space
- Begin passive exercises followed by active exercises to promote circulation and prevent venous stasis

Inadequate renal perfusion can occur as a complication of cardiac surgery. One possible cause is low cardiac output. Trauma to blood cells during CPB can cause hemolysis of red blood cells, which then occlude the renal glomeruli. Use of vasopressor agents to increase blood pressure may constrict the renal arterioles and reduce blood flow to the kidneys.

Nursing management includes accurate measurement of urine output. An output of less than 30 mL/h may indicate hypovolemia or renal insufficiency. The physician may prescribe fluids to increase cardiac output and renal blood flow or IV diuretics may be administered to increase urine output. The nurse should be aware of the patient's blood urea nitrogen, serum creatinine, glomerular filtration rate, and serum electrolyte levels. The nurse should report abnormal levels promptly because it may be necessary to adjust fluids and the dose or type of medication administered. If efforts to maintain renal perfusion are ineffective, the patient may require continuous renal replacement therapy or dialysis (see Chapter 44).

Maintaining Normal Body Temperature

Patients are usually hypothermic when admitted to the critical care unit following the cardiac surgical procedure. The patient must be gradually warmed to a normal temperature. This is accomplished partially by the patient's own basal metabolic processes and often with the assistance of air or water blanket systems. While the patient is hypothermic, the clotting process is less efficient, the heart is prone to dysrhythmias, and oxygen does not readily transfer from the hemoglobin to the tissues. Because anesthesia and hypothermia suppress normal basal metabolism, oxygen supply usually meets the cellular demand.

After cardiac surgery, the patient is at risk for developing elevated body temperature as a result of tissue inflammation or infection. The inflammatory/immune response to surgery includes the release of cytokines that cause fever (Porth & Matfin, 2009). The resultant increase in metabolic rate increases tissue oxygen demands and increases cardiac workload. Antipyretics and other measures are used to lower body temperature.

Common sites of postoperative infection include the lungs, urinary tract, incisions, and intravascular catheters. Meticulous care is used to prevent contamination at the sites of catheter and tube insertions. Aseptic technique is used when changing dressings and when providing endotracheal tube and catheter care. Clearance of pulmonary secretions is

accomplished by frequent repositioning of the patient, suctioning, and chest physical therapy, as well as teaching and encouraging the patient to breathe deeply and cough. Closed systems are used to maintain all IV and arterial lines. All invasive equipment is discontinued as soon as possible after surgery.

Postpericardiotomy syndrome may occur in patients who undergo cardiac surgery. The syndrome is characterized by fever, pericardial pain, pleural pain, dyspnea, pericardial effusion, pericardial friction rub, and arthralgia. These signs and symptoms may occur days to weeks after surgery, often after the patient has been discharged from the hospital.

It is necessary to differentiate postpericardiotomy syndrome from other postoperative complications (eg, infection, incisional pain, MI, pulmonary embolus, bacterial endocarditis, pneumonia, atelectasis). Treatment depends on the severity of the symptoms. Anti-inflammatory agents often produce a dramatic improvement in symptoms.

Promoting Home and Community-Based Care

Teaching Patients Self-Care. Depending on the type of surgery and postoperative progress, the patient may be discharged from the hospital 3 to 5 days after surgery. Following recovery from the surgery, patients can expect fewer symptoms from CAD and an improved quality of life. CABG has been shown to increase the lifespan of high-risk patients, including those with left main artery blockages and left ventricular dysfunction with multivessel blockages (Bravata, et al., 2007).

Although the patient may be eager to return home, the patient and family usually are apprehensive about this transition. The family members often express the fear that they are not capable of caring for the patient at home. They often are concerned that complications will occur that they are unprepared to handle.

The nurse helps the patient and family set realistic, achievable goals. A teaching plan that meets the patient's individual needs is developed with the patient and family. Specific instructions are provided about incision care; signs and symptoms of infection; diet; activity progression and exercise; deep breathing, incentive spirometry, and smoking cessation; weight and temperature monitoring; the medication regimen; and follow-up visits with home care nurses, the rehabilitation personnel, the surgeon, and the cardiologist or internist.

Some patients have difficulty learning and retaining information after cardiac surgery. The patient may experience recent memory loss, short attention span, difficulty with simple math, poor handwriting, and visual disturbances. Patients with these difficulties often become frustrated when they try to resume normal activities. The patient and family are reassured that the difficulty is almost always temporary and will subside, usually in 6 to 8 weeks. In the meantime, instructions are given to the patient at a slower pace than normal, and a family member assumes responsibility for making sure that the prescribed regimen is followed.

Continuing Care. Arrangements are made for a home care nurse when appropriate. Because the hospital stay is relatively short, it is particularly important for the nurse to assess the patient's and family's ability to manage care in the

home. The home care nurse continues the teaching process, monitors vital signs and incisions, assesses for signs and symptoms of complications, and provides support for the patient and family. Additional interventions may include dressing changes, diet counseling, and tobacco use cessation strategies. Women may experience a longer recovery and may require additional interventions to manage symptoms (Zimmerman, Barnason, Schulz, et al., 2007). They also have a higher risk of depression during the postoperative period (Doering, Cross, Magsarili, et al., 2007). Patients and families need to know that cardiac surgery did not cure the patient's underlying heart disease. Lifestyle changes for risk factor reduction are essential, and medications taken before surgery may still be necessary.

It is important to encourage the patient to contact the surgeon, cardiologist, or nurse with problems or questions. This provides the patient and family with reassurance that professional support is available. The patient is expected to have at least one follow-up visit with the surgeon.

Teaching does not end at the time of discharge from the hospital or home health care. Many patients and families benefit from supportive programs such as cardiac rehabilitation programs. These programs provide monitored exercise; instructions about diet and stress reduction; information about resuming work, driving, and sexual activity; assistance with tobacco use cessation; and support groups for patients and families. The AHA sponsors the Mended Hearts Club, which provides information as well as an opportunity for families to share experiences.

CRITICAL THINKING EXERCISES

EBP 1 While working in the cardiology clinic, you receive a phone call from a patient with known coronary artery disease. She reports that she is experiencing some shortness of breath and mild back pain. What evidence base is there to suggest that symptoms of an MI may be different for women than men? Discuss the strength of this evidence and its significance in determining assessment criteria to be used for women and men. What questions would you ask this patient? What would you instruct her to do? Provide rationale for your instructions.

2 A 72-year-old man is admitted to the surgical intensive care unit following four-vessel CABG surgery. Initially, his blood pressure is high at 164/88, but it drops to 92/60 mm Hg, his ECG shows sinus tachycardia, and his cardiac output is decreased. What are the most likely reasons for the drop in blood pressure? What other parameters should be assessed? Describe your interventions for this postoperative CABG patient with hypotension and low cardiac output. Identify your expected outcomes for these interventions.

3 You are caring for a patient who has been hospitalized with a diagnosis of unstable angina. His condition is stable and he will be discharged later in the day. He is anxious to go home, but agrees to an educational session with you prior to discharge. The patient is obese and has a history

of hypertension and cigarette smoking. Knowing that multiple lifestyle changes are recommended, how will you prioritize your teaching strategies? What type of follow-up care is available to assist this patient following discharge?

EBP 4 Your neighbor is a 60-year-old woman who was discharged from the hospital last month with ACS treated with thrombolytics. She asks you if she really needs to keep taking her beta-blocker indefinitely. She tells you that her husband read in a news magazine that care for women with heart disease has been traditionally based on treatment of men with heart disease. What is the strength of the evidence that supports maintaining women post-ACS on beta-blockers?

chapter 29

Management of Patients With Structural, Infectious, and Inflammatory Cardiac Disorders

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

- 1 Define valvular disorders of the heart and describe the pathophysiology, clinical manifestations, and management of patients with mitral and aortic disorders.
- 2 Describe types of cardiac valve repair and replacement procedures used to treat valvular problems and the care needed by patients who undergo these procedures.
- 3 Describe the pathophysiology, clinical manifestations, and management of patients with intracardiac septal defects.
- 4 Describe the pathophysiology, clinical manifestations, and management of patients with cardiomyopathies.
- 5 Describe the pathophysiology, clinical manifestations, and management of patients with infections of the heart.

GLOSSARY

- allograft:** heart valve replacement made from a human heart valve (synonym: homograft)
- annuloplasty:** repair of a cardiac valve's outer ring
- aortic valve:** semilunar valve located between the left ventricle and the aorta
- autograft:** heart valve replacement made from the patient's own heart valve (eg, the pulmonic valve is excised and used as an aortic valve)
- cardiomyopathy:** disease of the heart muscle
- chordae tendineae:** nondistensible fibrous strands connecting papillary muscles to atrioventricular (mitral, tricuspid) valve leaflets
- chordoplasty:** repair of the chordae tendineae
- commissurotomy:** splitting or separating fused cardiac valve leaflets
- heterograft:** heart valve replacement made of tissue from an animal heart valve (synonym: xenograft)
- homograft:** heart valve replacement made from a human heart valve (synonym: allograft)
- leaflet repair:** repair of a cardiac valve's movable "flaps" (leaflets)
- mitral valve:** atrioventricular valve located between the left atrium and left ventricle
- orthotopic transplantation:** the recipient's heart is removed and a donor heart is grafted into the same site; the patient has one heart
- prolapse (of a valve):** stretching of an atrioventricular heart valve leaflet into the atrium during systole
- pulmonic valve:** semilunar valve located between the right ventricle and the pulmonary artery
- regurgitation:** backward flow of blood through a heart valve
- stenosis:** narrowing or obstruction of a cardiac valve's orifice
- total artificial heart:** mechanical device used to aid a failing heart, assisting the right and left ventricles
- tricuspid valve:** atrioventricular valve located between the right atrium and right ventricle
- valve replacement:** insertion of a device at the site of a malfunctioning heart valve to restore blood flow in one direction through the heart
- valvuloplasty:** repair of a stenosed or regurgitant cardiac valve by commissurotomy, annuloplasty, leaflet repair, or chordoplasty (or a combination of procedures)
- ventricular assist device:** mechanical device used to aid a failing right or left ventricle
- xenograft:** heart valve replacement made of tissue from an animal heart valve (synonym: heterograft)

Structural, infectious, and inflammatory disorders of the heart present many challenges for the patient, family, and health care team. Problems with the heart valves, holes in the intracardiac septum, cardiomyopathies, and infectious diseases of the heart muscle alter cardiac output. Treatments for these disorders may be noninvasive, such as medication therapy and activity and dietary modification. Invasive treatments also may be used, such as valve repair or replacement, septal repair, ventricular assist devices, total artificial hearts, cardiac transplantation, and other procedures. Nurses have an integral role in the care of patients with structural, infectious, and inflammatory cardiac conditions.

VALVULAR DISORDERS

The valves of the heart control the flow of blood through the heart into the pulmonary artery and aorta by opening and closing in response to the blood pressure changes as the heart contracts and relaxes through the cardiac cycle.

The atrioventricular valves separate the atria from the ventricles and include the **tricuspid valve**, which separates the right atrium from the right ventricle, and the **mitral valve**, which separates the left atrium from the left ventricle. The tricuspid valve has three leaflets; the mitral valve has two. Both valves have **chordae tendineae** that anchor the valve leaflets to the papillary muscles of the ventricles.

The semilunar valves are located between the ventricles and their corresponding arteries. The **pulmonic valve** lies between the right ventricle and the pulmonary artery; the **aortic valve** lies between the left ventricle and the aorta. Figure 29-1 shows valves in the closed position.

When any of the heart valves do not close or open properly, blood flow is affected. When valves do not close completely, blood flows backward through the valve, a condition called **regurgitation**. When valves do not open completely, a condition called **stenosis**, the flow of blood through the valve is reduced.

Disorders of the mitral valve fall into the following categories: mitral valve **prolapse** (ie, stretching of the valve leaflet into the atrium during systole), mitral regurgitation, and mitral stenosis. Disorders of the aortic valve are categorized as aortic regurgitation and aortic stenosis. These valvular disorders may require surgical repair or replacement of the valve to correct the problem, depending on severity of symptoms (Fig. 29-2). Tricuspid and pulmonic

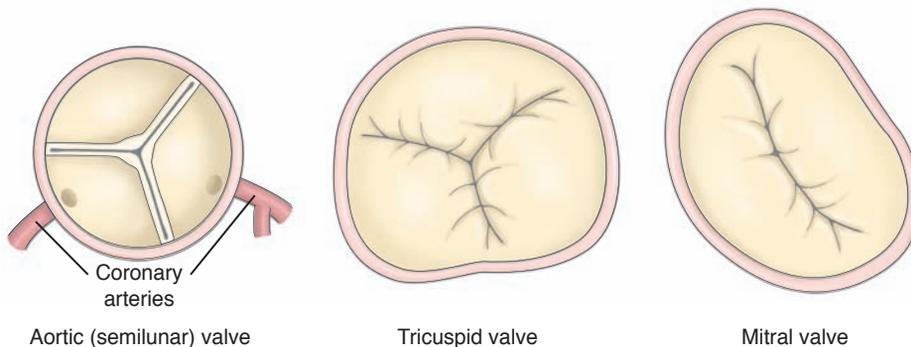

Figure 29-1 The valves of the heart (aortic or semilunar, tricuspid, and mitral) in the closed position.

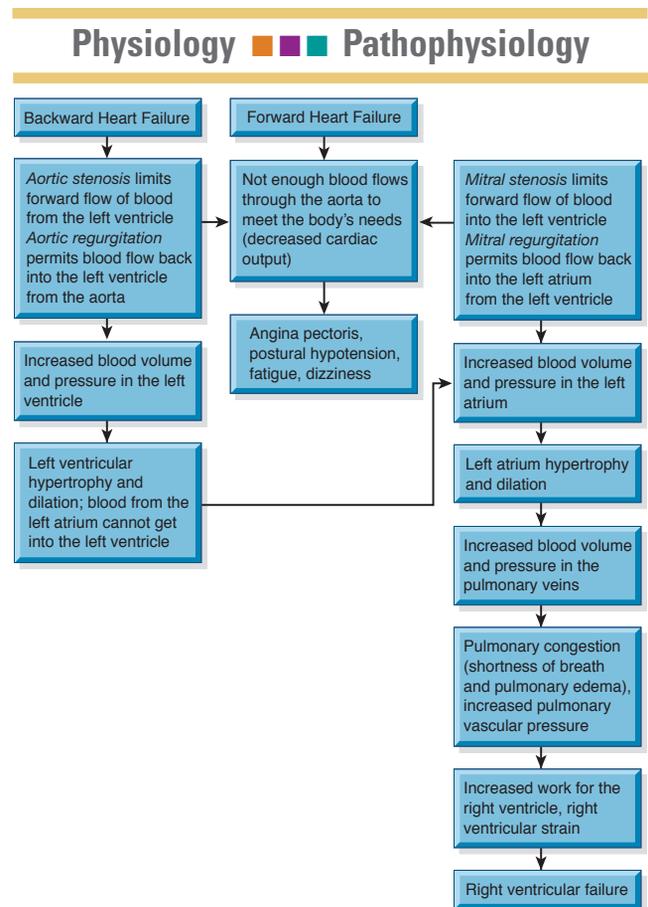

Figure 29-2 Pathophysiology: left-sided heart failure as a result of aortic and mitral valvular heart disease and the development of right ventricular failure.

valve disorders also occur, usually with fewer symptoms and complications. Regurgitation and stenosis may occur at the same time in the same or different valves.

Mitral Valve Prolapse

Mitral valve prolapse is a deformity that usually produces no symptoms. Rarely, it progresses and can result in sudden death. This condition occurs more frequently in women

than in men and is being diagnosed more frequently than it once was, probably because of improved diagnostic methods. The cause is usually an inherited connective tissue disorder resulting in enlargement of one or both of the mitral valve leaflets. The annulus often dilates. The chordae tendineae and papillary muscles may elongate.

Pathophysiology

In mitral valve prolapse, a portion of one or both mitral valve leaflets balloons back into the atrium during systole. Rarely, the ballooning stretches the leaflet to the point that the valve does not remain closed during systole (ie, ventricular contraction). Blood then regurgitates from the left ventricle back into the left atrium. About 15% of patients who develop murmurs eventually experience heart enlargement, atrial fibrillation, pulmonary hypertension, or heart failure (Libby, Bonow, Mann, et al., 2008).

Clinical Manifestations

Most people who have mitral valve prolapse never have symptoms. A few have symptoms of fatigue, shortness of breath, lightheadedness, dizziness, syncope, palpitations, chest pain, and anxiety (Fuster, O'Rourke, Walsh, et al., 2008; Libby, et al., 2008). Fatigue may occur regardless of activity level and amount of rest or sleep. Shortness of breath is not correlated with activity levels or pulmonary function. Atrial or ventricular dysrhythmias may produce the sensation of palpitations, but palpitations have been reported while the heart has been beating normally. Chest pain, which is often localized to the chest, is not correlated with activity and may last for days. Anxiety may be a response to the symptoms; however, some patients report anxiety as the only symptom. Some clinicians speculate that the symptoms may be explained by dysautonomia (a dysfunction of the autonomic nervous system that results in increased excretion of catecholamines). No consensus exists about the cause of the symptoms experienced by some patients (Libby, et al., 2008).

Assessment and Diagnostic Findings

Often the first and only sign of mitral valve prolapse is identified when a physical examination of the heart reveals an extra heart sound, referred to as a mitral click. A systolic click is an early sign that a valve leaflet is ballooning into the left atrium. In addition to the mitral click, a murmur of mitral regurgitation may be heard if progressive valve leaflet stretching and regurgitation have occurred. A few patients experience signs and symptoms of heart failure if mitral regurgitation exists. Doppler echocardiography may be used to diagnose and monitor the progression of mitral valve prolapse.

Medical Management

Medical management is directed at controlling symptoms. If dysrhythmias are documented and cause symptoms, the patient is advised to eliminate caffeine and alcohol from the diet and to stop smoking. Most patients do not require any medications; prophylactic antibiotics are no longer recommended prior to dental or invasive procedures (Wilson, Taubert, Gewitz, et al., 2007), although antiarrhythmic medications may be prescribed.

Chest pain that does not respond to nitrates may respond to calcium channel blockers or beta-blockers. Heart failure is treated the same as it would be for any other case of heart failure (see Chapter 30). In advanced stages of disease, mitral valve repair or replacement may be necessary (discussed later in this chapter).

Nursing Management

The nurse educates the patient about the diagnosis and the possibility that the condition is hereditary. First-degree relatives (eg, parents, siblings) may be advised to have echocardiograms. Patients with mitral valve prolapse may be at risk for infectious endocarditis that results from bacteria entering the bloodstream and adhering to the abnormal valve structures. The nurse teaches the patient how to minimize this risk: practicing good oral hygiene, obtaining routine dental care, avoiding body piercing and body branding, and not using toothpicks or other sharp objects in the oral cavity.

Because most patients with mitral valve prolapse are asymptomatic, the nurse explains the need to inform the health care provider about any symptoms that may develop. To minimize symptoms, the nurse teaches the patient to avoid caffeine and alcohol. The nurse encourages the patient to read product labels, particularly on over-the-counter products such as cough medicine, because these products may contain alcohol, caffeine, ephedrine, and epinephrine, which may produce dysrhythmias and other symptoms. In addition, the nurse also explores possible diet, activity, sleep, and other lifestyle factors that may correlate with symptoms. Treatment of dysrhythmias, chest pain, heart failure, or other complications of mitral valve prolapse is described in Chapter 30. Women diagnosed with mitral valve prolapse without mitral regurgitation or other complications may complete pregnancies and have vaginal deliveries.

Mitral Regurgitation

Mitral regurgitation involves blood flowing back from the left ventricle into the left atrium during systole. Often the edges of the mitral valve leaflets do not close during systole. The leaflets cannot close completely because the leaflets and chordae tendineae have thickened and fibrosed, resulting in their contraction. The most common causes of mitral valve regurgitation in developed countries are degenerative changes of the mitral valve (eg, mitral valve prolapse) and ischemia of the left ventricle (Bonow, Carabello, Chatterjee, et al., 2008). The most common causes in developing countries are rheumatic heart disease and its sequelae (Siddbotham, McKee, Gillham, et al., 2007).

Other conditions that lead to mitral regurgitation include myxomatous changes, which enlarge and stretch the left atrium and ventricle, causing leaflets and chordae tendineae to stretch or rupture. Infective endocarditis may cause perforation of a leaflet, or the scarring following the infection may cause retraction of the leaflets or chordae tendineae. Collagen-vascular diseases (eg, systemic lupus erythematosus), cardiomyopathy, and ischemic heart disease may also result in changes in the left ventricle, causing the papillary muscles, chordae tendineae, or leaflets to stretch, shorten, or rupture.

Pathophysiology

Mitral regurgitation may result from problems with one or more of the leaflets, the chordae tendineae, the annulus, or the papillary muscles. As previously stated, a mitral valve leaflet may shorten or tear, and the chordae tendineae may elongate, shorten, or tear. The annulus may be stretched by heart enlargement or deformed by calcification. The papillary muscle may rupture, stretch, or be pulled out of position by changes in the ventricular wall (eg, scar from a myocardial infarction or ventricular dilation). The papillary muscles may be unable to contract because of ischemia. Regardless of the cause, blood regurgitates into the atrium during systole.

With each beat of the left ventricle, some of the blood is forced back into the left atrium, adding to the blood flowing in from the lungs. This causes the left atrium to stretch and eventually hypertrophy and dilate. The backward flow of blood from the ventricle diminishes the volume of blood flowing into the atrium from the lungs. As a result, the lungs become congested, eventually adding extra strain on the right ventricle.

Clinical Manifestations

Chronic mitral regurgitation is often asymptomatic, but acute mitral regurgitation (eg, that resulting from a myocardial infarction) usually manifests as severe congestive heart failure. Dyspnea, fatigue, and weakness are the most common symptoms. Palpitations, shortness of breath on exertion, and cough from pulmonary congestion also occur.

Assessment and Diagnostic Findings

A systolic murmur is heard as a high-pitched, blowing sound at the apex. The pulse may be regular and of good volume, or it may be irregular as a result of extrasystolic beats or atrial fibrillation. Doppler echocardiography is used to diagnose and monitor the progression of mitral regurgitation. Transesophageal echocardiography (TEE) provides the best images of the mitral valve.

Medical Management

Management of mitral regurgitation is the same as that for heart failure (see Chapter 30). Patients with mitral regurgitation and heart failure benefit from afterload reduction (arterial dilation) by treatment with angiotensin-converting enzyme (ACE) inhibitors, such as captopril (Capoten), enalapril (Vasotec), lisinopril (Prinivil, Zestril), ramipril (Altace), or hydralazine (Apresoline); angiotensin receptor blockers (ARBs), such as losartan (Cozar) or valsartan (Diovan); and beta-blockers, such as carvedilol (Coreg). Once symptoms of heart failure develop, the patient needs to restrict his or her activity level to minimize symptoms. Surgical intervention consists of mitral valvuloplasty (ie, surgical repair of the valve) or valve replacement (discussed later).

Mitral Stenosis

Mitral stenosis is an obstruction of blood flowing from the left atrium into the left ventricle. It is most often caused by rheumatic endocarditis, which progressively thickens the

mitral valve leaflets and chordae tendineae. The leaflets often fuse together. Eventually, the mitral valve orifice narrows and progressively obstructs blood flow into the ventricle.

Pathophysiology

Normally, the mitral valve opening is as wide as the diameter of three fingers. In cases of marked stenosis, the opening narrows to the width of a pencil. The left atrium has great difficulty moving blood into the ventricle because of the increased resistance of the narrowed orifice. Poor left ventricular filling can cause decreased cardiac output. The increased blood volume in the left atrium causes it to dilate and hypertrophy. Because there is no valve to protect the pulmonary veins from the backward flow of blood from the atrium, the pulmonary circulation becomes congested. As a result, the right ventricle must contract against an abnormally high pulmonary arterial pressure and is subjected to excessive strain. Eventually, the right ventricle fails.

Clinical Manifestations

The first symptom of mitral stenosis is often dyspnea on exertion as a result of pulmonary venous hypertension. Symptoms usually develop after the valve opening is reduced by one-third to one-half its usual size. Patients are likely to show progressive fatigue as a result of low cardiac output. The enlarged left atrium may create pressure on the left bronchial tree, resulting in a dry cough or wheezing. Patients may expectorate blood (ie, hemoptysis) or experience palpitations, orthopnea, paroxysmal nocturnal dyspnea (PND), and repeated respiratory infections.

Assessment and Diagnostic Findings

The pulse is weak and often irregular because of atrial fibrillation (caused by the strain on the atrium). A low-pitched, rumbling, diastolic murmur is heard at the apex. As a result of the increased blood volume and pressure, the atrium dilates, hypertrophies, and becomes electrically unstable, and patients experience atrial dysrhythmias. Doppler echocardiography is used to diagnose mitral stenosis. Electrocardiography (ECG) and cardiac catheterization with angiography may be used to help determine the severity of the mitral stenosis.

Medical Management

Congestive heart failure is treated as described in Chapter 30. Patients with mitral stenosis may benefit from anticoagulants to decrease the risk for developing atrial thrombus and may also require treatment for anemia. Patients with mitral stenosis are advised to avoid strenuous activities and competitive sports, both of which increase the heart rate. Mitral stenosis decreases the amount of blood that can flow from the left atrium to the left ventricle during diastole. When the heart rate increases, diastole is shortened, and thus the amount of time for the forward flow of blood is less. Therefore, as the heart rate increases, cardiac output decreases and pulmonary pressures increase with the backup of blood from the left atrium into the pulmonary veins. Surgical intervention consists of valvuloplasty, usually a commissurotomy to open or rupture the fused commissures of the mitral valve. Percutaneous transluminal valvuloplasty or mitral valve replacement may be performed.

Aortic Regurgitation

Aortic regurgitation is the flow of blood back into the left ventricle from the aorta during diastole. It may be caused by inflammatory lesions that deform the leaflets of the aortic valve, preventing them from completely closing the aortic valve orifice. This valvular defect also may result from infective or rheumatic endocarditis, congenital abnormalities, diseases such as syphilis, a dissecting aneurysm that causes dilation or tearing of the ascending aorta, blunt chest trauma, or deterioration of an aortic valve replacement. In many cases, the cause is unknown and is classified as idiopathic.

Pathophysiology

Blood from the aorta returns to the left ventricle during diastole, in addition to the blood normally delivered by the left atrium. The left ventricle dilates in an attempt to accommodate the increased volume of blood. It also hypertrophies in an attempt to increase muscle strength to expel more blood with above-normal force, thus increasing systolic blood pressure. The arteries attempt to compensate for the higher pressures by reflex vasodilation; the peripheral arterioles relax, reducing peripheral resistance and diastolic blood pressure.

Clinical Manifestations

Aortic insufficiency develops without symptoms in most patients. Some patients are aware of a forceful heartbeat, especially in the head or neck. Marked arterial pulsations that are visible or palpable at the carotid or temporal arteries may be present as a result of the increased force and volume of the blood ejected from the hypertrophied left ventricle. Exertional dyspnea and fatigue follow. Signs and symptoms of progressive left ventricular failure include breathing difficulties (eg, orthopnea, PND).

Assessment and Diagnostic Findings

A diastolic murmur is heard as a high-pitched, blowing sound at the third or fourth intercostal space at the left sternal border. The pulse pressure (ie, difference between systolic and diastolic pressures) is considerably widened in patients with aortic regurgitation. One characteristic sign of the disease is the water-hammer (Corrigan's) pulse, in which the pulse strikes the palpating finger with a quick, sharp stroke and then suddenly collapses. The diagnosis may be confirmed by Doppler echocardiography (preferably transesophageal), radionuclide imaging, ECG, magnetic resonance imaging (MRI), and cardiac catheterization. Patients with symptoms usually have echocardiograms every 4 to 6 months, and those without symptoms have echocardiograms every 2 to 3 years.

Medical Management

The patient is advised to avoid physical exertion, competitive sports, and isometric exercise. Dysrhythmias and heart failure are treated as described in Chapters 27 and 30. The medications usually prescribed first for patients with symptoms of aortic regurgitation are vasodilators such as calcium channel blockers (eg, nifedipine [Adalat, Procardia]) and

ACE inhibitors (eg, captopril, enalapril, lisinopril, ramipril), or hydralazine. The treatment of choice is aortic valvuloplasty or valve replacement, preferably performed before left ventricular failure occurs. Surgery is recommended for any patient with left ventricular hypertrophy, regardless of the presence or absence of symptoms.

Aortic Stenosis

Aortic valve stenosis is narrowing of the orifice between the left ventricle and the aorta. In adults, the stenosis is often a result of degenerative calcifications. Calcifications may be caused by inflammatory changes that occur in response to years of normal mechanical stress. Diabetes mellitus, hypercholesterolemia, hypertension, and low levels of high-density lipoprotein cholesterol may be risk factors for degenerative changes of the valve. Congenital leaflet malformations or an abnormal number of leaflets (ie, one or two rather than three) may be involved. Rarely rheumatic endocarditis may cause adhesions or fusion of the commissures and valve ring, stiffening of the cusps, and calcific nodules on the cusps. However, the cause of cusp calcification may be unknown.

Pathophysiology

Progressive narrowing of the valve orifice occurs, usually over several years to several decades. The left ventricle overcomes the obstruction to circulation by contracting more slowly but with greater energy than normal, forcibly squeezing the blood through the smaller orifice. The obstruction to left ventricular outflow increases pressure on the left ventricle, and the ventricular wall thickens, or hypertrophies. When these compensatory mechanisms of the heart begin to fail, clinical signs and symptoms develop.

Clinical Manifestations

Many patients with aortic stenosis are asymptomatic. When symptoms develop, patients usually first have exertional dyspnea, caused by increased pulmonary venous pressure due to left ventricular failure. Orthopnea, PND, and pulmonary edema may also occur, along with dizziness and syncope because of reduced blood flow to the brain. Angina pectoris is a frequent symptom; it results from the increased oxygen demands of the hypertrophied left ventricle, the decreased time in diastole for myocardial perfusion, and the decreased blood flow into the coronary arteries. Blood pressure is usually normal but may be low. Pulse pressure may be low (30 mm Hg or less) because of diminished blood flow.

Assessment and Diagnostic Findings

On physical examination, a loud, rough systolic murmur may be heard over the aortic area. The sound to listen for is a systolic crescendo–decrescendo murmur, which may radiate into the carotid arteries and to the apex of the left ventricle. The murmur is low-pitched, rough, rasping, and vibrating. An S₄ sound may be heard. If the examiner rests a hand over the base of the heart (second intercostal space next to the sternum and above the suprasternal notch up along the carotid arteries), a vibration may be felt. The vibration is caused by turbulent blood flow across the

narrowed valve orifice. By having the patient lean forward during auscultation and palpation, especially during exhalation, it is possible to accentuate the signs of aortic stenosis.

Doppler echocardiography is used to diagnose and monitor the progression of aortic stenosis. Patients with symptoms usually have echocardiograms every 6 to 12 months, and those without symptoms have echocardiograms every 2 to 5 years. Evidence of left ventricular hypertrophy may be seen on a 12-lead ECG and an echocardiogram. After stenosis progresses to the point that surgical intervention is considered, left-sided heart catheterization is necessary to measure the severity of the valvular abnormality and to evaluate the coronary arteries. Pressure tracings are taken from the left ventricle and from the base of the aorta. The systolic pressure in the left ventricle is considerably higher than that in the aorta during systole. Graded exercise studies (stress tests) are not usually prescribed for patients with aortic stenosis because of the high risk of precipitating ventricular tachycardia or fibrillation.

Medical Management

Medications are prescribed to treat dysrhythmia or left ventricular failure (see Chapters 27 and 30). Definitive treatment for aortic stenosis is surgical replacement of the aortic valve. Patients who are symptomatic and are not surgical candidates may benefit from one-balloon or two-balloon percutaneous valvuloplasty procedures.

Nursing Management: Valvular Heart Disorders

The nurse teaches the patient with valvular heart disease about the diagnosis, the progressive nature of valvular heart disease, and the treatment plan. The patient is taught to report new symptoms or changes in symptoms to the health care provider. The nurse also teaches the patient that the infectious agent, usually a bacterium, is able to adhere to the diseased heart valve more readily than to a normal valve. Once attached to the valve, the infectious agent multiplies, resulting in endocarditis and further damage to the valve. In addition, the nurse teaches the patient how to minimize the risk of developing infectious endocarditis.

The nurse measures the patient's heart rate, blood pressure, and respiratory rate, compares these results with previous data, and notes any changes. Heart and lung sounds are auscultated and peripheral pulses palpated. The nurse assesses the patient with valvular heart disease for the following conditions:

- Signs and symptoms of heart failure, such as fatigue, dyspnea on exertion, an increase in coughing, hemoptysis, multiple respiratory infections, orthopnea, and PND (see Chapter 30)
- Dysrhythmias, by palpating the patient's pulse for strength and rhythm (ie, regular or irregular) and asking whether the patient has experienced palpitations or felt forceful heartbeats (see Chapter 27)
- Symptoms such as dizziness, syncope, increased weakness, or angina pectoris (see Chapter 28)

The nurse collaborates with the patient to develop a medication schedule and teaches about the name, dosage,

actions, adverse effects, and any drug–drug or drug–food interactions of the prescribed medications for heart failure, dysrhythmias, angina pectoris, or other symptoms. Specific precautions are emphasized, such as the risk to patients with aortic stenosis who experience angina pectoris and take nitroglycerin. The venous dilation that results from nitroglycerin decreases blood return to the heart, thus decreasing cardiac output and increasing the risk of syncope and decreased coronary artery blood flow. The nurse teaches the patient about the importance of attempting to relieve the symptoms of angina with rest and relaxation before taking nitroglycerin and to anticipate the potential adverse effects.

In addition, the nurse teaches the patient to weigh daily and report gains of 2 pounds in 1 day or 5 pounds in 1 week to the health care provider. The nurse may assist the patient with planning activity and rest periods to achieve an acceptable lifestyle. The patient may need to be advised to rest and sleep sitting in a chair or bed with the head elevated when experiencing symptoms of pulmonary congestion. Care of patients treated with valvuloplasty or surgical valve replacement is described later in this chapter.

VALVE REPAIR AND REPLACEMENT PROCEDURES

Valvuloplasty

The repair, rather than replacement, of a cardiac valve is referred to as **valvuloplasty**. In general, valves that undergo valvuloplasty function longer than prosthetic valve replacements, and patients do not require continuous anticoagulation. The type of valvuloplasty depends on the cause and type of valve dysfunction. Repair may be made to the commissures between the leaflets in a procedure known as **commissurotomy**, to the annulus of the valve by annuloplasty, to the leaflets, or to the chordae by chordoplasty. TEE is usually performed at the conclusion of a valvuloplasty to evaluate the effectiveness of the procedure.

Most valvuloplasty procedures require general anesthesia and often require cardiopulmonary bypass. However, some procedures can be performed in the cardiac catheterization laboratory and do not always require general anesthesia or cardiopulmonary bypass. Percutaneous partial cardiopulmonary bypass is used in some cardiac catheterization laboratories. Cardiopulmonary bypass is achieved by inserting a large catheter (ie, cannula) into two peripheral blood vessels, usually a femoral vein and an artery. Blood is diverted from the body through the venous catheter to the cardiopulmonary bypass machine (see Chapter 28) and returned to the patient through the arterial catheter.

Commissurotomy

The most common valvuloplasty procedure is commissurotomy. Each valve has leaflets; the site where the leaflets meet is called the commissure. The leaflets may adhere to one another and close the commissure (ie, stenosis). Less commonly, the leaflets fuse in such a way that in addition to stenosis, the leaflets are also prevented from closing completely, resulting in a backward flow of blood (ie, regurgita-

tion). A commissurotomy is the procedure performed to separate the fused leaflets.

Closed Commissurotomy/Balloon Valvuloplasty

Closed commissurotomies do not require cardiopulmonary bypass. The valve is not directly visualized. Closed commissurotomies, in which a surgical technique is used, are performed in the operating room with the patient under general anesthesia; a midsternal incision is made, a small hole is cut into the heart, and the surgeon's finger or a dilator is used to open the commissure.

Percutaneous balloon valvuloplasty is the technique most commonly performed in the United States for closed commissurotomy. Balloon valvuloplasty is beneficial for mitral valve stenosis in younger patients, for aortic valve stenosis in elderly patients, and for patients with complex medical conditions that place them at high risk for the complications of more extensive surgical procedures. Most often used for mitral and aortic valve stenosis, balloon valvuloplasty also has been used for tricuspid and pulmonic valve stenosis. The procedure is contraindicated for patients with left atrial or ventricular thrombus, severe aortic root dilation, significant mitral valve regurgitation, thoracolumbar scoliosis, rotation of the great vessels, and other cardiac conditions that require open heart surgery.

Balloon valvuloplasty (Fig. 29-3) is performed in the cardiac catheterization laboratory. The patient may receive light or moderate sedation or just a local anesthetic. Mitral balloon valvuloplasty involves advancing one or two catheters into the right atrium, through the atrial septum

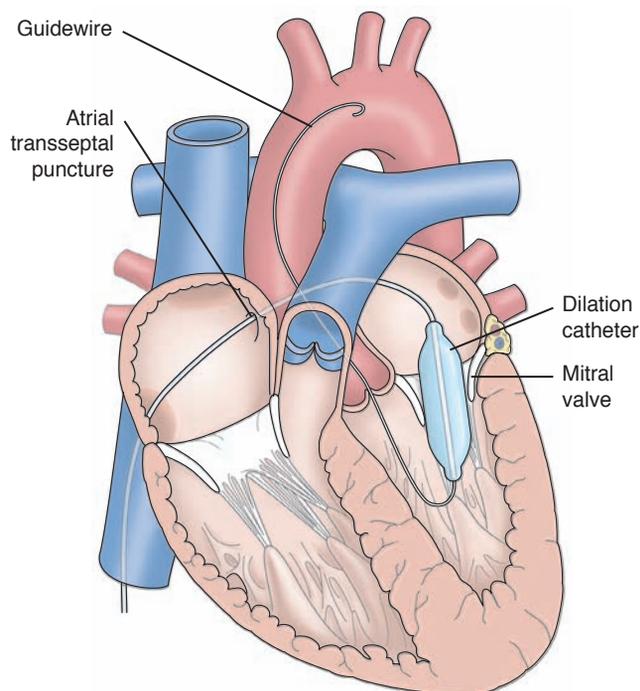

Figure 29-3 Balloon valvuloplasty: cross-section of heart illustrating the guidewire and dilation catheter placed through an atrial transseptal puncture and across the mitral valve. The guidewire is extended out from the aortic valve into the aorta for catheter support.

into the left atrium, across the mitral valve into the left ventricle, and out into the aorta. A guidewire is placed through each catheter, and the original catheter is removed. A large balloon catheter is then placed over the guidewire and positioned with the balloon across the mitral valve. The balloon is then inflated with a dilute angiographic solution. When two balloons are used, they are inflated simultaneously. The advantage of two balloons is that they are each smaller than the one large balloon often used, making smaller atrial septal defects. As the balloons are inflated, they usually do not completely occlude the mitral valve, thereby permitting some forward flow of blood during the inflation period. The balloons are usually inflated for 10 to 30 seconds. Multiple inflations are usually required to achieve the desired results.

All patients have some degree of mitral regurgitation after the procedure. Other possible complications include bleeding from the catheter insertion sites, emboli resulting in complications such as strokes, and rarely, left-to-right atrial shunts through an atrial septal defect caused by the procedure.

Aortic balloon valvuloplasty is performed most commonly by introducing a catheter through the aorta, across the aortic valve, and into the left ventricle, although it also may be performed by passing the balloon or balloons through the atrial septum. The one-balloon or the two-balloon technique can be used for treating aortic stenosis. Balloons are inflated for 15 to 60 seconds, and inflation is usually repeated multiple times. The aortic valve procedure is not as effective as the mitral valve procedure, and the rate of restenosis is 36% to 80% in the first 12 months after the procedure (Libby, et al., 2008). Possible complications include aortic regurgitation, emboli, ventricular perforation, rupture of the aortic valve annulus, ventricular dysrhythmia, mitral valve damage, and bleeding from the catheter insertion sites.

Open Commissurotomy

Open commissurotomies are performed with direct visualization of the valve. The patient is under general anesthesia. A midsternal or left thoracic incision is made. Cardiopulmonary bypass is initiated and an incision is made into the heart. The valve is exposed and the surgeon uses a scalpel, finger, balloon, or dilator to open the commissures.

An added advantage of direct visualization of the valve is that thrombus and calcifications may be identified and removed. If the valve has chordae or papillary muscles, they may be inspected and surgically repaired as necessary.

Annuloplasty

Annuloplasty is the repair of the valve annulus (ie, junction of the valve leaflets and the muscular heart wall). General anesthesia and cardiopulmonary bypass are required for all annuloplasties. The procedure narrows the diameter of the valve's orifice and is useful for the treatment of valvular regurgitation.

There are two annuloplasty techniques. One technique uses an annuloplasty ring (Fig. 29-4), which may be preshaped (rigid/semirigid) or flexible. The leaflets of the valve are sutured to a ring, creating an annulus of the desired size. When the ring is in place, the tension created by the moving

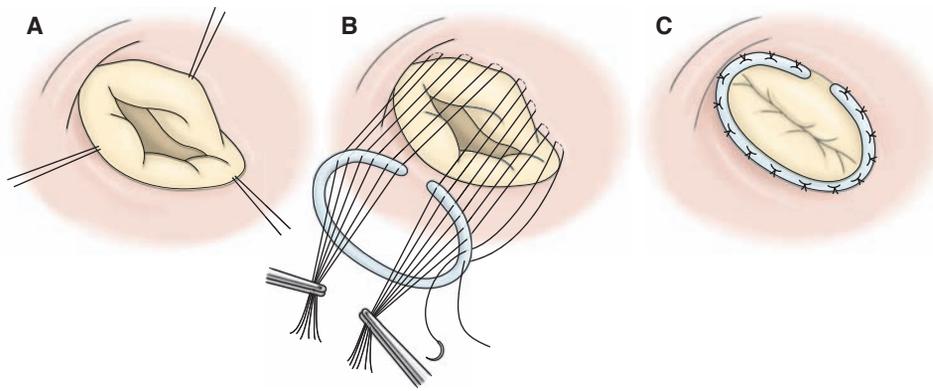

Figure 29-4 Annuloplasty ring insertion. **A**, Mitral valve regurgitation; leaflets do not close. **B**, Insertion of an annuloplasty ring. **C**, Completed valvuloplasty; leaflets close.

blood and contracting heart is borne by the ring rather than by the valve or a suture line. Progressive regurgitation is prevented by the repair. The second technique involves tacking the valve leaflets to the atrium with sutures or taking tucks to tighten the annulus. Because the valve's leaflets and the suture lines are subjected to the direct forces of the blood and heart muscle movement, the repair may degenerate more quickly than one using an annuloplasty ring.

Leaflet Repair

Damage to cardiac valve leaflets may result from stretching, shortening, or tearing. **Leaflet repair** for elongated, ballooning, or other excess tissue leaflets is removal of the extra tissue. The elongated tissue may be folded over onto itself (ie, tucked) and sutured (ie, leaflet plication). A wedge of tissue may be cut from the middle of the leaflet and the gap sutured closed (ie, leaflet resection) (Fig. 29-5). Short leaflets are most often repaired by chordoplasty. After the short chordae are released, the leaflets often unfurl and can resume their normal function (closing the valve during systole). A leaflet may be extended by suturing a piece of pericardium to it. A pericardial or synthetic patch may be used to repair holes in the leaflets.

Chordoplasty

Chordoplasty is repair of the chordae tendineae. The mitral valve is involved with chordoplasty (because it has chordae tendineae); the tricuspid valve seldom requires chordoplasty. Stretched, torn, or shortened chordae tendineae may cause regurgitation. Stretched chordae tendineae can be shortened, transposed to the other leaflet, or replaced with synthetic chordae. Torn chordae can be reattached to the

leaflet and shortened chordae can be elongated. Stretched papillary muscles, which may also cause regurgitation, can be shortened as well.

Valve Replacement

When valvuloplasty is not a viable alternative (eg, when the annulus or leaflets of the valve are immobilized by calcifications, severe fibrosis or fusion of the chordate tendineae, papillary muscles, and leaflets below the valve), **valve replacement** is performed. General anesthesia and cardiopulmonary bypass are used for valve replacements. Most procedures are performed through a median sternotomy (ie, incision through the sternum), although the mitral valve may be approached through a right thoracotomy incision. Mitral, and more rarely aortic, valve replacements may be performed with minimally invasive techniques that do not involve cutting through the length of the sternum. Instead, incisions are made in only the upper or lower half of the sternum or between ribs; these incisions are only 2 to 4 inches long. Some of these minimally invasive procedures are robot assisted; the surgical instruments are connected to a robot, and the surgeon, watching a video display, uses a joystick to control the robot and surgical instruments. With these procedures, patients have less bleeding, pain, risk of infection, and scarring. Hospital stays average 3 days, and recovery may be as short as 3 weeks.

After the valve is visualized, the leaflets of the aortic or pulmonic valve are removed, but some or all of the mitral valve structures (leaflets, chordae, and papillary muscles) are left in place to help maintain the shape and function of

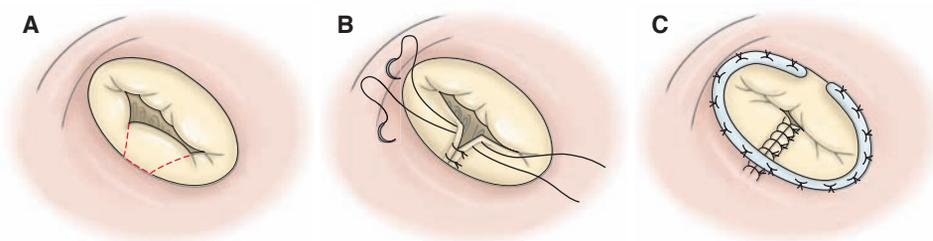

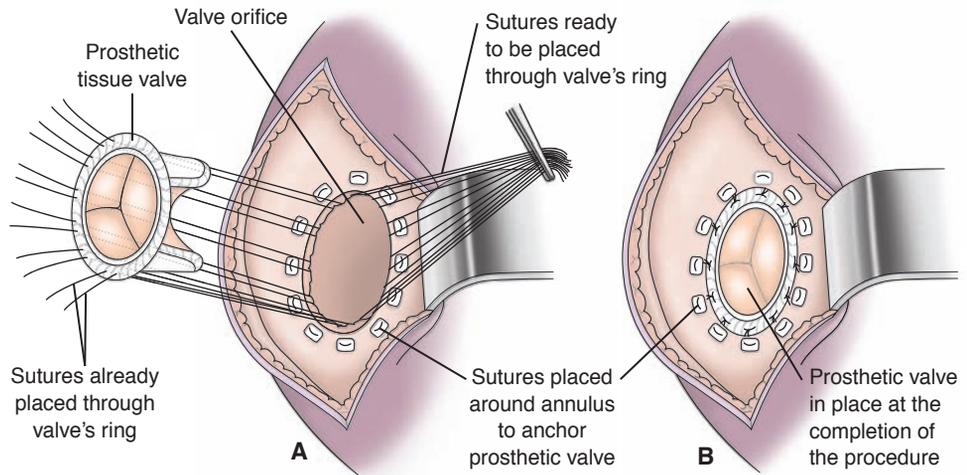

Figure 29-5 Valve leaflet resection and repair with a ring annuloplasty. **A**, Mitral valve regurgitation; the section indicated by dashed lines is excised. **B**, Approximation of edges and suturing. **C**, Completed valvuloplasty, leaflet repair, and annuloplasty ring.

Figure 29-6 Valve replacement. **A**, The native valve is trimmed, and the prosthetic valve is sutured in place. **B**, Once all sutures are placed through the ring, the surgeon slides the prosthetic valve down the sutures and into the natural orifice. The sutures are then tied off and trimmed.

the left ventricle after mitral valve replacement. Sutures are placed around the annulus and then through the valve prosthesis. The replacement valve is slid down the suture into position and tied into place (Fig. 29-6). The incision is closed, and the surgeon evaluates the function of the heart and the quality of the prosthetic repair. The patient is weaned from cardiopulmonary bypass, the surgical repair is often assessed with color flow Doppler TEE, and the surgery is completed.

Before surgery, the heart gradually adjusted to the pathology; but the surgery abruptly “corrects” the way blood flows through the heart. Complications unique to valve replacement are related to the sudden changes in intracardiac blood pressures. All prosthetic valve replacements create a degree of stenosis when they are implanted in the heart. Usually the stenosis is mild and does not affect heart function. If valve replacement was for a stenotic valve, blood flow through the heart is often improved. The signs and symptoms of the backward heart failure resolve in a few hours or days. If valve replacement was for a regurgitant valve, it may take months for the chamber into which blood had been regurgitating to achieve its optimal postoperative function. The signs and symptoms of heart failure resolve gradually as the heart function improves. Patients are at risk for many postoperative complications, such as bleeding, thromboembolism, infection, heart failure, hypertension, dysrhythmias, hemolysis, and mechanical obstruction of the valve.

Two types of valve prostheses may be used: mechanical and tissue (ie, biologic) valves (Fig. 29-7).

Mechanical Valves

Mechanical valves are of the bileaflet, ball-and-cage, or tilting-disk design and are thought to be more durable than tissue prosthetic valves; therefore, they are often used for younger patients. These valves are used for patients with renal failure, hypercalcemia, endocarditis, or sepsis who require valve replacement. The mechanical valves do not deteriorate or become infected as easily as the tissue valves

used for patients with these conditions. Significant complications associated with mechanical valves are thromboemboli requiring long-term use of anticoagulants. Some amount of hemolysis also occurs with these valves; usually it is not clinically significant.

Tissue (Biologic) Valves

Tissue (ie, biologic) valves are of three types: xenografts, homografts, and autografts. Tissue valves are less likely to generate thromboemboli, and long-term anticoagulation is not required. Tissue valves are not as durable as mechanical valves and require replacement more frequently.

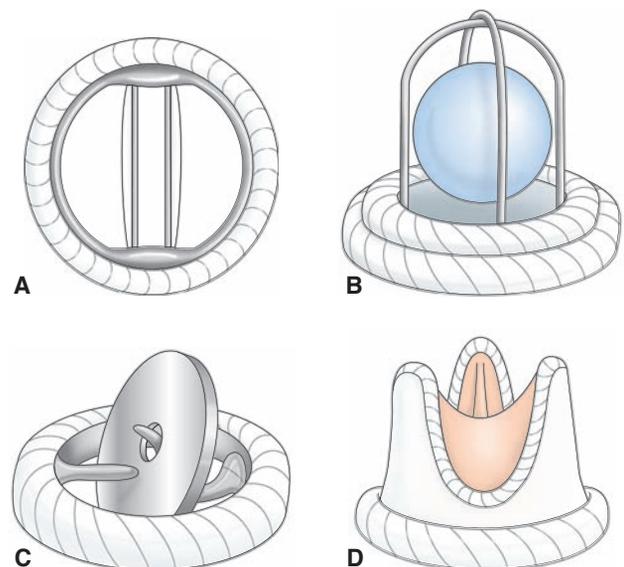

Figure 29-7 Common mechanical and tissue valve replacements. **A**, Bileaflet (St. Jude, mechanical). **B**, Caged ball valve (Starr-Edwards, mechanical). **C**, Tilting-disk valve (Medtronic-Hall, mechanical). **D**, Porcine heterograft valve (Carpenter-Edwards, tissue).

Xenografts

Xenografts are tissue valves (eg, bioprostheses, **heterografts**) that are used for tricuspid valve replacements. They are not thrombogenic, so patients do not need long-term anticoagulation therapy. They are used for women of childbearing age because the potential complications of long-term anticoagulation associated with menses, placental transfer to a fetus, and delivery of a child are avoided. They also are used for patients older than 70 years of age, patients with a history of peptic ulcer disease, and others who cannot tolerate long-term anticoagulation. Most xenografts come from pigs (porcine), but some come from cows (bovine). Viability is 7 to 10 years.

Homografts

Homografts, or **allografts** (ie, human valves), are obtained from cadaver tissue donations and are used for aortic and pulmonic valve replacement. The aortic valve and a portion of the aorta or the pulmonic valve and a portion of the pulmonary artery are harvested and stored cryogenically. Homografts are not always available and are very expensive. They last for about 10 to 15 years, somewhat longer than xenografts. They are resistant to infectious endocarditis.

Autografts

Autografts (ie, autologous valves) are obtained by excising the patient's own pulmonic valve and a portion of the pulmonary artery for use as the aortic valve. Anticoagulation is unnecessary because the valve is the patient's own tissue and is not thrombogenic. The autograft is an alternative for children (it may grow as the child grows), women of childbearing age, young adults, patients with a history of peptic ulcer disease, and people who cannot tolerate anticoagulation. Aortic valve autografts have remained viable for more than 20 years.

Most aortic valve autograft procedures are double valve–replacement procedures; a homograft can also be performed for pulmonic valve replacement. If pulmonary vascular pressures are normal, some surgeons elect not to replace the pulmonic valve. Patients can recover without a valve between the right ventricle and the pulmonary artery.

Patients who have undergone surgical valvuloplasty or valve replacements are admitted to the intensive care unit. Care focuses on recovery from anesthesia and hemodynamic stability. Vital signs are assessed every 5 to 15 minutes and as needed until the patient recovers from anesthesia or sedation, and then are assessed every 2 to 4 hours and as needed. Intravenous (IV) medications to increase or decrease blood pressure and to treat dysrhythmias or altered heart rates are administered and their effects monitored. The medications are gradually decreased until they are no longer required or the patient can take the needed medication by another route (eg, oral, topical). Patient assessments are conducted every 1 to 4 hours and as needed, with particular attention to neurologic, respiratory, and cardiovascular systems. (See Chapter 28, Chart 28-13, which presents a plan of nursing care for a patient recovering from cardiac surgery.)

After the patient has recovered from anesthesia and sedation, is hemodynamically stable without IV medications, and has stable physical assessment parameters, he or she is usually transferred to a telemetry unit, typically within 24 to 72 hours of surgery. Nursing care continues as for most postoperative patients, including wound care and patient teaching regarding diet, activity, medications, and self-care. The patient is usually discharged from the hospital in 3 to 7 days.

The nurse educates the patient about anticoagulant therapy, explaining the need for frequent follow-up appointments and blood laboratory studies. Patients who take warfarin (Coumadin) usually have individualized target international normalized ratios (INRs) between 2.0 and 3.5. Patients who have been treated with an annuloplasty ring or a tissue valve replacement usually require anticoagulation for only 3 months, unless there are other risk factors such as atrial fibrillation or a history of thromboembolism. Aspirin may be prescribed with warfarin for some patients. The nurse provides teaching about all prescribed medications: the name of the medication, dosage, its actions, prescribed schedule, potential adverse effects, and any drug–drug or drug–food interactions.

Patients with a mechanical valve prosthesis (including annuloplasty rings and other prosthetic materials used in valvuloplasty) require education to prevent infective endocarditis. Patients may be at risk for infectious endocarditis that results from bacteria entering the bloodstream and adhering to the abnormal valve structures or prosthetic devices. The nurse teaches the patient how to minimize the risk of developing infectious endocarditis. Antibiotic prophylaxis is necessary before dental procedures involving manipulation of gingival tissue, the periapical area of the teeth, or perforation of the oral mucosa (not including routine anesthetic injections, placement of orthodontic brackets, or loss of deciduous teeth). Antibiotic therapy should also be used before invasive procedures involving the respiratory tract (eg, biopsy of respiratory mucosa, tonsillectomy, and adenectomy).

Home care and office or clinic nurses reinforce all new information and self-care instructions with patients and families for 4 to 8 weeks after the procedure. Doppler echocardiograms are often performed 3 to 4 weeks after discharge from the hospital to further evaluate the effects and results of the surgery. The echocardiogram also provides a

Nursing Management: Valvuloplasty and Replacement

The nurse assists the patient and family to prepare for the procedure, reinforces and supplements explanations provided by the physician, and provides psychosocial support. Care of the surgical patient is described in Chapters 18 through 20.

Patients who have undergone percutaneous balloon valvuloplasty procedures may be admitted to a telemetry or intensive care unit. The nurse assesses for signs and symptoms of heart failure and emboli (see Chapter 30), listens for any changes in heart sounds at least every 4 hours, and provides the patient with the same care as for postprocedure cardiac catheterization or percutaneous transluminal coronary angioplasty (PTCA) (see Chapter 28). After undergoing percutaneous balloon valvuloplasty, the patient usually remains in the hospital for 24 to 48 hours.

baseline for future comparison if cardiac symptoms or complications develop. Doppler echocardiograms are usually repeated every 1 to 2 years.

Septal Defects

The atrial or ventricular septum may have an abnormal opening between the right and left sides of the heart (ie, septal defect). Most septal defects are congenital and are usually identified and repaired during infancy or childhood. Adults may not have undergone early repair or may develop septal defects as a result of myocardial infarction or trauma. In general, pressures in the left atria and ventricle are higher than those on the right, so blood initially flows from the left heart chamber into the right—a left-to-right shunt.

With an atrial septal defect (ASD), ultimately the right atrial pressures become greater than the left atrial pressures, and blood begins to flow from the right atrium into the left atrium—a right-to-left shunt. With a ventricular septal defect (VSD), the extra blood volume causes the right ventricle to dilate, as well as pulmonary vascular congestion and hypertension.

Patients with septal defects may not experience any symptoms, gradually develop symptoms, or rapidly develop heart failure. Patients with ASDs who gradually develop symptoms usually describe decreased exercise tolerance, dyspnea on exertion, palpitations, syncope, and symptoms of right ventricular or congestive heart failure. Cyanosis may result, or strokes (cerebrovascular accidents, brain attacks) may occur. Patients with VSDs who gradually develop symptoms describe shortness of breath, syncope, chest pain, and symptoms of left ventricular failure.

Medical Management

Treatment is individualized to the patient's symptoms. Heart failure is treated as described in Chapter 30. Vasodilators are often prescribed first to decrease resistance to ventricular ejection and minimize the left-to-right shunting.

Many septal defects can be repaired percutaneously in a cardiac catheterization laboratory. A guidewire is advanced through a vein into the right side of the heart and through the septal defect. A special catheter is placed over the guidewire and positioned across the septal defect. Two connected mesh disks (one on each side of the septum) are then used to close the septal defect.

Surgical repair of some septal defects requires general anesthesia and cardiopulmonary bypass. ASD repairs without mitral or tricuspid valve involvement have low morbidity and mortality rates. Generally, VSD repairs are uncomplicated, but close proximity of the defect to the intraventricular conduction system and the valves may make this repair more complex.

Nursing Management

Care for a patient recovering from a percutaneous septal defect repair is the same care as for postprocedure cardiac catheterization or PTCA (see Chapter 28). After undergoing percutaneous septal repair, the patient usually remains in the hospital for 24 to 48 hours. Care for a patient

recovering from a surgical septal defect repair is the same as other cardiac surgeries (see Chapter 28, Chart 28-13).

Cardiomyopathy

Cardiomyopathy is a heart muscle disease associated with cardiac dysfunction. It is classified according to the structural and functional abnormalities of the heart muscle: dilated cardiomyopathy (DCM), hypertrophic cardiomyopathy (HCM), restrictive or constrictive cardiomyopathy (RCM), arrhythmogenic right ventricular cardiomyopathy (ARVC), and unclassified cardiomyopathy (Libby, et al., 2008). A patient may have pathology representing more than one of these classifications, such as a patient with HCM developing dilation and symptoms of DCM. Ischemic cardiomyopathy is a term frequently used to describe an enlarged heart caused by coronary artery disease, which is usually accompanied by heart failure (see Chapter 30).

Pathophysiology

The pathophysiology of all cardiomyopathies is a series of events that culminate in impaired cardiac output. Decreased stroke volume stimulates the sympathetic nervous system and the renin-angiotensin-aldosterone response, resulting in increased systemic vascular resistance and increased sodium and fluid retention, which places an increased workload on the heart. These alterations can lead to heart failure (see Chapter 30).

Dilated Cardiomyopathy

DCM is the most common form of cardiomyopathy, with an incidence of 5 to 8 cases per 100,000 people per year (Libby, et al., 2008). DCM is distinguished by significant dilation of the ventricles without simultaneous hypertrophy (ie, increased muscle wall thickness) and systolic dysfunction (Fig. 29-8). The ventricles have elevated systolic and diastolic volumes but a decreased ejection fraction.

More than 75 conditions and diseases may cause DCM, including pregnancy, heavy alcohol intake, viral infection (eg, influenza), chemotherapeutic medications (eg, daunorubicin [Cerubidine], doxorubicin [Adriamycin]), and Chagas disease. When the causative factor cannot be identified, the diagnosis is idiopathic DCM, which accounts for approximately 25% of all heart failure cases. Because genetic factors may be involved, echocardiography and ECG should be used to screen all first-degree blood relatives (eg, parents, siblings, children) for DCM (Libby, et al., 2008).

Microscopic examination of the muscle tissue shows diminished contractile elements (actin and myosin filaments) of the muscle fibers and diffuse necrosis of myocardial cells. The result is poor systolic function. The structural changes decrease the amount of blood ejected from the ventricle with systole, increasing the amount of blood remaining in the ventricle after contraction. Less blood is then able to enter the ventricle during diastole, increasing end-diastolic pressure and eventually increasing pulmonary and systemic venous pressures. Altered valve function, usually regurgitation, can result from an enlarged stretched ventricle. Poor blood flow through the ventricle may also cause ventricular

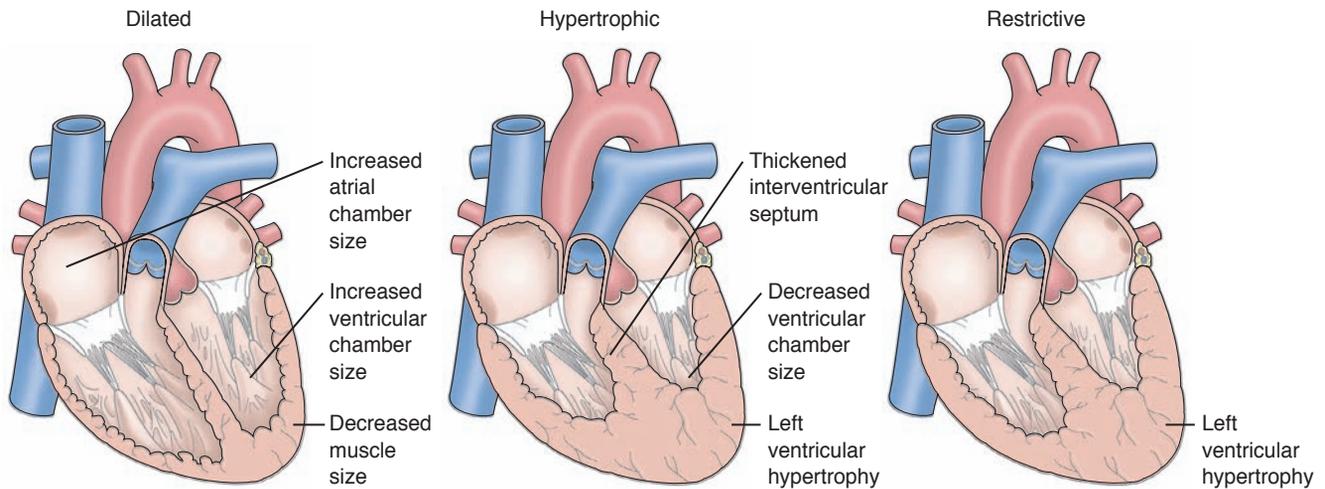

Figure 29-8 Cardiomyopathies that lead to congestive heart failure. Redrawn from Anatomical Chart Company. (2006). *Atlas of pathology* (2nd ed.). Ambler, PA: Lippincott Williams & Wilkins.

or atrial thrombi, which may embolize to other locations in the body. Early diagnosis and treatment can prevent or delay significant symptoms and sudden death from DCM.

Hypertrophic Cardiomyopathy

HCM is a rare autosomal dominant condition, occurring in men, women, and children (often detected after puberty) with an estimated prevalence rate of 0.05% to 0.2% of the population in the United States (Zevitz, 2006). Echocardiograms may be performed every year from 12 to 18 years of age and then every 5 years from 18 to 70 years of age in susceptible individuals. Doppler echocardiography may also be used to detect the HCM and blood flow alterations (Libby, et al., 2008). HCM also may be idiopathic (ie, no known cause).

In HCM, the heart muscle asymmetrically increases in size and mass, especially along the septum (see Fig. 29-8). HCM often affects nonadjacent areas of the ventricle. The increased thickness of the heart muscle reduces the size of the ventricular cavities and causes the ventricles to take a longer time to relax after systole. During the first part of diastole it is more difficult for the ventricles to fill with blood. The atrial contraction at the end of diastole becomes critical for ventricular filling and systolic contraction.

Cardiac muscle cells normally lie parallel to and end-to-end with each other. The hypertrophied cardiac muscle cells are disorganized, oblique, and perpendicular to each other, decreasing the effectiveness of contractions and possibly increasing the risk of dysrhythmias such as ventricular tachycardia and ventricular fibrillation. In HCM the coronary arteriole walls are thickened, which decreases the internal diameter of the arterioles. The narrow arterioles restrict the blood supply to the myocardium, causing numerous small areas of ischemia and necrosis. The necrotic areas of the myocardium ultimately fibrose and scar, further impeding ventricular contraction.

Restrictive Cardiomyopathy

RCM is characterized by diastolic dysfunction caused by rigid ventricular walls that impair diastolic filling and ven-

tricular stretch (see Fig. 29-8). Systolic function is usually normal. RCM may be associated with amyloidosis (amyloid, a protein substance, is deposited within cells) and other such infiltrative diseases. However, the cause is unknown (ie, idiopathic) in most cases. Signs and symptoms are similar to constrictive pericarditis: dyspnea, nonproductive cough, and chest pain. Echocardiography, as well as measurement of pulmonary artery systolic (PAS) pressure, pulmonary artery wedge pressure (PAWP), and central venous pressure (CVP) are used to differentiate the two conditions.

Arrhythmogenic Right Ventricular Cardiomyopathy

ARVC occurs when the myocardium of the right ventricle is progressively infiltrated and replaced by fibrous scar and adipose tissue. Initially, only localized areas of the right ventricle are affected, but as the disease progresses, the entire heart is affected. Eventually, the right ventricle dilates and develops poor contractility, right ventricular wall abnormalities, and dysrhythmias. The prevalence of ARVC is unknown because many cases are not recognized. Palpitations or syncope may develop between 15 and 40 years of age. ARVC should be considered in patients with ventricular tachycardia originating in the right ventricle (ie, a left bundle branch block configuration on ECG) or sudden death, especially among young athletes (Libby, et al., 2008). ARVC is genetic (ie, autosomal dominant) (Sen-Chowdhry, Syrris & McKenna, 2005). First-degree blood relatives (eg, parents, siblings, children) should be screened for the disease with a 12-lead ECG, Holter monitor, and echocardiography.

Unclassified Cardiomyopathies

Unclassified cardiomyopathies are different from or have characteristics of more than one of the previously described types. Examples of unclassified cardiomyopathies include fibroelastosis, noncompacted myocardium, systolic dysfunction with minimal dilation, and mitochondrial involvement (Libby, et al., 2008).

Clinical Manifestations

Patients with cardiomyopathy may remain stable and without symptoms for many years. As the disease progresses, so do the symptoms. Frequently, dilated or restrictive cardiomyopathy is first diagnosed when the patient presents with signs and symptoms of heart failure (eg, dyspnea on exertion, fatigue). Patients with cardiomyopathy may also report PND, cough (especially with exertion), and orthopnea, which may lead to a misdiagnosis of bronchitis or pneumonia. Other symptoms include fluid retention, peripheral edema, and nausea, which is caused by poor perfusion of the gastrointestinal system. The patient also may experience chest pain, palpitations, dizziness, nausea, and syncope with exertion. However, with HCM, cardiac arrest (ie, sudden cardiac death) may be the initial manifestation in young people, including athletes (Libby, et al., 2008; Zevitz, 2006).

Regardless of type and cause, cardiomyopathy may lead to severe heart failure, lethal dysrhythmias, and death. The mortality rate is highest for African Americans and the elderly.

Assessment and Diagnostic Findings

Physical examination at early stages may reveal tachycardia and extra heart sounds (eg, S₃, S₄). Patients with DCM may have diastolic murmurs, and patients with DCM and HCM may have systolic murmurs. With disease progression, examination also reveals signs and symptoms of heart failure (eg, crackles on pulmonary auscultation, jugular vein distention, pitting edema of dependent body parts, enlarged liver).

Diagnosis is usually made from findings disclosed by the patient history and by ruling out other causes of heart failure such as myocardial infarction. The echocardiogram is one of the most helpful diagnostic tools because the structure and function of the ventricles can be observed easily. Cardiac MRI may also be used, particularly to assist with the diagnosis of HCM (Rickers, Wilke, Jerosch-Herold, et al., 2005). ECG demonstrates dysrhythmias (atrial fibrillation, ventricular dysrhythmias) and changes consistent with left ventricular hypertrophy (left axis deviation, wide QRS, ST changes, inverted T waves). In ARVC, there often is a small deflection, an epsilon wave, at the end of the QRS. The chest x-ray reveals heart enlargement and possibly pulmonary congestion. Cardiac catheterization is sometimes used to rule out coronary artery disease as a causative factor. Endomyocardial biopsy may be performed to analyze myocardial cells.

Medical Management

Medical management is directed toward identifying and managing possible underlying or precipitating causes; correcting the heart failure with medications, a low-sodium diet, and an exercise/rest regimen (see Chapter 30); and controlling dysrhythmias with antiarrhythmic medications and possibly with an implanted electronic device, such as an implantable cardioverter defibrillator (see Chapter 27). Systemic anticoagulation to prevent thromboembolic events is usually recommended. If the patient has signs and symptoms of congestion, fluid intake may be limited to 2 L

each day. Patients with HCM should avoid dehydration and may need beta-blockers (atenolol [Tenormin], metoprolol [Lopressor], nadolol [Corgard], propranolol [Inderal]) to maintain cardiac output and minimize the risk of left ventricular outflow tract obstruction during systole. Patients with HCM or RCM may need to limit physical activity to avoid a life-threatening dysrhythmia.

A pacemaker may be implanted to alter the electrical stimulation of the muscle and prevent the forceful hyperdynamic contractions that occur with HCM. Atrial-ventricular and biventricular pacing have been used to decrease symptoms and obstruction of the left ventricular outflow tract. For some patients with DCM and HCM, biventricular pacing increases the ejection fraction and reverses some of the structural changes in the myocardium.

Nonsurgical septal reduction therapy, also called alcohol septal ablation, has been used to treat obstructive HCM. In the cardiac catheterization laboratory, a percutaneous catheter is positioned in one or more of the septal coronary arteries. Once the position is verified, 1 to 5 mL of 96% to 98% ethanol (ethyl alcohol) is injected at a rate of about 1 mL/min to destroy the myocardial cells; it is believed that the ethanol causes dehydration of the cardiac cells (Libby, et al., 2008; Zevitz, 2006). The slow rate of injection minimizes the risk of heart block and premature ventricular contractions. The procedure produces a septal myocardial infarction. The resulting scar is thinner than the living myocardium had been, so the obstruction is decreased. The patient may develop a left anterior hemibranch block or left bundle branch block. If the patient experiences pain, hydrocodone/acetaminophen (Vicodin) is usually administered. Nitrates and morphine are not used because coronary artery dilation is contraindicated.

Surgical Management

When heart failure progresses and medical treatment is no longer effective, surgical intervention, including heart transplantation, is considered. However, because of the limited number of organ donors, many patients die waiting for transplantation. In some cases, a left ventricular assist device is implanted to support the failing heart until a suitable donor heart becomes available.

Left Ventricular Outflow Tract Surgery

When patients with HCM become symptomatic despite medical therapy and a difference in pressure of 50 mm Hg or more exists between the left ventricle and the aorta, surgery is considered. The most common procedure is a myectomy (sometimes referred to as a myotomy-myectomy), in which some of the heart tissue is excised. Septal tissue approximately 1-cm wide and deep is cut from the enlarged septum below the aortic valve. The length of septum removed depends on the degree of obstruction caused by the hypertrophied muscle.

Instead of a septal myectomy, the surgeon may open the left ventricular outflow tract to the aortic valve by mitral valvuloplasty involving the leaflets, chordae, or papillary muscles, or the patient's mitral valve may be replaced with a low-profile disk valve. The space taken up by the mitral valve is substantially reduced by the valvuloplasty or prosthetic valve, allowing blood to move around the enlarged

septum to the aortic valve through the area the mitral valve once occupied. The primary complication of all the procedures is dysrhythmia. Additional complications include postoperative surgical complications such as pain, ineffective airway clearance, deep vein thrombosis, risk of infection, and delayed surgical recovery.

Latissimus Dorsi Muscle Wrap

DCM may be treated with a latissimus dorsi muscle wrap, also called dynamic cardiomyoplasty (Libby, et al., 2008; Woods, Froelicher, Motzer, et al., 2005). The left latissimus dorsi muscle is dissected from the lateral side and back of the chest, leaving the medial end of the muscle and the blood supply intact, and the lateral end of the muscle is pulled through the pleural space into the pericardium. The latissimus dorsi muscle flap is then wrapped around the ventricles and sutured in place. Pacemaker leads are implanted into the muscle flap, and a pacemaker generator is implanted in the chest wall. For at least 2 weeks following surgery, the pacemaker remains turned off to facilitate the development of adhesions between the muscle wrap and the ventricles. Eventually, the pacemaker is turned on and used to stimulate latissimus dorsi muscle contraction. Several weeks of training, or conditioning, are necessary before this skeletal muscle functions effectively. The ultimate goal is for the latissimus dorsi muscle wrap to augment ventricular contraction and increase cardiac output. This skeletal mus-

cle loses its contractility over time, and the patient may be evaluated for heart transplantation.

Heart Transplantation

Because of advances in surgical techniques and immunosuppressive therapies, heart transplantation is now a therapeutic option for patients with end-stage heart disease. Cyclosporine (Gengraf, Neoral, Sandimmune) is an immunosuppressant that greatly decreases the body's rejection of foreign proteins, such as transplanted organs. Unfortunately, cyclosporine also decreases the body's ability to resist infections, and a satisfactory balance must be achieved between suppressing rejection and avoiding infection.

Cardiomyopathy, ischemic heart disease, valvular disease, rejection of previously transplanted hearts, and congenital heart disease are the most common indications for transplantation (Fuster, et al., 2008; Libby, et al., 2008; Moser & Riegel, 2008). Typical candidates have severe symptoms uncontrolled by medical therapy, no other surgical options, and a prognosis of less than 2 years to live. A multidisciplinary team screens the candidate before recommending the transplantation procedure (Chart 29-1). The person's age, pulmonary status, other chronic health conditions, psychosocial status, family support, infections, history of other transplantations, compliance, and current health status are considered.

CHART 29-1

NURSING RESEARCH PROFILE

Patient and Family Needs While Awaiting Heart Transplantation

Haugh, K. H. & Salyer, J. (2007). Needs of patients and families during the wait for a donor heart. *Heart & Lung, 36*(5), 319–329.

Purpose

The purpose of this study of patients accepted for heart transplantation and their families was to identify interventions used during the wait for a donor heart, the perceived effectiveness of the interventions, and interventions not being used that may be helpful.

Design

This qualitative study used the focus group technique. The sample consisted of eight patients (four pretransplant, four posttransplant) and three family members from two heart transplant programs; the patients in the study spent an average of more than 300 days on the waiting list for a heart transplant. Researchers conducted a 2-hour videotaped focus group interview at each of two academic health care centers. The focus group moderator asked a series of eight open-ended questions to which the participants responded. The moderator encouraged participants to express themselves, reassured them that their contributions were important, and encouraged specific details in the responses. One researcher took notes during the focus group and summarized the discussion and sought verification from the participants at the end of each interview. After reviewing the videotape for both verbal content and nonverbal behaviors, the researchers identified themes, patterns, and similarities among the data from both the notes and videotape. They then mailed a writ-

ten summary to each participant so that each person had an opportunity to provide additional feedback.

Findings

The central theme identified by the participants regarding their perceptions about the time spent waiting for transplant was that of tolerating uncertainty. Interventions reported as helpful were sharing of information, being sensitive to the needs of the family during hospitalization, maintaining respect and dignity, doing the “extra little things,” and helping facilitate coping.

Nursing Implications

Patients and their families find nursing interventions helpful in tolerating the uncertainty of waiting for a donor heart. Nurses need to share information with patients and their families, but they must be sensitive to psychological needs and individualize the pace, amount, and depth of the information to each patient's preferences. Patients and families appreciate warm, receptive, friendly nurses. Nurses need to provide patients with as much control over their lives as possible and always treat patients with respect and dignity. Nurses must identify issues important to the patient's quality of life and try to address them whenever possible; for example, coordinating a visit between a hospitalized patient and his or her pet(s) may prove beneficial. Providing patients with control over their routine and tasks are important so that patients can “feel normal.” Facilitating coping is another important nursing intervention. Patients appreciate spirituality, humor, peer support, and honesty to help them cope.

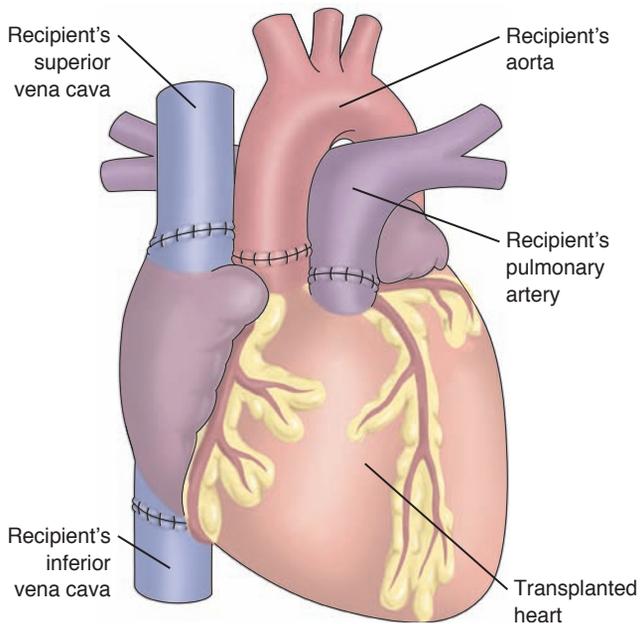

Figure 29-9 Orthotopic method of heart transplantation.

When a donor heart becomes available, a computer generates a list of potential recipients on the basis of ABO blood group compatibility, the body sizes of the donor and the potential recipient, age, severity of illness, length of time on the waiting list, and the geographic locations of the donor and potential recipient. Distance is a factor because postoperative function depends on the heart being implanted within 4 hours of harvest from the donor. Some patients are candidates for more than one organ transplant (eg, heart–lung, heart–kidney, heart–liver).

Orthotopic transplantation is the most common surgical procedure for cardiac transplantation (Fig. 29-9). The recipient's heart is removed, and the donor heart is implanted at the vena cava and pulmonary veins. Some surgeons prefer to remove the recipient's heart, leaving a portion of the recipient's atria (with the vena cava and pulmonary veins) in place. The donor heart, which usually has been preserved in ice, is prepared for implant by cutting away a small section of the atria that corresponds with the sections of the recipient's heart that were left in place. The donor heart is implanted by suturing the donor atria to the residual atrial tissue of the recipient's heart. After the venous or atrial anastomoses are complete, the recipient's pulmonary artery and aorta are sutured to those of the donor heart.

Patients who have had heart transplants are constantly balancing the risk of rejection with the risk of infection. They must adhere to a complex regimen of diet, medications, activity, follow-up laboratory studies, biopsies of the transplanted heart (to diagnose rejection), and clinic visits. Most commonly, patients receive tacrolimus (Prograf) or cyclosporine, mycophenolate mofetil (CellCept) or azathioprine (Imuran), and corticosteroids (eg, prednisone) to minimize rejection.

The transplanted heart has no nerve connections (ie, denervated heart) to the recipient's body, so the sympathetic and vagus nerves do not affect the transplanted heart. The resting rate of the transplanted heart is approximately

70 to 90 bpm (beats per minute), but it increases gradually if catecholamines are in the circulation. Patients must gradually increase and decrease their exercise (ie, extended warm-up and cool-down periods), because 20 to 30 minutes may be required to achieve the desired heart rate. Atropine does not increase the heart rate of transplanted hearts.

In addition to rejection and infection, complications may include accelerated atherosclerosis of the coronary arteries (ie, cardiac allograft vasculopathy, accelerated graft atherosclerosis, transplant coronary artery disease). Both immunologic and nonimmunologic factors cause arterial injury and inflammation of the coronary arteries. The arterial smooth muscle proliferates and there is hyperplasia of the coronary artery intima, accelerating atherosclerosis along the entire length of the coronary arteries (Libby, et al., 2008; Woods, et al., 2005). Hypertension may occur in patients taking cyclosporine or tacrolimus; the cause has not been identified. Osteoporosis is a frequent side effect of the anti-rejection medications as well as pretransplantation dietary insufficiency and medications. Patients with a long-term sedentary lifestyle are at greater risk for osteoporosis. Post-transplantation lymphoproliferative disease and cancer of the skin and lips are the most common malignancies after transplantation, possibly caused by immunosuppression. Weight gain; obesity; diabetes; dyslipidemias (eg, hypercholesterolemia); hypotension; renal failure; and central nervous system, respiratory, and gastrointestinal disturbances may be adverse effects of the corticosteroids or other immunosuppressants. Toxicity from immunosuppressant medications may occur. The 1-year survival rate for patients with transplanted hearts is approximately 81% to 95%, and the 10-year survival rate is approximately 50% to 70% (Fuster, et al., 2008; Libby, et al., 2008; Moser & Reigel, 2008).

In the first year after transplant, patients respond to the psychosocial stresses imposed by organ transplantation in various ways. Most report a better quality of life after transplantation. Some experience guilt that someone had to die for them to be able to live, have anxiety about the new heart, experience depression or fear about rejection, or have difficulty with family role changes before and after transplantation (Fuster, et al., 2008; Kaba, Thompson, Burnard, et al., 2005; Moser & Reigel, 2008). After the first year, many patients believe that their lives have purpose, they are connected to a force greater than themselves, and look forward to the future (Flattery, Salyer, Maltby, et al., 2006).

Mechanical Assist Devices and Total Artificial Hearts

The use of cardiopulmonary bypass in cardiovascular surgery and the possibility of performing heart transplantation in patients with end-stage cardiac disease, as well as the desire for a treatment option for patients with such disease who are not transplant candidates, have increased the need for mechanical assist devices. Patients who cannot be weaned from cardiopulmonary bypass and patients in cardiogenic shock may benefit from a period of mechanical heart assistance. The most commonly used device is the intra-aortic balloon pump (see Chapter 30). This pump decreases the work of the heart during contraction but does not perform the actual work of the heart.

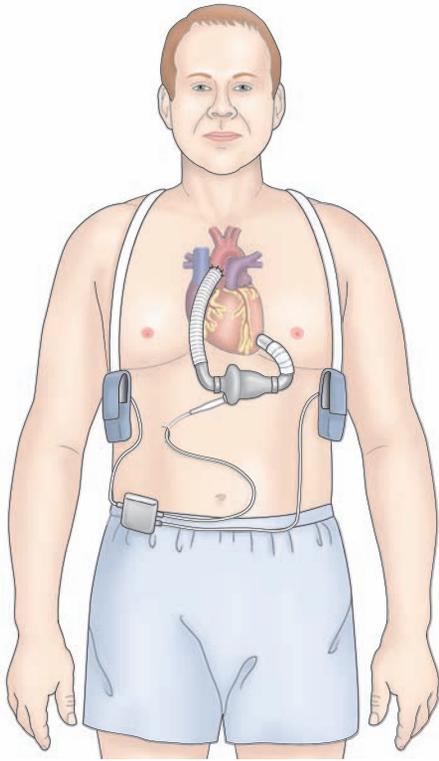

Figure 29-10 Left ventricular assist device.

Ventricular Assist Devices

More complex devices that actually perform some or all of the pumping function for the heart also are being used. These more sophisticated **ventricular assist devices** (VADs) can circulate as much blood per minute as the heart, if not more (Fig. 29-10). Each VAD is used to support one ventricle. Some VADs can be combined with an oxygenator; the combination is called extracorporeal membrane oxygenation (ECMO). The oxygenator–VAD combination is used for the patient whose heart cannot pump adequate blood through the lungs or the body.

VADs may be used as (1) a “bridge to recovery” for patients who require temporary assistance for reversible ventricular failure, (2) a “bridge to transplant” for patients with end-stage heart failure until a donor organ becomes available for transplant (most common), and (3) “destination therapy” for patients with end-stage heart failure who are not candidates for or decline heart transplantation. When VADs are used as destination therapy, patients are discharged from the hospital with the devices in place (Fuster, et al., 2008; Libby, et al., 2008; Moser & Reigel, 2008).

VADs may be external, internal (ie, implanted) with an external power source, or completely internal, and they may generate a pulsatile or continuous blood flow. There are three types of VADs: pneumatic, electric or electromagnetic, and axial flow. Pneumatic VADs are external or implanted pulsatile devices with a flexible reservoir housed in a rigid exterior. The reservoir usually fills with blood drained from the atrium or ventricle. The device then forces pressurized air into the rigid housing, compressing the reservoir and

returning the blood to the circulation, usually into the aorta. Electric or electromagnetic VADs are similar to the pneumatic VADs, but instead of using pressurized air to return the blood to the circulation, one or more flat metal plates are pushed against the reservoir. Axial flow VADs use a rotary mechanism (an impeller) to create a nonpulsatile blood flow. The impeller spins rapidly within the VAD, creating a vacuum that pulls blood into the VAD and then pushes the blood out into the systemic circulation—the process is similar to a fan spinning in a tunnel, pulling air in one end of the tunnel and pushing it out the other.

Total Artificial Hearts

Total artificial hearts are designed to replace both ventricles. Some require the removal of the patient’s heart to implant the total artificial heart and others do not. One total artificial heart has been approved for use in the United States. Although there has been some short-term success, the long-term results have been disappointing. Researchers hope to develop a device that can be permanently implanted and that will eliminate the need for donated human heart transplantation for end-stage cardiac disease (Libby, et al., 2008; Moser & Reigel, 2008).

Complications of VADs and total artificial hearts include bleeding disorders, hemorrhage, thrombus, emboli, hemolysis, infection, renal failure, right-sided heart failure, multisystem failure, and mechanical failure (Libby, et al., 2008; Moser & Reigel, 2008). Nursing care of patients with these mechanical assist devices focuses on assessment for and minimization of these complications as well as providing emotional support and education about the device as well as the underlying cardiac disease.

NURSING PROCESS

THE PATIENT WITH CARDIOMYOPATHY

Assessment

Nursing assessment for the patient with cardiomyopathy begins with a detailed history of the presenting signs and symptoms. The nurse identifies possible etiologic factors, such as heavy alcohol intake, recent illness or pregnancy, or history of the disease in immediate family members. If the patient reports chest pain, a thorough review of the pain, including its precipitating factors, is warranted. The review of systems includes the presence of orthopnea, PND, and syncope or dyspnea with exertion. The number of pillows needed to sleep, usual weight, any weight change, and limitations on activities of daily living are assessed. The New York Heart Association Classification for heart failure is determined (see Table 30-1). The patient’s usual diet is evaluated to determine the need to reduce sodium intake, optimize nutrition, or supplement with vitamins.

Because of the chronicity of cardiomyopathy, the nurse conducts a careful psychosocial history, exploring the impact of the disease on the patient’s role within the family and community. Identification of perceived stressors helps the patient and the health care team to implement activities to relieve anxiety related to changes in health status.

Very early on, the patient's support systems are identified, and members are encouraged to become involved in the patient's care and therapeutic regimen. The assessment addresses the effect the diagnosis has had on the patient and members of his or her support system and the patient's emotional status. Depression is common in a patient with cardiomyopathy who has developed heart failure.

The physical assessment focuses on signs and symptoms of heart failure. The baseline assessment includes such key components as:

- Vital signs
- Calculation of pulse pressure and identification of pulse paradoxus
- Current weight and any weight gain or loss
- Detection by palpation of the point of maximal impulse, often shifted to the left
- Cardiac auscultation for a systolic murmur and S₃ and S₄ heart sounds
- Pulmonary auscultation for crackles
- Measurement of jugular vein distention
- Assessment of edema and its severity

Diagnosis

Nursing Diagnoses

Based on the assessment data, major nursing diagnoses may include:

- Decreased cardiac output related to structural disorders caused by cardiomyopathy or to dysrhythmia from the disease process and medical treatments
- Ineffective cardiopulmonary, cerebral, peripheral, and renal tissue perfusion related to decreased peripheral blood flow (resulting from decreased cardiac output)
- Impaired gas exchange related to pulmonary congestion caused by myocardial failure (resulting from decreased cardiac output)
- Activity intolerance related to decreased cardiac output or excessive fluid volume, or both
- Anxiety related to the change in health status and in role functioning
- Powerlessness related to disease process
- Noncompliance with medication and diet therapies

Collaborative Problems/Potential Complications

Based on the assessment data, potential complications include:

- Heart failure
- Ventricular dysrhythmias
- Atrial dysrhythmias
- Cardiac conduction defects
- Pulmonary or cerebral embolism
- Valvular dysfunction

These complications are discussed earlier in this chapter and in Chapters 27 and 30.

Planning and Goals

The major goals for patients include improvement or maintenance of cardiac output, increased activity tolerance, reduction of anxiety, adherence to the self-care program, increased sense of power with decision making, and absence of complications.

Nursing Interventions

Improving Cardiac Output

During a symptomatic episode, rest is indicated. Many patients with DCM find that sitting up with their legs down is more comfortable than lying down in a bed. This position is helpful in pooling venous blood in the periphery and reducing preload. Assessing the patient's oxygen saturation at rest and during activity may assist with determining a need for supplemental oxygen. Oxygen is usually administered through a nasal cannula when indicated.

Ensuring that medications are taken as prescribed is important to preserving adequate cardiac output. The nurse may assist the patient with planning a schedule for taking medications and identifying methods to remember to follow it, such as associating the time to take a medication with an activity (eg, eating a meal, brushing teeth). It is important to ensure that patients with DCM avoid verapamil (Calan, Isoptin), patients with HCM avoid diuretics, and patients with RCM avoid nifedipine to maintain contractility. In patients with HCM, the inotropic action of digoxin may create or worsen left ventricular outflow tract obstruction. Patients with RCM have increased sensitivity to digoxin, and the nurse must anticipate that low doses will be prescribed and assess for digoxin toxicity.

It is also important to ensure that the patient receives or chooses food selections that are appropriate for a low-sodium diet. One way to monitor a patient's response to treatment is to determine the patient's weight every day and identify any significant change. Another indication of the effect of treatment involves assessment of shortness of breath after activity and comparison to before treatment. Patients with low cardiac output may need assistance keeping warm and frequently changing position to stimulate circulation and reduce the possibility of skin breakdown. Patients with HCM must be taught to avoid dehydration. One guideline for patients to use for self-assessment is to anticipate the urge to void at least every 4 hours while awake; if the urge to void is not present or the urine is a deep yellow color, more fluid intake is necessary.

Increasing Activity Tolerance

The nurse plans the patient's activities so that they occur in cycles, alternating rest with activity periods. This benefits the patient's physiologic status, and it helps teach the patient about the need for planned cycles of rest and activity. For example, after taking a bath or shower, the patient should plan to sit and read a newspaper or engage in other relaxing activities. Suggesting that the patient sit while chopping vegetables, drying his or her hair, or shaving helps the patient learn to balance rest with activity. The nurse also makes sure that the patient recognizes the symptoms indicating the need for rest and actions to take when the symptoms occur. Patients with HCM or RCM must avoid strenuous activity, isometric exercises, and competitive sports.

Reducing Anxiety

Spiritual, psychological, and emotional support may be indicated for patients, families, and significant others. Interventions are directed toward eradicating or alleviating

perceived stressors. Patients receive appropriate information about cardiomyopathy and self-management activities. It is important to provide an atmosphere in which patients feel free to verbalize concerns and receive assurance that their concerns are legitimate. If the patient is awaiting transplantation or facing death, it is necessary to allow time to discuss these issues. Providing the patient with realistic hope helps reduce anxiety while he or she awaits a donor heart. The nurse helps the patient, family, and significant others with anticipatory grieving.

Decreasing the Sense of Powerlessness

Patients often go through a grieving process when cardiomyopathy is diagnosed. The patient is assisted in identifying the things in life that he or she has lost (eg, foods that the patient enjoyed eating but are high in sodium, the ability to engage in an active lifestyle, the ability to play sports, the ability to lift grandchildren) and his or her emotional responses to the loss (eg, anger, depression). The nurse assists the patient in identifying the amount of control that he or she still has over life, such as making food choices, managing medications, and working with health care providers to achieve the best possible outcomes. A diary in which the patient records food selections and weight may help with understanding the relationship between sodium intake and weight gain. Some patients can manage a self-titrating diuretic regimen in which they adjust the dose of diuretic to their symptoms.

Promoting Home and Community-Based Care

TEACHING PATIENTS SELF-CARE. A key part of the plan of nursing care involves teaching patients about the medication regimen, symptom monitoring, and symptom management. The nurse plays an integral role as the patient learns to balance lifestyle and work while accomplishing therapeutic activities. Helping patients cope with their disease status helps them adjust their lifestyles and implement a self-care program at home. Attainment of a goal, no matter how small, also promotes the patient's sense of well-being.

CONTINUING CARE. The nurse reinforces previous teaching and performs ongoing assessment of the patient's symptoms and progress. The nurse also assists the patient and family to adjust to lifestyle changes. Patients are taught to read nutrition labels, to maintain a record of daily weights and symptoms, and to organize daily activities to increase activity tolerance. In addition, the nurse assesses the patient's response to recommendations about diet and fluid intake and to the medication regimen and stresses the signs and symptoms that should be reported to the physician. Because of the risk of dysrhythmia, it may be necessary to teach the patient's family cardiopulmonary resuscitation. Women are often advised to avoid pregnancy, but each case is assessed individually. The nurse assesses the psychosocial needs of the patient and family on an ongoing basis. There may be concerns and fears about the prognosis, changes in lifestyle, effects of medications, and the possibility of others in the family having the same condition; these often increase the patient's anxiety and interfere with effective coping strategies. Establishing trust is vital to the nurse's relationship with these chronically ill patients and their families.

This is particularly significant when the nurse is involved with a patient and family in discussions about end-of-life decisions. Patients who have significant symptoms of heart failure or other complications of cardiomyopathy may benefit from a home care referral.

Evaluation

Expected Patient Outcomes

1. Maintains or improves cardiac function
 - a. Exhibits heart and respiratory rates within normal limits
 - b. Reports decreased dyspnea and increased comfort; maintains or improves gas exchange
 - c. Reports no weight gain; appropriate weight for height
 - d. Maintains or improves peripheral blood flow
2. Maintains or increases activity tolerance
 - a. Carries out activities of daily living (eg, brushes teeth, feeds self)
 - b. Reports increased tolerance to activity
3. Is less anxious
 - a. Discusses prognosis freely
 - b. Verbalizes fears and concerns
 - c. Participates in support groups if appropriate
4. Decreases sense of powerlessness
 - a. Identifies emotional response to diagnosis
 - b. Discusses control that he or she has
5. Adheres to self-care program
 - a. Takes medications according to prescribed schedule
 - b. Modifies diet to accommodate sodium and fluid recommendations
 - c. Modifies lifestyle to accommodate activity and rest behavior recommendations
 - d. Identifies signs and symptoms to be reported to health care professionals

INFECTIOUS DISEASES OF THE HEART

Any of the heart's three layers may be affected by an infectious process. The infections are named for the layer of the heart most involved in the infectious process: infective endocarditis (endocardium), myocarditis (myocardium), and pericarditis (pericardium). Rheumatic endocarditis is a unique infective endocarditis syndrome. The diagnosis of infection is made primarily on the basis of the patient's symptoms and echocardiography. The ideal management for all infectious diseases is prevention. IV antibiotics are usually necessary once an infection has developed in the heart.

Rheumatic Endocarditis

Acute rheumatic fever, which occurs most often in school-age children, may develop after an episode of group A beta-hemolytic streptococcal pharyngitis (Chart 29-2). Patients with rheumatic fever may develop rheumatic heart disease

Chart 29-2 • Rheumatic Fever

Rheumatic fever is a preventable disease. Diagnosing and treating streptococcal pharyngitis can prevent rheumatic fever and, therefore, rheumatic heart disease. Signs and symptoms of streptococcal pharyngitis include:

- Fever (38.9°C to 40°C [101°F to 104°F])
- Chills
- Sore throat (sudden in onset)
- Diffuse redness of throat with exudate on oropharynx (may not appear until after the first day)
- Enlarged and tender lymph nodes
- Abdominal pain (more common in children)
- Acute sinusitis and acute otitis media (may cause or result from streptococcal pharyngitis)

If signs and symptoms of streptococcal pharyngitis are present, a throat culture is necessary to make an accurate diagnosis. All patients with throat cultures positive for streptococcal pharyngitis must adhere to the prescribed antibiotic treatment. Penicillin is the most common antibiotic prescribed. Completing the course of prescribed antibiotics minimizes the risk of developing rheumatic fever (and subsequent rheumatic heart disease).

as evidenced by a new heart murmur, cardiomegaly, pericarditis, and heart failure. Prompt treatment of “strep” throat with antibiotics can prevent the development of rheumatic fever. The streptococcus is spread by direct contact with oral or respiratory secretions. Although the bacteria are the causative agents, malnutrition, overcrowding, poor hygiene, and lower socioeconomic status may predispose individuals to rheumatic fever (Lutwick & Ravishankar, 2006; Moser & Reigel, 2008). The incidence of rheumatic fever in the United States and other developed countries generally has decreased, but the exact incidence is difficult to determine because the infection may go unrecognized, and people may not seek treatment (Lutwick & Ravishankar, 2006; Libby, et al., 2008). Clinical diagnostic criteria are not standardized, and autopsies are not routinely performed. Further information about rheumatic fever and rheumatic endocarditis can be found in pediatric nursing books.

Infective Endocarditis

Infective endocarditis is a microbial infection of the endothelial surface of the heart. It usually develops in people with prosthetic heart valves or structural cardiac defects (eg, valve disorders, HCM) (Chart 29-3). It is more common in older people, who are more likely to have degenerative or calcific valve lesions, reduced immunologic response to infection, and the metabolic alterations associated with aging. Staphylococcal endocarditis infections of the valves in the right side of the heart are common among IV injection drug users (Libby, et al., 2008; Moser & Reigel, 2008). Hospital-acquired infective endocarditis occurs most often in patients with debilitating disease or indwelling catheters and in patients who are receiving hemodialysis or prolonged IV fluid or antibiotic therapy. Patients taking

**CHART
29-3****Risk Factors for Infective Endocarditis**

- Prosthetic cardiac valves or prosthetic material used for cardiac valve repair
- History of bacterial endocarditis (even without heart disease)
- Congenital heart disease
- Unrepaired cyanotic congenital heart disease, including patients with palliative shunts and conduits
- Repaired congenital heart disease with prosthetic material or device either by surgery or catheter intervention during the first 6 months after the procedure
- Repaired congenital heart disease with residual defects at the site or adjacent to the site of a prosthetic patch or device
- Cardiac transplant recipients with valvulopathy

Adapted from Wilson, W., Taubert, K. A., Gewitz, M., et al. (2007). The American Heart Association guideline: Prevention of infective endocarditis. *Circulation*, 116(15), 1736–1754.

immunosuppressive medications or corticosteroids are more susceptible to fungal endocarditis.

Invasive procedures, particularly those involving mucosal surfaces, can cause a bacteremia, which rarely lasts for more than 15 minutes. However, if a patient has any anatomic cardiac defects, bacteremia can cause bacterial endocarditis. From 1950 to the mid-1980s, the incidence of infective endocarditis remained steady at about 3.6 cases per 100,000 patients. The incidence then increased, partially attributed to increased IV injection drug abuse and body piercing, especially oral, nasal, and nipple piercings (Libby, et al., 2008; Moser & Reigel, 2008).

Pathophysiology

A deformity or injury of the endocardium leads to accumulation on the endocardium of fibrin and platelets (clot formation). Infectious organisms, usually staphylococci, streptococci, enterococci, pneumococci, or chlamydia, invade the clot and endocardial lesion. Other causative micro-organisms include fungi (eg, *Candida*, *Aspergillus*) and Rickettsiae. The infection most frequently results in platelets, fibrin, blood cells, and microorganisms that cluster as vegetations on the endocardium. The vegetations may embolize to other tissues throughout the body. As the clot on the endocardium continues to expand, the infecting organism is covered by the new clot and concealed from the body's normal defenses. The infection may erode through the endocardium into the underlying structures (eg, valve leaflets), causing tears or other deformities of valve leaflets, dehiscence of prosthetic valves, deformity of the chordae tendineae, or mural abscesses.

Usually the onset of infective endocarditis is insidious. The signs and symptoms develop from the toxic effect of the infection, from destruction of the heart valves, and from embolization of fragments of vegetative growths on the heart. Systemic emboli occur with left-sided heart infective endocarditis; pulmonary emboli occur with right-sided heart infective endocarditis (Libby, et al., 2008; Moser & Reigel, 2008).

Clinical Manifestations

The primary presenting symptoms of infective endocarditis are fever and a heart murmur. The fever may be intermittent or absent, especially in patients who are receiving antibiotics or corticosteroids, in those who are elderly, or those who have heart failure or renal failure. A heart murmur may be absent initially but develops in almost all patients. Murmurs that worsen over time indicate progressive damage from vegetations or perforation of the valve or the chordae tendineae.

In addition to the fever and heart murmur, clusters of petechiae may be found on the body. Small, painful nodules (Osler nodes) may be present in the pads of fingers or toes. Irregular, red or purple, painless, flat macules (Janeway lesions) may be present on the palms, fingers, hands, soles, and toes. Hemorrhages with pale centers (Roth spots) caused by emboli may be observed in the fundi of the eyes. Splinter hemorrhages (ie, reddish-brown lines and streaks) may be seen under the fingernails and toenails, and petechiae may appear in the conjunctiva and mucous membranes. Cardiomegaly, heart failure, tachycardia, or splenomegaly may occur.

Central nervous system manifestations of infective endocarditis include headache; temporary or transient cerebral ischemia; and strokes, which may be caused by emboli to the cerebral arteries. Embolization may be a presenting symptom, and it may occur at any time and may involve other organ systems. Embolic phenomena may occur, as discussed in the previous section on rheumatic endocarditis.

Heart failure, which may result from perforation of a valve leaflet, rupture of chordae, blood flow obstruction due to vegetations, or intracardiac shunts from dehiscence of prosthetic valves, indicates a poor prognosis with medical therapy alone and a higher surgical risk (Libby, et al., 2008). Valvular stenosis or regurgitation, myocardial damage, and mycotic (fungal) aneurysms are potential cardiac complications. First-degree, second-degree, and third-degree atrioventricular blocks may occur and are often a sign of a valve ring abscess. Emboli, immunologic responses, abscess of the spleen, mycotic aneurysms, cerebritis, and hemodynamic deterioration may cause complications in other organs.

Assessment and Diagnostic Findings

Although the previously described characteristics may indicate infective endocarditis, the signs and symptoms may indicate other diseases as well. Vague complaints of malaise, anorexia, weight loss, cough, and back and joint pain may be mistaken for influenza. The virulence of the causative organism usually correlates with the speed and degree of symptom development. A definitive diagnosis is made when a micro-organism is found in two separate blood cultures, in a vegetation, or in an abscess. Three sets of blood cultures (with each set including one aerobic and one anaerobic culture) drawn over a 24-hour period (or every 30 minutes if the patient's condition is unstable) should be obtained before administration of any antimicrobial agents. Negative blood cultures do not definitely rule out infective endocarditis. Patients may have elevated white blood cell (WBC) counts. In addition, patients may be anemic and have a positive rheumatoid factor and an elevated erythro-

cyte sedimentation rate (ESR) or C-reactive protein. Microscopic hematuria may be present on urinalysis.

Doppler echocardiography may assist in the diagnosis by demonstrating a mass on the valve, prosthetic valve, or supporting structures and by identifying vegetations, abscesses, new prosthetic valve dehiscence, or new regurgitation (Fuster, et al., 2008; Libby, et al., 2008; Moser & Reigel, 2008). The echocardiogram may reveal the development of heart failure. TEE may provide better data than transthoracic imaging.

Prevention

Although rare, bacterial endocarditis may be life-threatening. A key strategy is primary prevention in high-risk patients (eg, those with previous infective endocarditis, prosthetic heart valves). Antibiotic prophylaxis is recommended for high-risk patients immediately before and sometimes after the following procedures (Nishimura, Carabello, Faxon, et al., 2008; Wilson, et al., 2007):

- Dental procedures that involve manipulation of gingival tissue or the periapical area of the teeth or perforation of the oral mucosa (except routine anesthetic injections through noninfected tissue, placement of orthodontic brackets, loss of deciduous teeth, bleeding from trauma to the lips or oral mucosa, dental x-rays, adjustment of orthodontic appliances, and placement of removable prosthodontic or orthodontic appliances)
- Tonsillectomy or adenoidectomy
- Surgical procedures that involve respiratory mucosa
- Bronchoscopy with biopsy or incision of respiratory tract mucosa
- Cystoscopy or urinary tract manipulation for patients with enterococcal urinary tract infections or colonization
- Surgery involving infected skin or musculoskeletal tissue

The type of antibiotic used for prophylaxis varies with the type of procedure and the degree of risk. Patients are usually instructed to take 2 g of amoxicillin (Amoxil) orally 1 hour before the procedure. If patients are allergic to penicillin, clindamycin (Cleocin), cephalexin (Keflex), cefazolin (Ancef, Kefzol), ceftriaxone (Rocephin), azithromycin (Zithromax), or clarithromycin (Biaxin) may be used.

Equally important is ongoing good oral hygiene. Poor dental hygiene can lead to bacteremia, particularly in the setting of a dental procedure. The severity of oral inflammation and infection is a significant factor in the incidence and degree of bacteremia. Regular professional oral care combined with personal oral care may reduce the risk of bacteremia. Personal oral care includes using a soft toothbrush and toothpaste to brush the teeth, gums, tongue, and oral mucosa at least twice a day, as well as rinsing the mouth with an antiseptic mouthwash for 30 seconds intermittently between tooth brushing. Patients must be advised to avoid nail biting and to minimize outbreaks of acne and psoriasis. Female patients are advised not to use intrauterine devices (IUDs) and to avoid body piercing and branding.

Increased vigilance is also required in patients with IV catheters and during invasive procedures. To minimize the risk of infection, nurses must ensure meticulous hand hygiene, site preparation, and aseptic technique during insertion and maintenance procedures. All catheters, tubes,

drains, and other devices are removed as soon as they are no longer needed or no longer function.

Medical Management

The objective of treatment is to eradicate the invading organism through adequate doses of an appropriate antimicrobial agent. Antibiotic therapy is usually administered parenterally in a continuous IV infusion for 2 to 6 weeks. Parenteral therapy is administered in doses that produce a high serum concentration for a significant period to ensure eradication of the dormant bacteria within the dense vegetations. This therapy is often delivered in the patient's home and is monitored by a home care nurse. Serum levels of the antibiotic are monitored. If there is insufficient bactericidal activity, increased dosages of the antibiotic are prescribed or a different antibiotic is used. Numerous antimicrobial regimens are in use, but penicillin is usually the medication of choice. Blood cultures are taken periodically to monitor the effect of therapy. In fungal endocarditis, an antifungal agent, such as amphotericin B (eg, Abelcet, Amphotec, Fungizone), is the usual treatment.

In addition, the patient's temperature is monitored at regular intervals because the course of the fever is one indication of the effectiveness of treatment. However, febrile reactions also may occur as a result of medication. After adequate antimicrobial therapy is initiated, the infective organism is usually eliminated. The patient should begin to feel better, regain an appetite, and have less fatigue. During this time, patients require psychosocial support because although they feel well, they may find themselves confined to the hospital or home with restrictive IV therapy.

Surgical Management

Surgical intervention may be required if the infection does not respond to medications, the patient has a prosthetic heart valve endocarditis, has a vegetation larger than 1 cm, or develops complications such as a septal perforation. Surgical interventions include valve débridement or excision, débridement of vegetations, débridement and closure of an abscess, and closure of a fistula. Aortic or mitral valve débridement, excision, or replacement is required in patients who:

- Develop congestive heart failure despite adequate medical treatment
- Have more than one serious systemic embolic episode
- Develop a valve obstruction
- Develop a periannular (heart valve), myocardial, or aortic abscess
- Have uncontrolled infection, persistent or recurrent infection, or fungal endocarditis

Surgical valve replacement greatly improves the prognosis for patients with severe symptoms from damaged heart valves. The aortic valve may be best treated with an autograft, as previously described. Most patients who have prosthetic valve endocarditis (ie, infected valve replacements) require valve replacement.

Nursing Management

The nurse monitors the patient's temperature. The patient may have a fever for weeks. Heart sounds are assessed. A new or worsening murmur may indicate dehiscence of a

prosthetic valve, rupture of an abscess, or injury to valve leaflets or chordae tendineae. The nurse monitors for signs and symptoms of systemic embolization, or, for patients with right-sided heart endocarditis, for signs and symptoms of pulmonary infarction and infiltrates. In addition, the nurse assesses signs and symptoms of organ damage such as stroke (ie, cerebrovascular accident or brain attack), meningitis, heart failure, myocardial infarction, glomerulonephritis, and splenomegaly.

Patient care is directed toward management of infection. Long-term IV antimicrobial therapy is often necessary; therefore, many patients have peripherally inserted central catheters or other long-term IV access. All invasive lines and wounds must be assessed daily for redness, tenderness, warmth, swelling, drainage, or other signs of infection. The patient and family are instructed about activity restrictions, medications, and signs and symptoms of infection. Patients with infective endocarditis are at high risk for another episode of infectious endocarditis. The nurse emphasizes the antibiotic prophylaxis previously described. If the patient has undergone surgical treatment, the nurse provides postoperative care and instructions.

As appropriate, the home care nurse supervises and monitors IV antibiotic therapy delivered in the home setting and educates the patient and family about prevention and health promotion. The nurse provides the patient and family with emotional support and facilitates coping strategies during the prolonged course of the infection and antibiotic treatment.

Myocarditis

Myocarditis, an inflammatory process involving the myocardium, can cause heart dilation, thrombi on the heart wall (mural thrombi), infiltration of circulating blood cells around the coronary vessels and between the muscle fibers, and degeneration of the muscle fibers themselves. Mortality varies with the severity of symptoms. Most patients with mild symptoms recover completely, but some patients develop cardiomyopathy and heart failure.

Pathophysiology

Myocarditis usually results from viral (eg, coxsackievirus A and B, human immunodeficiency virus [HIV], influenza A), bacterial, rickettsial, fungal, parasitic, metazoal, protozoal (eg, Chagas disease), or spirochetal infection. It also may be immune related, occurring after acute systemic infections such as rheumatic fever. It may develop in patients receiving immunosuppressive therapy or those with infective endocarditis, Crohn disease, or systemic lupus erythematosus.

Myocarditis may result from an inflammatory reaction to toxins such as pharmacologic agents used in the treatment of other diseases (eg, anthracyclines for cancer therapy), ethanol, or radiation (especially to the left chest or upper back). It may begin in one small area of the myocardium and then spread throughout the myocardium. The degree of myocardial inflammation and necrosis determines the degree of interstitial collagen and elastin destruction. The greater the destruction, the greater the hemodynamic effect and resulting signs and symptoms. It is theorized that DCM

and HCM are latent manifestations of myocarditis (Ellis & Di Salvo, 2007; Libby, et al., 2008).

Clinical Manifestations

The symptoms of acute myocarditis depend on the type of infection, the degree of myocardial damage, and the capacity of the myocardium to recover. Patients may be asymptomatic, with an infection that resolves on its own. However, they may develop mild to moderate symptoms and seek medical attention, often reporting fatigue and dyspnea, palpitations, and occasional discomfort in the chest and upper abdomen. The most common symptoms are flulike. Patients may also sustain sudden cardiac death or quickly develop severe congestive heart failure.

Assessment and Diagnostic Findings

Assessment of the patient may reveal no detectable abnormalities; as a result, the entire illness can go undiagnosed. Patients may be tachycardic or may report chest pain (with a subsequent cardiac catheterization demonstrating normal coronary arteries). Cardiac MRI with contrast may be diagnostic and can guide clinicians to sites for endocardial biopsies, which may be diagnostic for an organism or its genome, immune process, or a radiation reaction causing the myocarditis. Patients without any abnormal heart structure (at least initially) may suddenly develop dysrhythmias or ST–T-wave changes. If the patient has structural heart abnormalities (eg, systolic dysfunction), a clinical assessment may disclose cardiac enlargement, faint heart sounds (especially S_1), a gallop rhythm, or a systolic murmur. The WBC count and ESR may be elevated.

Prevention

Prevention of infectious diseases by means of appropriate immunizations (eg, influenza, hepatitis) and early treatment appears to be important in decreasing the incidence of myocarditis (Libby, et al., 2008).

Medical Management

Patients are given specific treatment for the underlying cause if it is known (eg, penicillin for hemolytic streptococci) and are placed on bed rest to decrease cardiac workload. Bed rest also helps decrease myocardial damage and the complications of myocarditis. In young patients with myocarditis, activities, especially athletics, should be limited for a 6-month period or at least until heart size and function have returned to normal. Physical activity is increased slowly, and the patient is instructed to report any symptoms that occur with increasing activity, such as a rapidly beating heart. If heart failure or dysrhythmia develops, management is essentially the same as for all causes of heart failure and dysrhythmias (see Chapters 27 and 30), except that beta-blockers are avoided because they decrease the strength of ventricular contraction (have a negative inotropic effect).

Nursing Management

The nurse assesses for resolution of tachycardia, fever, and any other clinical manifestations. The cardiovascular assessment focuses on signs and symptoms of heart failure and dysrhythmias. Patients with dysrhythmias should have continuous cardiac monitoring with personnel and equipment readily available to treat life-threatening dysrhythmias.

NURSING ALERT

Patients with myocarditis are sensitive to digitalis. Nurses must closely monitor these patients for digitalis toxicity, which is evidenced by dysrhythmia, anorexia, nausea, vomiting, headache, and malaise.

Anti-embolism stockings and passive and active exercises should be used because embolization from venous thrombosis and mural thrombi can occur, especially in patients on bed rest.

Pericarditis

Pericarditis refers to an inflammation of the pericardium, the membranous sac enveloping the heart. It may be a primary illness or it may develop during various medical and surgical disorders. For example, pericarditis may occur after pericardectomy (opening of the pericardium) following cardiac surgery. Pericarditis also may occur 10 days to 2 months after acute myocardial infarction (Dressler syndrome). Pericarditis may be subacute, acute, or chronic. It is classified either as adhesive (constrictive), because the layers of the pericardium become attached to each other and restrict ventricular filling, or by what accumulates in the pericardial sac: serous (serum), purulent (pus), calcific (calcium deposits), fibrinous (clotting proteins), or sanguinous (blood). Pericarditis also may be described as exudative or noneffusive.

Pathophysiology

Causes underlying or associated with pericarditis are listed in Chart 29-4. The inflammatory process of pericarditis may lead to an accumulation of fluid in the pericardial sac (pericardial

Chart 29-4 • Causes of Pericarditis

- Idiopathic or nonspecific causes
- Infection: usually viral (eg, human immunodeficiency virus, coxsackievirus, influenza); rarely bacterial (eg, streptococci, staphylococci, meningococci, gonococci, gram-negative rods); and mycotic (fungal)
- Disorders of connective tissue: systemic lupus erythematosus, rheumatic fever, rheumatoid arthritis, polyarteritis, scleroderma
- Hypersensitivity states: immune reactions, medication reactions, serum sickness
- Disorders of adjacent structures: myocardial infarction, dissecting aneurysm, pleural and pulmonary disease (pneumonia)
- Neoplastic disease: caused by metastasis from lung cancer or breast cancer, leukemia, and primary (mesothelioma) neoplasms
- Radiation therapy of chest and upper torso (peak occurrence 5–9 months after treatment)
- Trauma: chest injury, cardiac surgery, cardiac catheterization, implantation of pacemaker or implantable cardioverter defibrillator (ICD)
- Renal failure and uremia
- Tuberculosis

effusion) and increased pressure on the heart, leading to cardiac tamponade (see Chapter 30). Frequent or prolonged episodes of pericarditis may also lead to thickening and decreased elasticity of the pericardium, or scarring may fuse the visceral and parietal pericardium. These conditions restrict the heart's ability to fill with blood (constrictive pericarditis). The pericardium may become calcified, further restricting ventricular expansion during ventricular filling (diastole). With less filling, the ventricles pump less blood, leading to decreased cardiac output and signs and symptoms of heart failure. Restricted diastolic filling may result in increased systemic venous pressure, causing peripheral edema and hepatic failure.

Clinical Manifestations

Pericarditis may be asymptomatic. The most characteristic symptom of pericarditis is chest pain, although pain also may be located beneath the clavicle, in the neck, or in the left trapezius (scapula) region. The pain or discomfort usually remains fairly constant, but it may worsen with deep inspiration and when lying down or turning. It may be relieved with a forward-leaning or sitting position. The most characteristic sign of pericarditis is a creaky or scratchy friction rub heard most clearly at the left lower sternal border. Other signs may include a mild fever, increased WBC count, anemia, and an elevated ESR or C-reactive protein level. Patients may have a nonproductive cough or hiccough. Dyspnea and other signs and symptoms of heart failure may occur as the result of pericardial compression due to constrictive pericarditis or cardiac tamponade.

Assessment and Diagnostic Findings

The diagnosis is most often made on the basis of the history, signs, and symptoms. An echocardiogram may detect inflammation, pericardial effusion or tamponade, and heart failure. It may help confirm the diagnosis and may be used to guide pericardiocentesis (needle or catheter drainage of the pericardium). TEE may be useful in diagnosis but may underestimate the extent of pericardial effusions. Computed tomography (CT) may be the best diagnostic tool for determining the size, shape, and location of pericardial effusions and may be used to guide pericardiocentesis. MRI may assist with detection of inflammation and adhesions. Occasionally a video-assisted pericardioscope-guided biopsy of the pericardium or epicardium is performed to obtain tissue samples for culture and microscopic examination. Because the pericardial sac surrounds the heart, a 12-lead ECG may show concave ST elevations in many, if not all, leads (with no reciprocal changes) and may show depressed PR segments or atrial dysrhythmias.

Medical Management

The objectives of management of pericarditis are to determine the cause, administer therapy for treatment and symptom relief, and detect signs and symptoms of cardiac tamponade. When cardiac output is impaired, the patient is placed on bed rest until the fever, chest pain, and friction rub have subsided.

Analgesics and nonsteroidal anti-inflammatory drugs (NSAIDs) such as aspirin or ibuprofen (Motrin) may be

prescribed for pain relief during the acute phase. These agents also hasten the reabsorption of fluid in patients with rheumatic pericarditis. Indomethacin (Indocin) is contraindicated because it may decrease coronary blood flow. Corticosteroids (eg, prednisone) may be prescribed if the pericarditis is severe or if the patient does not respond to NSAIDs. Colchicine may also be used as alternative therapy.

Pericardiocentesis, a procedure in which some of the pericardial fluid is removed, is rarely necessary. It may be performed to assist in the identification of the cause or relieve symptoms, especially if there are signs and symptoms of heart failure or tamponade. Pericardial fluid is cultured if bacterial, tubercular, or fungal disease is suspected, and a sample is sent for cytology if neoplastic disease is suspected. A pericardial window, a small opening made in the pericardium, may be performed to allow continuous drainage into the chest cavity. Surgical removal of the tough encasing pericardium (pericardiectomy) may be necessary to release both ventricles from the constrictive and restrictive inflammation and scarring.

Nursing Management

Patients with acute pericarditis require pain management with analgesics, positioning, and psychological support. Patients with chest pain often benefit from education and reassurance that the pain is not due to a heart attack. To minimize complications, the nurse helps the patient with activity restrictions until the pain and fever subside. As the patient's condition improves, the nurse encourages gradual increases of activity. However, if pain, fever, or friction rub reappear, activity restrictions must be resumed. The nurse educates the patient and family about a healthy lifestyle to enhance the patient's immune system.

Nurses caring for patients with pericarditis must be alert to cardiac tamponade (see Chapter 30). The nurse monitors the patient for heart failure. Patients with hemodynamic instability or pulmonary congestion are treated as they would be if they had heart failure (see Chapter 30).

NURSING PROCESS

THE PATIENT WITH PERICARDITIS

Assessment

The primary symptom of the patient with pericarditis is pain, which is assessed by evaluating the patient in various positions. The nurse tries to identify whether the pain is influenced by respiratory movements, while holding an inhaled breath or holding an exhaled breath; by flexion, extension, or rotation of the spine, including the neck; by movements of the shoulders and arms; by coughing; or by swallowing. Recognizing the events that precipitate or intensify pain may help establish a diagnosis and differentiate the pain of pericarditis from the pain of myocardial infarction.

A pericardial friction rub occurs when the pericardial surfaces lose their lubricating fluid because of inflammation. The rub is audible on auscultation and is synchronous with

the heartbeat. However, it may be elusive and difficult to detect.

NURSING ALERT

A pericardial friction rub is diagnostic of pericarditis. It has a creaky or scratchy sound and is louder at the end of exhalation. Nurses should monitor for the pericardial friction rub by placing the diaphragm of the stethoscope tightly against the thorax and auscultating the left sternal edge in the fourth intercostal space, the site where the pericardium comes into contact with the left chest wall. The rub may be heard best when a patient is sitting and leaning forward.

If there is difficulty in distinguishing a pericardial friction rub from a pleural friction rub, the patient is asked to hold his or her breath; a pericardial friction rub will continue.

The patient's temperature is monitored frequently. Pericarditis may cause an abrupt onset of fever in a patient who has been afebrile.

Diagnosis

Nursing Diagnosis

Based on the assessment data, the major nursing diagnosis may be acute pain related to inflammation of the pericardium.

Collaborative Problems/Potential Complications

Based on the assessment data, potential complications that may develop include:

- Pericardial effusion
- Cardiac tamponade

Planning and Goals

The patient's major goals may include relief of pain and absence of complications.

Nursing Interventions

Relieving Pain

Relief of pain is achieved by rest. Because sitting upright and leaning forward is the posture that tends to relieve pain, chair rest may be more comfortable. It is important to instruct the patient to restrict activity until the pain subsides. As the chest pain and friction rub abate, activities of daily living may be resumed gradually. If the patient is taking analgesics, antibiotics, or corticosteroids for the pericarditis, his or her responses are monitored and recorded. Patients taking NSAIDs are assessed for gastrointestinal adverse effects. If chest pain and friction rub recur, bed rest or chair rest is resumed.

Monitoring and Managing Potential Complications

PERICARDIAL EFFUSION. Fluid may accumulate between the pericardial linings (ie, in the pericardial sac), a condition called pericardial effusion (see Chapter 30). Most patients have no effects or symptoms. However, enough fluid can accumulate to constrict the myocardium, impairing ventricular filling and the myocardium's ability to

pump, a condition known as cardiac tamponade (discussed below). Failure to identify and treat this problem can lead to death.

CARDIAC TAMPONADE. The signs and symptoms of cardiac tamponade may begin with the patient reporting shortness of breath, chest tightness, or dizziness. The nurse may observe that the patient is becoming progressively more restless. Assessment of blood pressure may reveal a decrease of 10 mm Hg or more in the systolic blood pressure during inspiration (pulsus paradoxus). Usually, the systolic pressure decreases and the diastolic pressure remains stable; hence, the pulse pressure narrows. The patient usually has tachycardia, and the ECG voltage may be decreased or the QRS complexes may alternate in height (electrical alternans). Heart sounds may progress from distant to imperceptible. Blood continues to return to the heart from the periphery but cannot flow into the heart to be pumped back into the circulation. The patient develops neck vein distention and other signs of rising central venous pressure.

In such situations, the nurse notifies the physician immediately and prepares to assist with diagnostic echocardiography and pericardiocentesis (see Chapter 30). The nurse stays with the patient and continues to assess and record signs and symptoms while intervening to decrease patient anxiety.

Promoting Home and Community-Based Care

Because patients, their family members, and their health care providers tend to focus on the most obvious needs and issues related to pericarditis, the nurse reminds them about the importance of continuing health promotion and screening practices. The nurse educates patients who have not been involved in these practices in the past about their importance and refers them to appropriate health care providers.

Evaluation

Expected Patient Outcomes

1. Freedom from pain
 - a. Performs activities of daily living without pain, fatigue, or shortness of breath
 - b. Temperature returns to normal range
 - c. Exhibits no pericardial friction rub
2. Absence of complications
 - a. Sustains blood pressure in normal range
 - b. Has heart sounds that are strong and can be auscultated
 - c. Shows absence of neck vein distention

CRITICAL THINKING EXERCISES

EBP 1 A 70-year-old woman experiences exertional dyspnea while training for the senior Olympics. She has been diagnosed with aortic stenosis, and a cardiologist has recommended an aortic valve replacement. However, the woman is reluctant to “go under the knife.” Based on your knowledge of aortic stenosis, what would you discuss with the patient? What patient teaching would you provide?

On what evidence do you base your response? What is the strength of that evidence?

EBP 2 A 19-year-old man with dilated cardiomyopathy experiences ventricular dysrhythmias, for which he is hospitalized. A cardiologist has inserted an implantable cardioverter defibrillator (ICD) and has prescribed an ACE inhibitor. The patient tells you that he will not take any medications after he leaves the hospital because he believes that he is cured and that “drugs are bad for you.” The cardiologist has also recommended consultation with a transplant physician for consideration of a heart transplant. The patient tells you that he “might consider it. It will depend on how bad the shocks are, assuming this thing ever gives me a shock.” Based on your knowledge of the antidrug campaign in the United States, dilated cardiomyopathy, and the developmental tasks of 19-year-olds, how would you respond? On what evidence do you base your response? What is the strength of that evidence?

3 A 35-year-old woman with atrial fibrillation is recovering from a mitral valvuloplasty for mitral regurgitation. The cardiologist prescribes warfarin (Coumadin). What are this patient’s teaching and discharge planning needs? As you care for the patient, you learn that she is interested in having another child. What information would you provide to the patient regarding mitral valve repair, warfarin treatment, and pregnancy?

4 You are caring for a 55-year-old man with infective endocarditis. The clinical assistant who has just obtained the patient’s vital signs reports that he has both tachycardia and tachypnea. As you enter the room, you find a very anxious, restless patient. Describe the actions you would take and explain why. Which actions would take priority over other ones?

chapter 30

Management of Patients With Complications From Heart Disease

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

- 1 Describe the management of patients with heart failure (HF).
- 2 Use the nursing process as a framework for care of patients with HF.
- 3 Develop a teaching plan for patients with HF.
- 4 Describe the management of patients with pulmonary edema.
- 5 Describe the management of patients with thromboembolism, pericardial effusion, and sudden cardiac death.

GLOSSARY

acute decompensated heart failure: acute exacerbation of heart failure, with signs and symptoms resulting in markedly lower systemic perfusion

afterload: the resistance to ejection of blood from a ventricle

anuria: urine output of less than 50 mL/24 h

ascites: an accumulation of serous fluid in the peritoneal cavity

cardiac output (CO): the amount of blood pumped out of the heart in 1 minute

cardiac resynchronization therapy (CRT): a treatment for heart failure in which a device paces both ventricles to synchronize contractions

compliance: the elasticity or amount of “give” when blood enters the ventricle

congestive heart failure (CHF): a fluid overload condition (congestion) associated with heart failure

contractility: the force of ventricular contraction; related to the number and state of myocardial cells

diastolic heart failure: the inability of the heart to pump sufficiently because of an alteration in the ability of the heart to fill; current term used to describe a type of heart failure

GLOSSARY (Continued)

ejection fraction (EF): percentage of blood volume in the ventricles at the end of diastole that is ejected during systole; a measurement of contractility

heart failure (HF): the inability of the heart to pump sufficient blood to meet the needs of the tissues for oxygen and nutrients; signs and symptoms of pulmonary and systemic congestion may or may not be present

left-sided heart failure (left ventricular failure): inability of the left ventricle to fill or pump (empty) sufficient blood to meet the needs of the tissues for oxygen and nutrients; traditional term used to describe patient’s symptoms of heart failure

oliguria: diminished urine output; less than 500 mL/24 h

orthopnea: shortness of breath when laying flat

paroxysmal nocturnal dyspnea (PND): shortness of breath that occurs suddenly during sleep

pericardiocentesis: procedure that involves aspiration of fluid from the pericardial sac

pericardiotomy: surgically created opening of the pericardium

preload: the amount of myocardial stretch just before systole caused by the volume of blood presented to the ventricle

pulmonary edema: abnormal accumulation of fluid in the interstitial spaces and alveoli of the lungs

pulseless electrical activity (PEA): condition in which electrical activity is present but there is not an adequate pulse or blood pressure

pulsus paradoxus: systolic blood pressure that is more than 10 mm Hg higher during exhalation than during inspiration; difference is normally less than 10 mm Hg

right-sided heart failure (right ventricular failure): inability of the right ventricle to fill or pump (empty) sufficient blood to the pulmonary circulation

stroke volume (SV): amount of blood pumped out of the ventricle with each contraction

systolic heart failure: inability of the heart to pump sufficiently because of an alteration in the ability of the heart to contract; current term used to describe a type of heart failure.

Today it is possible to help the patient with heart disease live longer and achieve a high quality of life. Advances in diagnostic procedures, treatments, technologies, and pharmacotherapies allow earlier and more accurate diagnoses and treatment that can begin well before significant debilitation occurs. However, heart disease remains a chronic and often progressive condition, and complications may develop. This chapter presents the complications most often resulting from heart diseases and the collaborative treatment options for these complications.

Cardiac Hemodynamics

The basic function of the heart is to pump blood. The heart's ability to pump is measured by **cardiac output (CO)**, the amount of blood pumped per minute. CO is determined by measuring the heart rate (HR) and multiplying it by the **stroke volume (SV)**, the amount of blood pumped out of the ventricle with each contraction. CO usually is calculated using the equation $CO = HR \times SV$.

The HR is primarily controlled by the autonomic nervous system. When SV decreases, the nervous system is stimulated to increase HR and thereby maintain adequate CO. SV depends on three factors: preload, afterload, and contractility (Fig. 30-1). Precise measurement of these factors requires hemodynamic monitoring.

Preload is the amount of blood presented to the ventricle just before systole. It increases pressure in the ventricle, which stretches the ventricular wall. Like a piece of elastic, the ventricular muscle fibers need to be stretched (by blood

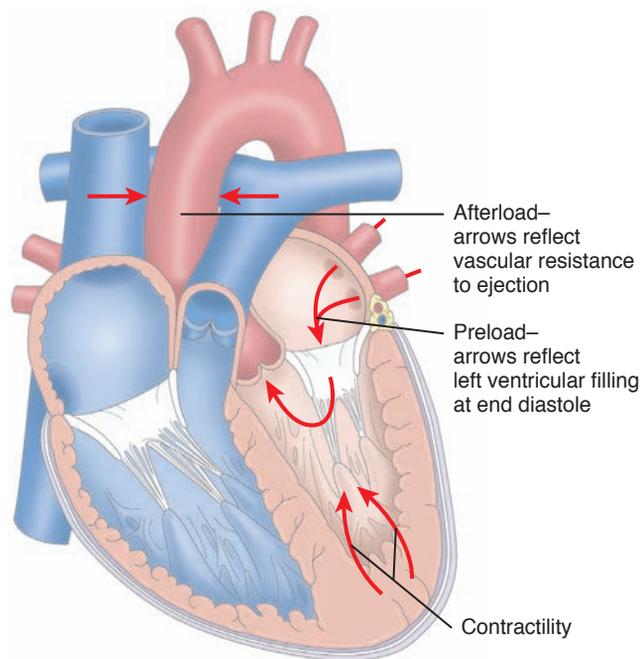

Figure 30-1 The determinants of stroke volume (SV). The SV is determined by the amount of preload presented to the ventricle, the amount of afterload or resistance to ventricular ejection, and the strength of cardiac contractility. The cardiac output is the product of SV and heart rate. Redrawn from Porth, C. M. & Matfin, G. (2009). *Pathophysiology: Concepts of altered health states* (8th ed.). Philadelphia: Lippincott Williams & Wilkins.

volume) to produce optimal recoil and forceful ejection of blood. Too little or too much muscle fiber stretch decreases the volume of blood ejected. The major factor that determines preload is venous return of blood to the heart, which creates the volume of blood that enters the ventricle during diastole. Another factor that determines preload is ventricular **compliance**, the elasticity or amount of “give” when blood enters the ventricle. Elasticity is decreased when the muscle thickens, as in hypertrophic cardiomyopathy (see Chapter 29) or when there is increased fibrotic tissue within the ventricle. Fibrotic tissue replaces dead myocardial cells, such as after a myocardial infarction (MI) (see Chapter 28). Fibrotic tissue has little compliance, making the ventricle stiff. Given the same volume of blood, a noncompliant ventricle has a higher intraventricular pressure than a compliant one. Higher pressure increases the workload of the heart and can lead to **heart failure (HF)** if it is sustained.

Afterload refers to the amount of resistance to the ejection of blood from the ventricle. To eject blood, the ventricle must overcome the resistance caused by tension in the aorta and systemic vessels. Afterload is inversely related to SV, and an increase in afterload causes the ventricle to work harder and may decrease the amount of blood ejected. The major factors that determine afterload are the diameter and distensibility of the great vessels (aorta and pulmonary artery) and the opening and competence of the semilunar valves (pulmonic and aortic valves). When the valves open easily, resistance is lower. If the patient has significant vasoconstriction, hypertension, or a narrowed valvular opening from stenosis, resistance (afterload) increases. When afterload increases, the workload of the heart must increase to overcome the resistance and eject blood.

Contractility, the force of contraction, is related to the status of the myocardium. Catecholamines, released by sympathetic stimulation during exercise or from administration of positive inotropic medications, can increase contractility and SV. MI causes necrosis and subsequent fibrosis of some myocardial cells, shifting the workload to the remaining cells. Significant loss of myocardial cells can decrease contractility and cause HF. Afterload can be reduced by medications to match the lower contractility and maintain adequate CO.

Noninvasive Assessment of Cardiac Hemodynamics

There are several noninvasive assessment parameters that estimate preload, afterload, and contractility. Right ventricular preload may be estimated by measuring jugular venous distention (JVD). Mean arterial blood pressure is an approximate indicator of left ventricular afterload. Activity tolerance may be used as an indicator of overall cardiac functioning. Noninvasive assessments are described in more detail later in this chapter and in Chapter 26.

Invasive Assessment of Cardiac Hemodynamics

A number of types of central venous catheters can be used to obtain more precise hemodynamic information. One important tool for evaluating the components of SV is the

pulmonary artery catheter, which is used to obtain the hemodynamic data essential for diagnosis and treatment (see Chapter 26). Measurements of intracardiac pressures, pulmonary artery pressures, and cardiac output are made at intervals. Therapy, especially intravenous (IV) medication, is adjusted based on the hemodynamic data. The patient with an invasive hemodynamic catheter is usually managed in an intensive care environment because of the need for frequent nursing assessments and interventions.

HEART FAILURE

HF is the inability of the heart to pump sufficient blood to meet the needs of the tissues for oxygen and nutrients. In the past, HF was often referred to as **congestive heart failure (CHF)**, because many patients experience pulmonary or peripheral congestion. Currently HF is recognized as a clinical syndrome characterized by signs and symptoms of fluid overload or of inadequate tissue perfusion. Fluid overload and decreased tissue perfusion result when the heart cannot generate a CO sufficient to meet the body's demands. The term HF indicates myocardial disease in which there is a problem with contraction of the heart (systolic dysfunction) or filling of the heart (diastolic dysfunction) that may or may not cause pulmonary or systemic congestion. Some cases of HF are reversible, depending on the cause. Most often, HF is a progressive, life-long condition that is managed with lifestyle changes and medications to prevent episodes of **acute decompensated heart failure**. These episodes are characterized by an increase in symptoms, decreased CO, and low perfusion (Varughese, 2007). They are associated with increased hospitalizations, increased health care costs, and decreased quality of life.

Chronic Heart Failure

As with coronary artery disease, the incidence of HF increases with age. More than 5 million people in the United States have HF, and 550,000 new cases are diagnosed each year (American Heart Association [AHA], 2007). Although HF can affect people of all ages, it is most common in people older than 75 years of age; as the U.S. population ages, HF has become an epidemic that challenges the country's health care resources. HF is the most common reason for hospitalization of people older than 65 years of age and is the second most common reason for visits to a physician's office. The rate of emergency department visits and hospital readmissions for this condition remains very high. The estimated economic burden caused by HF is more than \$33 billion annually in direct and indirect costs and is expected to increase (AHA, 2007).

The increase in the incidence of HF reflects not only the increased number of elderly people but also improvements in treatment of cardiac diseases such as MI, resulting in increased survival rates. Many hospitalizations for HF can be prevented by appropriate outpatient care. Prevention and early intervention to arrest the progression of HF are major health initiatives in the United States.

Two major types of HF are identified by assessment of left ventricular functioning, usually by echocardiogram. The more common type is an alteration in ventricular contraction called **systolic heart failure**, which is characterized by a weakened heart muscle. The less common type is **diastolic heart failure**, which is characterized by a stiff and noncompliant heart muscle, making it difficult for the ventricle to fill. An assessment of the **ejection fraction (EF)** is performed to assist in determining the type of HF. EF is calculated by subtracting the amount of blood present in the left ventricle at the end of systole from the amount present at the end of diastole and calculating the percentage of blood that is ejected. A normal EF is 55% to 65% of the ventricular volume; the ventricle does not completely empty between contractions. The EF is normal in diastolic HF but severely reduced in systolic HF.

Although a low EF is a hallmark of systolic HF, which is the most common type of HF, the severity of HF is frequently classified according to the patient's symptoms. The New York Heart Association (NYHA) Classification is described in Table 30-1. The American College of Cardiology and the American Heart Association (ACC/AHA) have developed another a HF classification system (Hunt, Abraham, Chin, et al., 2005). This system, described in Table 30-2, takes into consideration the natural history and progressive nature of HF. Treatment guidelines have been developed for each stage.

Pathophysiology

HF results from a variety of cardiovascular conditions, including chronic hypertension, coronary artery disease, and valvular disease. These conditions can result in systolic failure, diastolic failure, or both. Significant myocardial dysfunction usually occurs before the patient experiences signs and symptoms of HF such as shortness of breath, edema, or fatigue.

Table 30-1 NEW YORK HEART ASSOCIATION (NYHA) CLASSIFICATION OF HEART FAILURE

Classification	Signs and Symptoms	Prognosis
I	Ordinary physical activity does not cause undue fatigue, dyspnea, palpitations, or chest pain No pulmonary congestion or peripheral hypotension Patient is considered asymptomatic Usually no limitations of activities of daily living (ADLs)	Good
II	Slight limitation on ADLs Patient reports no symptoms at rest but increased physical activity will cause symptoms Basilar crackles and S ₃ murmur may be detected	Good
III	Marked limitation on ADL Patient feels comfortable at rest but less than ordinary activity will cause symptoms	Fair
IV	Symptoms of cardiac insufficiency at rest	Poor

Table 30-2 AMERICAN COLLEGE OF CARDIOLOGY AND AMERICAN HEART ASSOCIATION (ACC/AHA) CLASSIFICATION OF HEART FAILURE

Classification	Criteria
Stage A	Patients at high risk for developing left ventricular dysfunction but without structural heart disease or symptoms of heart failure
Stage B	Patients with left ventricular dysfunction or structural heart disease who have not developed symptoms of heart failure
Stage C	Patients with left ventricular dysfunction or structural heart disease with current or prior symptoms of heart failure
Stage D	Patients with refractory end-stage heart failure requiring specialized interventions

As HF develops, the body activates neurohormonal compensatory mechanisms. These mechanisms represent the body's attempt to cope with the HF and are responsible for the signs and symptoms that eventually develop. Understanding these mechanisms is important because the treatment of HF is aimed at opposing them and relieving symptoms.

Systolic HF results in decreased blood volume being ejected from the ventricle. The decreased ventricular stretch is sensed by baroreceptors in the aortic and carotid bodies. The sympathetic nervous system is then stimulated to release epinephrine and norepinephrine (Fig. 30-2). The purpose of this initial response is to increase heart rate and contractility and support the failing myocardium, but the

Physiology ■■■ Pathophysiology

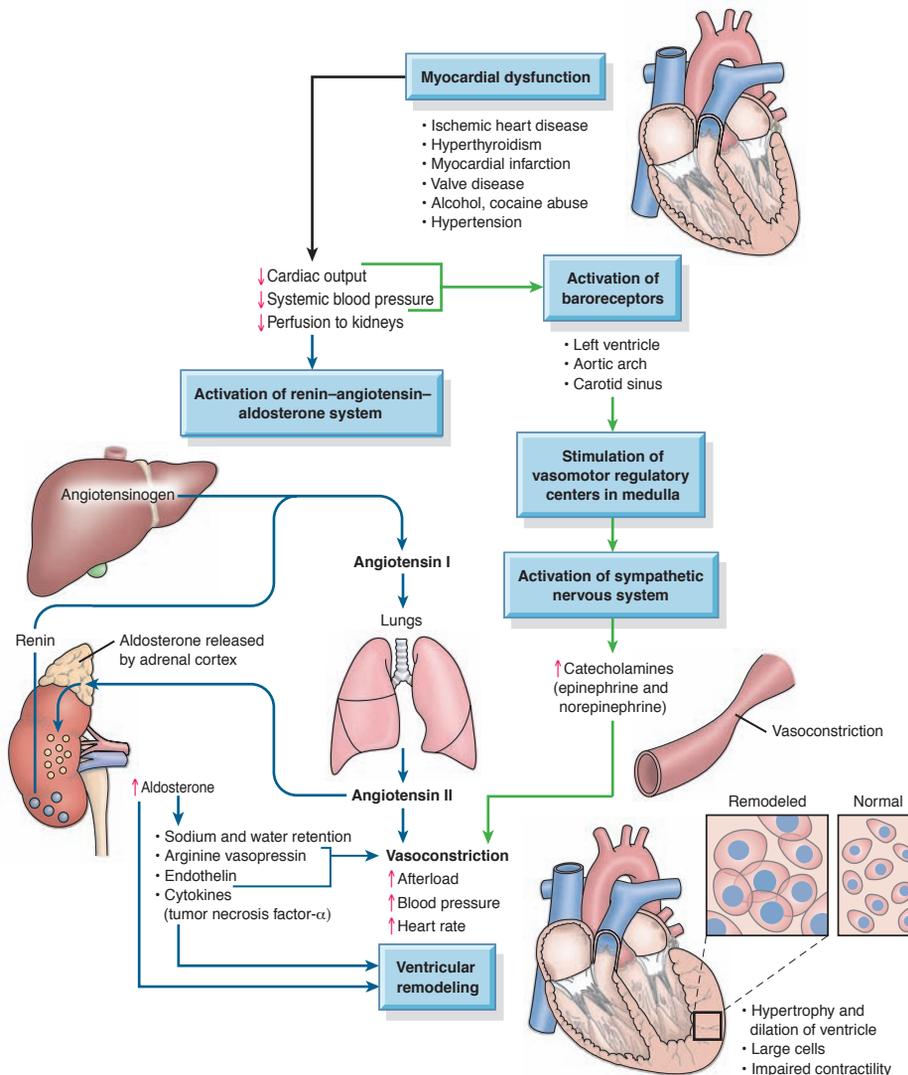

Figure 30-2 The pathophysiology of heart failure. A decrease in cardiac output activates multiple neurohormonal mechanisms that ultimately result in the signs and symptoms of heart failure.

continued response has multiple negative effects. Sympathetic stimulation causes vasoconstriction in the skin, gastrointestinal tract, and kidneys. A decrease in renal perfusion due to low CO and vasoconstriction then causes the release of renin by the kidneys. Renin promotes the formation of angiotensin I, a benign, inactive substance. Angiotensin-converting enzyme (ACE) in the lumen of pulmonary blood vessels converts angiotensin I to angiotensin II, a potent vasoconstrictor, which then increases the blood pressure and afterload. Angiotensin II also stimulates the release of aldosterone from the adrenal cortex, resulting in sodium and fluid retention by the renal tubules and stimulation of antidiuretic hormone. These mechanisms lead to the fluid volume overload commonly seen in HF. Angiotensin, aldosterone, and other neurohormones (eg, endothelin, prostacyclin) lead to an increase in preload and afterload, which increases stress on the ventricular wall, causing an increase in the workload of the heart. A counter-regulatory mechanism is attempted through the release of natriuretic peptides. Atrial natriuretic peptide (ANP) and B-type (ie, brain type) natriuretic peptide (BNP) are released from the overdistended cardiac chambers. These substances promote vasodilation and diuresis. However, their effect is usually not strong enough to overcome the negative effects of the other mechanisms.

As the heart's workload increases, contractility of the myocardial muscle fibers decreases. Decreased contractility results in an increase in end-diastolic blood volume in the ventricle, stretching the myocardial muscle fibers and increasing the size of the ventricle (ventricular dilation). The increased size of the ventricle further increases the stress on the ventricular wall, adding to the workload of the heart. One way the heart compensates for the increased workload is to increase the thickness of the heart muscle (ventricular hypertrophy). However, hypertrophy results in an abnormal proliferation of myocardial cells, a process known as ventricular remodeling. Under the influence of neurohormones (eg, angiotensin II), large myocardial cells are produced that are dysfunctional and die early, leaving the other normal myocardial cells to struggle to maintain CO. The compensatory mechanisms of HF have been called the "vicious cycle of HF" because the heart does not pump sufficient blood to the body, which causes the body to stimulate the heart to work harder; thus, the heart cannot respond and failure becomes worse.

Diastolic HF develops because of continued increased workload on the heart, which responds by increasing the number and size of myocardial cells (ie, ventricular hypertrophy and altered cellular functioning). These responses cause resistance to ventricular filling, which increases ventricular filling pressures despite a normal or reduced blood volume. Less blood in the ventricles causes decreased CO. The low CO and high ventricular filling pressures can cause the same neurohormonal responses as described for systolic HF.

Etiology

Myocardial dysfunction is most often caused by coronary artery disease, cardiomyopathy, hypertension, or valvular disorders. Patients with diabetes mellitus are also at high risk for HF. Atherosclerosis of the coronary arteries is the pri-

mary cause of HF, and coronary artery disease is found in more than 60% of the patients with HF (Zipes, Libby & Bonow, 2005). Ischemia causes myocardial dysfunction because it deprives heart cells of oxygen and leads to acidosis from the accumulation of lactic acid. MI causes focal heart muscle necrosis, the death of myocardial cells, and a loss of contractility; the extent of the infarction correlates with the severity of HF. Revascularization of the coronary artery by a percutaneous coronary intervention (PCI) or by coronary artery bypass surgery (CABG) may improve myocardial oxygenation and ventricular function.

Cardiomyopathy is a disease of the myocardium. There are three types: dilated, hypertrophic, and restrictive (see Chapter 29). Dilated cardiomyopathy, the most common type of cardiomyopathy, causes diffuse cellular necrosis and fibrosis, leading to decreased contractility (systolic failure). Dilated cardiomyopathy can be idiopathic (unknown cause) or it can result from an inflammatory process, such as myocarditis, or from a cytotoxic agent, such as alcohol or doxorubicin (Adriamycin). Hypertrophic cardiomyopathy and restrictive cardiomyopathy lead to decreased distensibility and ventricular filling (diastolic failure). Usually, HF due to cardiomyopathy becomes chronic and progressive. However, cardiomyopathy and HF may resolve following removal of the causative agent, such as with the cessation of alcohol ingestion.

Systemic or pulmonary hypertension increases afterload (resistance to ejection), which increases the workload of the heart and leads to hypertrophy of myocardial muscle fibers. This can be considered a compensatory mechanism because it increases contractility. However, the hypertrophy may impair the heart's ability to fill properly during diastole, and the hypertrophied ventricle may eventually dilate and fail.

Valvular heart disease is also a cause of HF. The valves ensure that blood flows in one direction. With valvular dysfunction, blood has increasing difficulty moving forward, increasing pressure within the heart and increasing cardiac workload, leading to HF. Chapter 29 discusses the effects of valvular heart disease.

Several systemic conditions, including progressive renal failure and uncontrolled hypertension, contribute to the development and severity of HF (Varughese, 2007). Acute illness such as pneumonia with fever and hypoxia increase the metabolic rate and may precipitate HF. All of these conditions require an increase in CO to satisfy the systemic oxygen demand, and they stress the compromised myocardium. Cardiac dysrhythmias may cause HF or may be a result of HF; either way, the altered electrical stimulation impairs myocardial contraction and decreases the overall efficiency of myocardial function. Other factors, such as acidosis (respiratory or metabolic), electrolyte abnormalities, and antiarrhythmic medications, can worsen myocardial function.

Clinical Manifestations

The clinical manifestations produced by the different types of HF (systolic, diastolic, or both) are similar (Chart 30-1) and therefore do not assist in differentiating the types of HF. The signs and symptoms of HF can be related to which ventricle is affected. **Left-sided heart failure (left ventricular failure)** causes different manifestations than **right-sided**

CHART
30-1

Assessing for Heart Failure

Be alert for the following signs and symptoms:

General

- Fatigue
- Decreased activity tolerance
- Dependent edema
- Weight gain

Cardiovascular

- Third heart sound (S_3)
- Apical impulse enlarged with left lateral displacement
- Pallor and cyanosis
- Jugular venous distention (JVD)

Respiratory

- Dyspnea on exertion
- Pulmonary crackles that do not clear with cough
- Orthopnea
- Paroxysmal nocturnal dyspnea (PND)
- Cough on exertion or when supine

Cerebrovascular

- Unexplained confusion or altered mental status
- Lightheadedness

Renal

- Oliguria and decreased frequency during the day
- Nocturia

Gastrointestinal

- Anorexia and nausea
- Enlarged liver
- Ascites
- Hepatojugular reflux

heart failure (right ventricular failure). In chronic HF, patients may have signs and symptoms of both left and right ventricular failure.

Left-Sided Heart Failure

Pulmonary congestion occurs when the left ventricle cannot effectively pump blood out of the ventricle into the aorta and the systemic circulation. The increased left ventricular end-diastolic blood volume increases the left ventricular end-diastolic pressure, which decreases blood flow from the left atrium into the left ventricle during diastole. The blood volume and pressure in the left atrium increases, which decreases blood flow from the pulmonary vessels. Pulmonary venous blood volume and pressure increase, forcing fluid from the pulmonary capillaries into the pulmonary tissues and alveoli, causing pulmonary interstitial edema and impaired gas exchange. The clinical manifestations of pulmonary congestion include dyspnea, cough, pulmonary crackles, and low oxygen saturation levels. An extra heart sound, the S_3 , or “ventricular gallop,” may be detected on auscultation. It is caused by a large volume of fluid entering the ventricle at the beginning of diastole.

Dyspnea, or shortness of breath, may be precipitated by minimal to moderate activity (dyspnea on exertion [DOE]);

dyspnea also can occur at rest. The patient may report **orthopnea**, difficulty breathing when lying flat. Patients with orthopnea usually prefer not to lie flat. They may need pillows to prop themselves up in bed, or they may sit in a chair and even sleep sitting up. Some patients have sudden attacks of dyspnea at night, a condition known as **paroxysmal nocturnal dyspnea (PND)**. Fluid that accumulates in the dependent extremities during the day may be reabsorbed into the circulating blood volume when the patient lies down. Because the impaired left ventricle cannot eject the increased circulating blood volume, the pressure in the pulmonary circulation increases, shifting fluid into the alveoli. The fluid-filled alveoli cannot exchange oxygen and carbon dioxide. Without sufficient oxygen, the patient experiences dyspnea and has difficulty sleeping.

The cough associated with left ventricular failure is initially dry and nonproductive. Most often, patients complain of a dry hacking cough that may be mislabeled as asthma or chronic obstructive pulmonary disease (COPD). The cough may become moist over time. Large quantities of frothy sputum, which is sometimes pink (blood-tinged), may be produced, usually indicating severe pulmonary congestion (pulmonary edema).

Adventitious breath sounds may be heard in various areas of the lungs. Usually, bibasilar crackles that do not clear with coughing are detected in the early phase of left ventricular failure. As the failure worsens and pulmonary congestion increases, crackles may be auscultated throughout all lung fields. At this point, oxygen saturation may decrease.

In addition to increased pulmonary pressures that cause decreased oxygenation, the amount of blood ejected from the left ventricle decreases. The dominant feature in HF is inadequate tissue perfusion. The diminished CO has widespread manifestations because not enough blood reaches all the tissues and organs (low perfusion) to provide the necessary oxygen. The decrease in SV can also lead to stimulation of the sympathetic nervous system, which further impedes perfusion to many organs.

A reduction in CO decreases blood flow to the kidneys, reducing urine output (**oliguria**). Renal perfusion pressure falls, which results in the release of renin from the kidney. Release of renin leads to aldosterone secretion and increased intravascular volume. However, when the patient is sleeping, the cardiac workload is decreased, improving renal perfusion, which in some patients leads to frequent urination at night (nocturia).

As HF progresses, decreased CO may cause other symptoms. Decreased gastrointestinal perfusion causes altered digestion. Decreased brain perfusion causes dizziness, lightheadedness, confusion, restlessness, and anxiety due to decreased oxygenation and blood flow. As anxiety increases, so does dyspnea, increasing anxiety and creating a vicious cycle. Stimulation of the sympathetic system also causes the peripheral blood vessels to constrict, so the skin appears pale or ashen and feels cool and clammy.

A decrease in SV causes the sympathetic nervous system to increase the HR (tachycardia), often causing the patient to complain of palpitations. The pulses become weak and thready. Without adequate CO, the body cannot respond to increased energy demands, and the patient becomes easily

fatigued and has decreased activity tolerance. Fatigue also results from the increased energy expended in breathing and the insomnia that results from respiratory distress, coughing, and nocturia.

Right-Sided Heart Failure

When the right ventricle fails, congestion in the peripheral tissues and the viscera predominates. This occurs because the right side of the heart cannot eject blood and cannot accommodate all the blood that normally returns to it from the venous circulation. Increased venous pressure leads to JVD and increased capillary hydrostatic pressure throughout the venous system.

The systemic clinical manifestations include edema of the lower extremities (dependent edema), hepatomegaly (enlargement of the liver), **ascites** (accumulation of fluid in the peritoneal cavity), anorexia and nausea, and weakness and weight gain due to retention of fluid.

Edema usually affects the feet and ankles and worsens when the patient stands or sits for a long period. The edema decreases when the patient elevates the legs. The edema can gradually progress up the legs and thighs and eventually into the external genitalia and lower trunk. Edema in the abdomen, as evidenced by increased abdominal girth, may be the only edema present. Sacral edema is common in patients who are on bed rest, because the sacral area is dependent. Pitting edema, in which indentations in the skin remain after even slight compression with the fingertips (Fig. 30-3), is obvious only after retention of at least 4.5 kg (10 lb) of fluid (4.5 L).

Hepatomegaly and tenderness in the right upper quadrant of the abdomen result from venous engorgement of the liver. The increased pressure may interfere with the liver's ability to function (secondary liver dysfunction). As hepatic dysfunction progresses, increased pressure within the portal vessels may force fluid into the abdominal cavity, causing ascites. Ascites may increase pressure on the stomach and intestines and cause gastrointestinal distress. Hepatomegaly

may also increase pressure on the diaphragm, causing respiratory distress.

Anorexia (loss of appetite) and nausea or abdominal pain result from the venous engorgement and venous stasis within the abdominal organs. The weakness that accompanies right-sided HF results from reduced CO, impaired circulation, and inadequate removal of catabolic waste products from the tissues.

Assessment and Diagnostic Findings

HF may go undetected until the patient presents with signs and symptoms of pulmonary and peripheral edema. However, the physical signs that suggest HF may also occur with other diseases, such as renal failure and COPD. Assessment of ventricular function is an essential part of the initial diagnostic workup.

An echocardiogram is usually performed to confirm the diagnosis of HF, identify the underlying cause, and determine the EF, which helps identify the type and severity of HF. This information may also be obtained noninvasively by radionuclide ventriculography or invasively by ventriculography as part of a cardiac catheterization procedure. A chest x-ray and an electrocardiogram (ECG) are obtained to assist in the diagnosis. Laboratory studies usually performed during the initial workup include serum electrolytes, blood urea nitrogen (BUN), creatinine, thyroid-stimulating hormone, complete blood cell count, BNP, and routine urinalysis. The BNP level is a key diagnostic indicator of HF; high levels are a sign of high cardiac filling pressure and can aid in the diagnosis of HF (Heart Failure Society of America [HFSA], 2006). The results of these laboratory studies assist in determining the underlying cause and can also be used to establish a baseline to assess effects of treatment. Cardiac stress testing or cardiac catheterization may be performed to determine whether coronary artery disease and cardiac ischemia are causing the HF.

Medical Management

The overall goals of management of HF are to relieve patient symptoms, to improve functional status and quality of life, and to extend survival. Medical management is based on the type, severity, and cause of HF. Specific objectives of medical management include the following:

- Eliminate or reduce any etiologic contributory factors, such as uncontrolled hypertension or atrial fibrillation with a rapid ventricular response
- Optimize pharmacologic and other therapeutic regimens
- Reduce the workload on the heart by reducing preload and afterload
- Promote a lifestyle conducive to cardiac health
- Prevent episodes of acute decompensated HF

Treatment options vary according to the severity of the patient's condition and may include oral and IV medications, major lifestyle changes, supplemental oxygen, implantation of assistive devices, and surgical approaches, including cardiac transplantation.

Managing the patient with HF includes providing comprehensive education and counseling to the patient and family. It is important that the patient and family understand the nature of HF and the importance of their participation

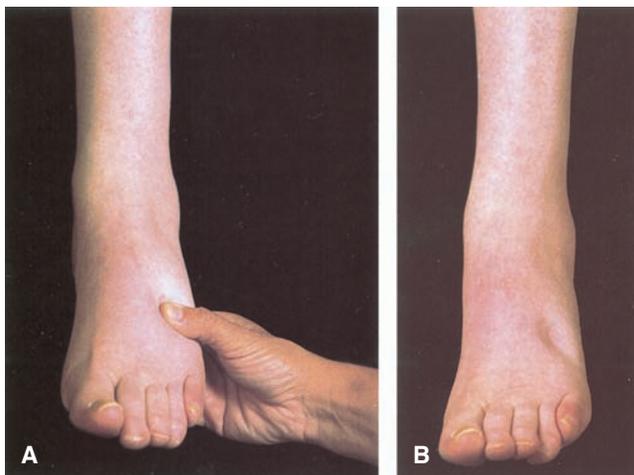

Figure 30-3 Example of pitting edema. **A**, The nurse applies finger pressure to an area near the ankle. **B**, When the pressure is released, an indentation remains in the edematous tissue. From Bickley, L. S. (2007). *Bates' guide to physical examination and history taking* (9th ed.). Philadelphia: Lippincott Williams & Wilkins.

in the treatment regimen. Lifestyle recommendations include restriction of dietary sodium; avoidance of excessive fluid intake, alcohol, and smoking; weight reduction when indicated; and regular exercise. The patient must know how to recognize signs and symptoms that need to be reported to a health care professional.

Pharmacologic Therapy

Several medications are routinely prescribed for systolic HF, including ACE inhibitors, beta-blockers, diuretics, and digitalis (Table 30-3). Target doses for these medications are identified in the AHA/ACC guidelines, and nurses and physicians work collaboratively toward achieving effective dosing of these medications (Albert, 2006).

Angiotensin-Converting Enzyme Inhibitors

ACE inhibitors play a pivotal role in the management of systolic HF. They have been found to relieve the signs and symptoms of HF and significantly decrease mortality and morbidity. ACE inhibitors (eg, lisinopril [Prinivil, Zestril]) slow the progression of HF, improve exercise tolerance, and

decrease the number of hospitalizations for HF (Institute for Clinical Systems Improvement [ICS], 2006). Available as oral and IV medications, ACE inhibitors promote vasodilation and diuresis by decreasing afterload and preload. By doing so, they decrease the workload of the heart. Vasodilation reduces resistance to left ventricular ejection of blood, diminishing the heart's workload and improving ventricular emptying. In promoting diuresis, ACE inhibitors decrease the secretion of aldosterone, a hormone that causes the kidneys to retain sodium and water. ACE inhibitors stimulate the kidneys to excrete sodium and fluid (while retaining potassium), thereby reducing left ventricular filling pressure and decreasing pulmonary congestion. ACE inhibitors may be the first medication prescribed for patients in mild failure—patients with fatigue or DOE but without signs of fluid overload and pulmonary congestion. These agents are also recommended for prevention of heart failure in patients who are at risk (Hunt, et al., 2005).

ACE inhibitors are started at a low dose that is increased every 2 weeks until the optimal dose is achieved and the patient is hemodynamically stable. The final maintenance

Table 30-3  **MEDICATIONS USED TO TREAT HEART FAILURE**

Medication	Therapeutic Effects	Key Nursing Considerations
Angiotensin-Converting Enzyme (ACE) Inhibitors		
Lisinopril (Prinivil, Zestril)	↓ BP and ↓ afterload	Observe for symptomatic hypotension, increased serum K ⁺ , cough, and worsening renal function.
Benazepril (Lotensin)	Relieves signs and symptoms of HF	
Captopril (Capoten)	Prevents progression of HF	
Enalapril/enalaprilat (Vasotec)		
Fosinopril (Monopril)		
Moexipril (Univasc)		
Perindopril (Aceon)		
Quinapril (Accupril)		
Ramipril (Altace)		
Trandolapril (Mavik)		
Angiotensin Receptor Blockers (ARBs)		
Valsartan (Diovan)	↓ BP and ↓ afterload	Observe for symptomatic hypotension, increased serum K ⁺ , and worsening renal function.
Candesartan (Atacand)	Relieves signs and symptoms of HF	
Eprosartan (Teveten)	Prevents progression of HF	
Irbesartan (Avapro)		
Telmisartan (Micardis)		
Losartan (Cozaar)		
Beta-adrenergic Blocking Agents (beta-blockers)		
Metoprolol (Lopressor, Toprol)	Dilates blood vessels and ↓ afterload	Observe for decreased heart rate, symptomatic hypotension, and fatigue.
Atenolol (Tenormin)	↓ signs and symptoms of HF	
Carvedilol (Coreg)	Improves exercise capacity	
Diuretics		
<i>Loop diuretic:</i>	↓ fluid volume overload	Observe for electrolyte abnormalities, renal dysfunction, diuretic resistance, and decreased BP. Carefully monitor I&O and daily weight (see Chart 30-2).
Furosemide (Lasix)	↓ signs and symptoms of HF	
<i>Thiazide diuretic:</i>		
Metolazone (Zaroxolyn)		
Hydrochlorothiazide (HCTZ)		
<i>Aldosterone antagonist:</i>		
Spirolactone (Aldactone)		
Digitalis		
Digoxin (Lanoxin)	Improves contractility ↓ signs and symptoms of HF	Observe for bradycardia and digitalis toxicity (see Chart 30-3).
Calcium Channel Blockers		
<i>Dihydropyridines:</i>	Vasodilation and reduction of systemic vascular resistance	Observe for symptomatic hypotension, drowsiness, or dizziness.
Amlodipine (Norvasc)		
Felodipine (Plendil)		

BP, blood pressure; HF, heart failure; I&O, input and output; ↓, decreases

dose depends on the patient's blood pressure, fluid status, and renal status, as well as the severity of the HF.

Patients receiving ACE inhibitors are monitored for hypotension, hypovolemia, hyperkalemia, and alterations in renal function, especially if they are also receiving diuretics. Hypotension is most likely to develop from ACE inhibitor therapy in patients older than 75 years of age and in those with a systolic blood pressure of 100 mm Hg or less, a serum sodium level of lower than 135 mEq/L, or severe HF. Adjusting the dose or type of diuretic in response to the patient's blood pressure and renal function may result in continued increases in the dosage of ACE inhibitors.

Because ACE inhibitors cause the kidneys to retain potassium, the patient who is also receiving a diuretic may not need to take oral potassium supplements. However, patients receiving potassium-sparing diuretics (which do not cause potassium loss with diuresis) must be carefully monitored for hyperkalemia, an increased level of potassium in the blood. Before the initiation of the ACE inhibitor, hyperkalemic and hypovolemic states must be corrected. ACE inhibitors may be discontinued if the potassium level remains greater than 5.5 mEq/L or if the serum creatinine rises.

Other side effects of ACE inhibitors include a dry, persistent cough that may not respond to cough suppressants. However, cough can also indicate a worsening of ventricular function and failure. Rarely, the cough indicates angioedema. If angioedema affects the oropharyngeal area and impairs breathing, the ACE inhibitor must be stopped immediately.

If the patient cannot continue taking an ACE inhibitor because of development of cough, an elevated creatinine level, or hyperkalemia, an angiotensin II receptor blocker (ARB) or a combination of hydralazine and isosorbide dinitrate is prescribed.

Angiotensin II Receptor Blockers

Although the action of ARBs is different from that of ACE inhibitors, ARBs (eg, valsartan [Diovan]) have similar hemodynamic effects: decreased blood pressure, decreased systemic vascular resistance, and improved cardiac output (ICSI, 2006). Whereas ACE inhibitors block the conversion of angiotensin I to angiotensin II, ARBs block the effects of angiotensin II at the angiotensin II receptor. ACE inhibitors and ARBs also have similar side effects: hyperkalemia, hypotension, and renal dysfunction. ARBs are prescribed as an alternative to ACE inhibitors, especially when patients cannot tolerate ACE inhibitors because of cough.

Hydralazine and Isosorbide Dinitrate

A combination of hydralazine and isosorbide dinitrate may be another alternative for patients who cannot take ACE inhibitors (Hunt, et al., 2005). Nitrates (eg, isosorbide dinitrate) cause venous dilation, which reduces the amount of blood return to the heart and lowers preload. Hydralazine lowers systemic vascular resistance and left ventricular afterload. This combination of medications is also recommended in heart failure guidelines.

Beta-Blockers

Beta-blockers, such as carvedilol (Coreg) and metoprolol (Lopressor, Toprol), have been found to reduce mortality and morbidity in patients with HF by reducing the adverse

effects from the constant stimulation of the sympathetic nervous system. Beta-blockers are routinely prescribed in addition to ACE inhibitors, diuretics, and digitalis (ICSI, 2006). In addition, they have been recommended for patients with asymptomatic systolic dysfunction, such as those with a decreased EF, to prevent the onset of symptoms of HF.

Beta-blockers may produce a number of side effects and may potentially exacerbate symptoms of HF. Side effects are most common in the initial few weeks of treatment. The most frequent side effects are dizziness, hypotension, and bradycardia. Because of these side effects, beta-blockers are started at a low dose and only after the patient is stabilized and euvolemic (ie, state of normal volume). The dose is titrated slowly (every 2 weeks), with close monitoring after each dosage increase. If symptoms of HF increase during the titration phase, treatment options include increasing the dose of the diuretic, reducing the dose of the ACE inhibitor, or decreasing the dose of the beta-blocker.

An important nursing role during titration is educating the patient about the potential worsening of symptoms during the early phase of treatment and stressing that improvement may take several weeks. It is very important for nurses to provide support to patients going through this symptom-provoking phase of treatment. Because beta-blockade can cause bronchiole constriction, a beta-1–selective beta-blocker (ie, one that primarily blocks the beta-adrenergic receptor sites in the heart), such as metoprolol, is recommended for patients with well-controlled, mild to moderate asthma. Patients need to be monitored closely for increased asthma symptoms nonetheless, because even cardioselective beta-blockers retain some modest beta-2 effects. Any type of beta-blocker is contraindicated in patients with severe or uncontrolled asthma.

Diuretics

Diuretics are prescribed to remove excess extracellular fluid by increasing the rate of urine produced in patients with signs and symptoms of fluid overload. Of the types of diuretics prescribed for patients with edema from HF, three are most common: loop, thiazide, and aldosterone blocking (potassium-sparing) diuretics. These medications are classified according to their site of action in the kidney and their effects on renal electrolyte excretion and reabsorption.

Loop diuretics, such as furosemide (Lasix), inhibit sodium and chloride reabsorption mainly in the ascending loop of Henle. Patients are generally treated with a loop diuretic first (HFSA, 2006). Thiazide diuretics, such as metolazone (Zaroxolyn), inhibit sodium and chloride reabsorption in the early distal tubules. Both of these classes of diuretics increase the excretion of potassium; therefore, patients treated with these medications must have their serum potassium levels closely scrutinized. A medication from each of these classes may be used for patients in severe HF who are unresponsive to a single diuretic. Diuretics may be most effective if the patient assumes a supine position for 1 or 2 hours after taking them. The need for diuretics can be decreased if the patient avoids excessive fluid intake (eg, more than 2 qt/day) and adheres to a low-sodium diet (eg, less than 2 g/day).

Spironolactone (Aldactone) is a potassium-sparing diuretic that blocks the effects of aldosterone in the late distal tubule and collecting duct. It has been found to be effective in reducing mortality and morbidity in patients with moderate to severe HF (ICSI, 2006). Serum creatinine and potassium levels are monitored frequently (eg, within the first week and then every 4 weeks) when this medication is first administered.

Side effects of diuretics include electrolyte imbalances, symptomatic hypotension (especially with overdiuresis), hyperuricemia (causing gout), and ototoxicity. The type and dose of diuretic prescribed depend on clinical signs and symptoms and renal function. Careful patient monitoring and dose adjustments are necessary to balance the effectiveness of these medications with the side effects (Chart 30-2). Diuretics are administered IV for exacerbations of HF when rapid diuresis is necessary. Diuretics improve the patient's symptoms, provided that renal function is adequate (ICSI, 2006). As HF progresses, there may be a decline in renal function known as cardiorenal syndrome. Patients with this syndrome are resistant to diuretics and may require other interventions to deal with congestive signs and symptoms (Varughese, 2007).

Digitalis

The most commonly prescribed form of digitalis for patients with HF is digoxin (Lanoxin). Until recently, this medication was considered an essential agent for the treatment of HF, but with the advent of new medications, it may or may not be prescribed. Digoxin increases the force of myocardial contraction and slows conduction through the atrioventricular node. It improves contractility, increasing left ventricular output, which also enhances diuresis. Although the use of digitalis does not result in decreased mortality rates among patients with HF, it is effective in decreasing the symptoms of systolic HF and may help prevent hospitalization (ICSI, 2006).

A key concern associated with digitalis therapy is digitalis toxicity. Chart 30-3 summarizes the actions and uses of digoxin along with the nursing surveillance required when

it is administered. The patient is observed for indications that digitalis therapy is effective: lessening dyspnea and orthopnea, decrease in pulmonary crackles on auscultation, relief of peripheral edema, weight loss, and increase in activity tolerance. The serum potassium level is measured at intervals because the effect of digoxin is enhanced in the presence of hypokalemia and digoxin toxicity may occur. A serum digoxin level is obtained if there have been changes in the patient's renal function or symptoms.

Calcium Channel Blockers

First-generation calcium channel blockers, such as verapamil (Calan), nifedipine (Procardia), and diltiazem (Cardizem), are contraindicated in patients with systolic HF, although they may be used in patients with diastolic HF (ICSI, 2006). Amlodipine (Norvasc) and felodipine (Plendil), which are dihydropyridine calcium channel blockers, cause vasodilation, reducing systemic vascular resistance. They may be used to improve symptoms, especially in patients with nonischemic cardiomyopathy.

Intravenous Infusions

Nesiritide. Nesiritide (Natrecor), a BNP that is made using recombinant technology, is indicated for patients with acute decompensated HF. BNP's are produced by the failing myocardium to mount a compensatory response in the presence of the myocardial demands, including increased ventricular end-diastolic pressure, myocardial wall stress, and increased release of neurohormones (eg, norepinephrine, renin, aldosterone) that occur with HF. Specifically, BNP binds to vascular smooth muscle and endothelial cells, causing dilation of arteries and veins. It also suppresses the neurohormones responsible for fluid retention, thus promoting diuresis. The result is reduced preload and afterload and increased SV (Fontana, 2006).

Nesiritide causes rapid improvement in the symptoms of HF. It may be used to treat hospitalized patients with acute exacerbations or to prevent exacerbations in outpatients when given as a series of intermittent IV infusions. The most common side effect is dose-related hypotension.

CHART
30-2

PHARMACOLOGY

Administering and Monitoring Diuretic Therapy

When nursing care involves diuretic therapy for conditions such as heart failure, the nurse needs to administer the medication and monitor the patient's response carefully, as follows:

- Administer the diuretic at a time conducive to the patient's lifestyle; for example, early in the day to avoid nocturia.
- Give supplementary potassium with thiazide and loop diuretics as prescribed to replace potassium loss.
- Check laboratory results for electrolyte depletion, especially potassium, magnesium, and sodium; and for electrolyte elevation, especially potassium with potassium-sparing agents.
- Monitor daily weights, intake, and output to assess response. Monitor serum blood urea nitrogen and creatinine for increasing levels, which indicate renal dysfunction.
- Assess lung sounds, jugular vein distention, daily weight, and peripheral, abdominal, or sacral edema to identify response to therapy.
- Monitor for adverse reactions, such as nausea and gastrointestinal distress, vomiting, diarrhea, weakness, headache, fatigue, anxiety or agitation, and cardiac dysrhythmias.
- Assess for signs of volume depletion, such as postural hypotension, dizziness, and balance problems.
- Monitor for glucose intolerance in patients with and without diabetes mellitus who are receiving thiazide diuretics.
- Monitor for potential ototoxicity in patients, especially those with renal failure, who are receiving a loop diuretic.
- Advise patients to avoid prolonged exposure to the sun because of the risk of photosensitivity.
- Monitor for elevated serum uric acid levels and the development of gout.
- Implement nursing actions to facilitate effect of medication, such as positioning patient supine after dose is taken.

CHART
30-3

PHARMACOLOGY

Digoxin Use and Toxicity in Heart Failure

The therapeutic level of digoxin is usually 0.5 to 2.0 mg/mL. Blood samples are usually obtained and analyzed to determine digitalis concentration at least 6 to 10 hours after the last dose. Toxicity may occur despite normal serum levels, and recommended dosages vary considerably.

Preparations**Digoxin**

- Tablets: 0.125, 0.25, 0.5 mg (Lanoxin)
- Capsules: 0.05, 0.1, 0.2 mg (Lanoxicaps)
- Elixir: 0.05 mg/mL (Lanoxin Pediatric elixir)
- Injection: 0.25 mg/mL, 0.1 mg/mL (Lanoxin)

Digoxin Toxicity

A serious complication of digoxin therapy is toxicity. Diagnosis of digoxin toxicity is based on the patient's clinical symptoms, which include the following:

- Anorexia, nausea, vomiting, fatigue, depression, and malaise (early effects of digitalis toxicity)
- Changes in heart rate or rhythm; onset of irregular rhythm
- ECG changes indicating SA or AV block; new onset of irregular rhythm indicating ventricular dysrhythmias; and atrial tachycardia with block, junctional tachycardia, and ventricular tachycardia

Reversal of Toxicity

Digoxin toxicity is treated by holding the medication while monitoring the patient's symptoms and serum digoxin level. If the toxicity is severe, digoxin immune FAB (Digibind) may be prescribed. Digibind binds with digoxin and makes it unavailable for use. The Digibind dosage is based on the digoxin level and the patient's weight. Serum digoxin values are not accurate for several days after administration of Digibind because they do not differentiate between bound and unbound digoxin. Because Digibind quickly decreases the amount of available digoxin, an increase in ventricular rate due to atrial fibrillation and worsening of symptoms of HF may ensue shortly after its administration.

Nursing Considerations and Actions

1. Assess the patient's clinical response to digoxin therapy by evaluating relief of symptoms such as dyspnea, orthopnea, crackles, hepatomegaly, and peripheral edema.
2. Monitor the patient for factors that increase the risk of toxicity:
 - Decreased potassium level (hypokalemia), which may be caused by diuretics. Hypokalemia increases the action of digoxin and predisposes patients to digoxin toxicity and dysrhythmias.
 - Use of medications that enhance the effects of digoxin, including oral antibiotics and cardiac drugs that slow AV conduction and can further decrease heart rate.
 - Impaired renal function, particularly in patients age 65 and older. Because digoxin is eliminated by the kidneys, renal function (serum creatinine) is monitored and doses of digoxin are adjusted accordingly.
3. Before administering digoxin, it is standard nursing practice to assess apical heart rate. When the patient's rhythm is atrial fibrillation and the heart rate is less than 60 bpm, or the rhythm becomes regular, the nurse may withhold the medication and notify the physician, because these signs indicate the development of AV conduction block. Although withholding digoxin is a common practice, the medication does not need to be withheld for a heart rate of less than 60 bpm if the patient is in sinus rhythm because digoxin does not affect SA node automaticity. Measuring the PR interval for a patient with cardiac monitoring is more important than the apical pulse in determining whether digoxin should be held.
4. Monitor for gastrointestinal side effects: anorexia, nausea, vomiting, abdominal pain, and distention.
5. Monitor for neurologic side effects: headache, malaise, nightmares, forgetfulness, social withdrawal, depression, agitation, confusion, paranoia, hallucinations, decreased visual acuity, yellow or green halo around objects (especially lights), or "snowy" vision.

AV, atrioventricular; bpm, beats per minute; ECG, electrocardiogram; HF, heart failure; SA, sinoatrial.

Milrinone. Milrinone (Primacor) is a phosphodiesterase inhibitor that delays the release of calcium from intracellular reservoirs and prevents the uptake of extracellular calcium by the cells. This promotes vasodilation, resulting in decreased preload and afterload and reduced cardiac workload. Milrinone is administered intravenously if the patient has not responded to other therapies. The major side effects are hypotension, gastrointestinal dysfunction, increased ventricular dysrhythmias, and, rarely, decreased platelet counts. Blood pressure is monitored closely during and following infusions of milrinone.

Dobutamine. Dobutamine (Dobutrex) is an IV medication administered to patients with significant left ventricular dysfunction and hypoperfusion. A catecholamine, dobutamine stimulates the beta-1-adrenergic receptors. Its major action is to increase cardiac contractility. However, at high doses, it also increases the heart rate and can precipitate ectopic beats and tachydysrhythmias. Because it also increases

atrioventricular conduction, care must be taken in patients who have underlying atrial fibrillation.

IV inotropes such as dobutamine and milrinone are reserved for patients with severe ventricular dysfunction, who must be monitored continuously via ECG. Some patients require admission to the intensive care unit and hemodynamic monitoring with a pulmonary artery catheter or impedance cardiography. A form of noninvasive monitoring, impedance cardiography uses external electrodes placed on the chest that generate a small current between the electrodes to assess fluid status and cardiac output (Folan & Funk, 2008). Hemodynamic data guide therapy and assess patient response (Varughese, 2007).

Medications for Diastolic Dysfunction

Patients with predominant diastolic HF may be treated with different medications than indicated for patients with systolic HF. After contributing causes such as hypertension and

ischemic heart disease are evaluated and treated, patients may be started on beta-blockers and other HF medications. An effort is made to restore normal sinus rhythm in patients with concomitant atrial fibrillation (Hunt, et al., 2005).

Other Medications for Heart Failure

Anticoagulants may be prescribed, especially if the patient has a history of atrial fibrillation or a thromboembolic event. Medications that manage hyperlipidemia (eg, statins) are also routinely prescribed for the HF population (Albert, 2006). Nonsteroidal anti-inflammatory drugs (NSAIDs) such as ibuprofen (Motrin) should be avoided because they decrease renal perfusion, especially in the elderly.

Nutritional Therapy

A low-sodium (2 to 3 g/day) diet and avoidance of drinking excessive amounts of fluid are usually recommended. Dietary restriction of sodium reduces fluid retention and the symptoms of peripheral and pulmonary congestion. The purpose of sodium restriction is to decrease the amount of circulating blood volume, which decreases myocardial work. A balance needs to be achieved between the ability of the patient to comply with the diet and the recommended dietary restriction. Any change in diet needs to be made with consideration of good nutrition as well as the patient's likes, dislikes, and cultural food patterns. Patient compliance is important because dietary indiscretions may result in severe exacerbations of HF requiring hospitalization (Albert, 2005). However, behavioral changes in this area are difficult for many patients.

Additional Therapy

Supplemental Oxygen

Oxygen therapy may become necessary as HF progresses. The need is based on the degree of pulmonary congestion and resulting hypoxia. Some patients require supplemental oxygen only during periods of activity.

Other Interventions

A number of procedures and surgical approaches may benefit patients with HF. If the patient has underlying coronary artery disease, coronary artery revascularization with percutaneous coronary intervention or coronary artery bypass surgery (see Chapter 28) may be considered. Ventricular function may improve in some patients when coronary flow is increased.

Patients with HF are at high risk for dysrhythmias. Sudden cardiac death is a common cause of death among patients with advanced HF (Jensen, Galvin, Thompson, et al., 2007). In patients with severe left ventricular dysfunction and the possibility of life-threatening dysrhythmias, placement of an implantable cardioverter defibrillator (ICD) can prevent sudden cardiac death and extend survival (Ezekowitz, Rowe, Dryden, et al., 2007).

In the patient with HF who does not improve with standard therapy, **cardiac resynchronization therapy (CRT)** is another treatment that may be beneficial. CRT involves the use of a biventricular pacemaker to treat electrical conduction defects. Left bundle branch block, a type of delayed conduction that is frequently seen in patients with HF,

results in dyssynchronous conduction and contraction of the right and left ventricles, which can further decrease EF (Jensen, et al., 2007). Use of a pacing device with leads placed in the right atrium, right ventricle, and left ventricular cardiac vein can synchronize the contractions of the right and left ventricles. This intervention has been shown to improve cardiac output, optimize myocardial energy consumption, reduce mitral regurgitation, and slow the ventricular remodeling process. For selected patients, this results in fewer symptoms and increased functional status (Saul, 2007). Combination devices are available for patients who require CRT and an ICD.

Ultrafiltration is an alternative intervention for patients with severe fluid overload. A dual-lumen central IV catheter is used, which could be a peripherally inserted central catheter or a midline or central catheter, and the patient's blood is circulated through a small bedside machine. Liters of excess fluid and plasma are removed slowly from the patient's intravascular circulating volume over a number of hours. This fluid is then discarded, and the filtered blood products are returned to the patient (Constanzo, Saltzberg, O'Sullivan, et al., 2005; Soat, 2008; Walsh & Wagemester, 2007).

For some patients with end-stage HF, cardiac transplantation is the only option for long-term survival. Some of these patients require mechanical circulatory assistance with an implanted ventricular assist device as a bridge therapy to cardiac transplantation (see Chapter 29).

Gerontologic Considerations

Several normal age-related changes increase the frequency of HF: increased systolic blood pressure, increased ventricular wall thickness, and increased myocardial fibrosis. Elderly people may present with atypical signs and symptoms: fatigue, weakness, and somnolence. Decreased renal function makes the elderly patient resistant to diuretics and more sensitive to changes in volume. The administration of diuretics to elderly men requires nursing surveillance for bladder distention caused by urethral obstruction from an enlarged prostate gland. The bladder may be assessed with an ultrasound scanner or the suprapubic area palpated for an oval mass and percussed for dullness, indicative of bladder fullness. Urinary frequency and urgency may be particularly stressful to the elderly patient.

NURSING PROCESS

THE PATIENT WITH HEART FAILURE

Despite advances in treatment of HF, morbidity and mortality remains high. Nurses have a major impact on outcomes for patients with HF.

Assessment

The nursing assessment for the patient with HF focuses on observing for effectiveness of therapy and for the patient's ability to understand and implement self-management strategies. Signs and symptoms of pulmonary and systemic fluid overload are recorded and reported immediately so that adjustments can be made in therapy. The nurse also

explores the patient's emotional response to the diagnosis of HF because it is a chronic and often progressive condition.

Health History

The health history focuses on the signs and symptoms of HF, such as dyspnea, shortness of breath, fatigue, and edema. Sleep disturbances, particularly sleep suddenly interrupted by shortness of breath, may be reported. Patients are asked about the number of pillows needed for sleep, edema, abdominal symptoms, altered mental status, activities of daily living, and the activities that cause fatigue. The nurse explores each patient's understanding of HF, self-management strategies, and the ability and willingness to adhere to those strategies. Patients are asked to identify the impact that HF has had on their quality of life and successful coping skills that they have used. Family and significant others are often included in these discussions.

Physical Examination

The lungs are auscultated to detect crackles and wheezes. Crackles are produced by the sudden opening of edematous small airways and alveoli. They may be heard at the end of inspiration and are not cleared with coughing. Wheezing may also be heard in some patients. The rate and depth of respirations are also documented.

The heart is auscultated for an S₃ heart sound, a sign that the heart is beginning to fail and that increased blood volume fills the ventricle with each beat. HR and rhythm are also documented. When the heart rate is rapid, the SV decreases because the ventricle has less time to fill. This in turn produces increased pressure in the atria and eventually in the pulmonary vascular bed.

JVD is also assessed; distention greater than 3 cm above the sternal angle is considered abnormal. This is an estimate, not a precise measurement, of central venous pressure.

Sensorium and level of consciousness must be evaluated. As the volume of blood ejected by the heart decreases, so does the amount of oxygen transported to the brain.

The nurse assesses dependent parts of the patient's body for perfusion and edema. With significant decreases in SV, there is a decrease in perfusion to the periphery, causing the skin to feel cool and appear pale or cyanotic. The feet and lower legs are examined for edema; if the patient is supine in bed, the sacrum and back are also assessed for edema. Fingers and hands may also become edematous.

The liver is assessed for hepatojugular reflux. The patient is asked to breathe normally while manual pressure is applied over the right upper quadrant of the abdomen for 30 to 60 seconds. If neck vein distention increases more than 1 cm, the finding is positive for increased venous pressure.

If the patient is hospitalized, the nurse measures urinary output carefully to establish a baseline against which to assess the effectiveness of diuretic therapy. Intake and output records are rigorously maintained. It is important to know whether the patient has ingested more fluid than he or she has excreted (positive fluid balance), which is then compared with any gain in weight. The patient must be monitored for oliguria (diminished urine output, less than 500 mL/24 h) or **anuria** (urine output less than 50 mL/24 h).

The patient is weighed daily in the hospital or at home, at the same time of day, with the same type of clothing, and

on the same scale. If there is a significant change in weight (ie, 2- to 3-lb increase in a day or 5-lb increase in a week), the physician is notified and medications are adjusted (eg, the diuretic dose is increased).

Diagnosis

Nursing Diagnoses

Based on the assessment data, major nursing diagnoses for the patient with HF may include the following:

- Activity intolerance and fatigue related to decreased CO
- Excess fluid volume related to the HF syndrome
- Anxiety related to breathlessness from inadequate oxygenation
- Powerlessness related to chronic illness and hospitalizations
- Ineffective therapeutic regimen management related to lack of knowledge

Collaborative Problems/Potential Complications

Based on the assessment data, potential complications that may develop include the following:

- Hypotension, poor perfusion, and cardiogenic shock (see Chapter 15)
- Dysrhythmias (see Chapter 27)
- Thromboembolism (see Chapter 31)
- Pericardial effusion and cardiac tamponade (see Chapter 29)

Planning and Goals

Major goals for the patient may include promoting activity and reducing fatigue, relieving fluid overload symptoms, decreasing anxiety or increasing the patient's ability to manage anxiety, encouraging the patient to verbalize his or her ability to make decisions and influence outcomes, and teaching the patient about the self-care program.

Nursing Interventions

Promoting Activity Tolerance

Reduced physical activity caused by HF symptoms leads to physical deconditioning that worsens the patient's symptoms and exercise tolerance. Prolonged bed rest, which may be self-imposed, should be avoided because of its deconditioning effects and risks such as pressure ulcers (especially in edematous patients), venous thrombosis, and pulmonary embolism. An acute illness that exacerbates HF symptoms or that requires hospitalization may be an indication for temporary bed rest. Otherwise, a total of 30 minutes of physical activity every day should be encouraged (HFSA, 2006). Exercise training has many favorable effects for HF, including increasing functional capacity and decreasing dyspnea. The exercise regimen should include 5 minutes of warm-up activities followed by about 30 minutes of exercise at the prescribed intensity level. A typical program for a patient with HF might include a daily walking regimen, with duration increased over a 6-week period. The physician, nurse, and patient collaborate to develop a schedule that promotes pacing and prioritization of activities. The schedule should alternate activities with periods of rest and avoid having two significant energy-consuming activities occur on the same day or in immediate succession.

Before undertaking physical activity, the patient should be given the following safety guidelines:

- Begin with a few minutes of warm-up activities.
- Avoid performing physical activities outside in extreme hot, cold, or humid weather.
- Ensure that you are able to talk during the physical activity; if you cannot do so, decrease the intensity of activity.
- Wait 2 hours after eating a meal before performing the physical activity.
- Stop the activity if severe shortness of breath, pain, or dizziness develops.
- End with cool-down activities and a cool-down period.

Because some patients may be severely debilitated, they may need to limit physical activities to only 3 to 5 minutes at a time, one to four times per day. The patient should increase the duration of the activity, then the frequency, before increasing the intensity of the activity.

Barriers to performing other activities are identified, and methods of adjusting an activity are discussed. For example, vegetables can be chopped or peeled while sitting at the kitchen table rather than standing at the kitchen counter. Small, frequent meals decrease the amount of energy needed for digestion while providing adequate nutrition. The nurse helps the patient identify peak and low periods of energy, planning energy-consuming activities for peak periods. For example, the patient may prepare the meals for the entire day in the morning. Pacing and prioritizing activities help maintain the patient's energy to allow participation in regular physical activity.

The patient's response to activities needs to be monitored. If the patient is hospitalized, vital signs and oxygen saturation level are monitored before, during, and immedi-

ately after an activity to identify whether they are within the desired range. HR should return to baseline within 3 minutes following the activity. If the patient is at home, the degree of fatigue felt after the activity can be used to assess the response. If the patient tolerates the activity, short-term and long-term goals can be developed to gradually increase the intensity, duration, and frequency of activity.

Adherence to exercise training is essential if the patient is to benefit from it, but it may be difficult for patients with other conditions (eg, arthritis) and longer duration of heart failure. Referral to a cardiac rehabilitation program may be needed, especially for HF patients with recent myocardial infarction, recent open heart surgery, or increased anxiety. A supervised program may also benefit those who need a structured environment, significant educational support, regular encouragement, and interpersonal contact.

Managing Fluid Volume

Patients with severe HF may receive IV diuretic therapy, but patients with less severe symptoms may receive oral diuretic medication. Oral diuretics should be administered early in the morning so that diuresis does not interfere with the patient's nighttime rest. Discussing the timing of medication administration is especially important for elderly patients who may have urinary urgency or incontinence. A single dose of a diuretic may cause the patient to excrete a large volume of fluid shortly after its administration.

The patient's fluid status is monitored closely, auscultating the lungs, monitoring daily body weight, and assisting the patient to adhere to a low-sodium diet by reading food labels and avoiding high-sodium foods such as canned, processed, and convenience foods (Chart 30-4). If the diet

CHART
30-4

HEALTH PROMOTION Facts About Dietary Sodium

Although the major source of sodium in the average American diet is salt, many types of natural foods contain varying amounts of sodium. Even if no salt is added in cooking and if salty foods are avoided, the daily diet will still contain about 2000 mg of sodium. Fresh fruits and vegetables are low in sodium and should be encouraged.

Additives in Food

In general, food prepared at home is lower in sodium than restaurant or processed foods. Added food substances (additives), such as sodium alginate, which improves food texture; sodium benzoate, which acts as a preservative; and disodium phosphate, which improves cooking quality in certain foods, increase the sodium intake when included in the daily diet. Therefore, patients on low-sodium diets should be advised to check labels carefully for such words as "salt" or "sodium," especially on canned foods. For example, without looking at the sodium content per serving found on the nutrition labels, when given a choice between a serving of potato chips and a cup of canned cream of mushroom soup, most would think that soup is lower in sodium. However, when the labels are examined, the lower sodium choice is found to be the chips. Although potato chips are *not* recommended in a low sodium diet, this example illustrates that it is important to read food labels to determine both sodium content and serving size.

Nonfood Sodium Sources

Sodium is also contained in municipal water. Water softeners also increase the sodium content of drinking water. Patients on sodium-restricted diets should be cautioned against using nonprescription medications such as antacids, cough syrups, and laxatives. Salt substitutes may be allowed, but it is recognized that they are high in potassium. Over-the-counter medications should not be used without first consulting the physician.

Promoting Dietary Adherence

If patients find food unpalatable because of the dietary sodium restrictions and/or the taste disturbances caused by the medications, they may refuse to eat or to comply with the dietary regimen. For this reason, severe sodium restrictions should be avoided and the amount of medication should be balanced with the patient's ability to restrict dietary sodium. A variety of flavorings, such as lemon juice, vinegar, and herbs, may be used to improve the taste of the food and facilitate acceptance of the diet. The patient's food preferences should be taken into account—diet counseling and educational handouts can be geared to individual and ethnic preferences. It is very important to involve the family in the dietary teaching.

includes fluid restriction, the nurse can assist the patient to plan fluid intake throughout the day while respecting the patient's dietary preferences. If the patient is receiving IV fluids, the amount of fluid needs to be monitored closely, and the physician or pharmacist can be consulted about the possibility of maximizing the amount of medication in the same volume of IV fluid (eg, double concentrating to decrease the fluid volume administered).

The patient is positioned or taught how to assume a position that facilitates breathing. The number of pillows may be increased, the head of the bed may be elevated, or the patient may sit in a comfortable armchair. In these positions, the venous return to the heart (preload) is reduced, pulmonary congestion is alleviated, and pressure on the diaphragm is minimized. The lower arms are supported with pillows to eliminate the fatigue caused by the pull of the patient's weight on the shoulder muscles.

Because decreased circulation in edematous areas increases the risk of pressure ulcers, the nurse assesses for skin breakdown and institutes preventive measures. Frequent changes of position, positioning to avoid pressure, and leg exercises may help prevent pressure ulcers.

Controlling Anxiety

Because patients with HF have difficulty maintaining adequate oxygenation, they are likely to be restless and anxious and feel overwhelmed by breathlessness. These symptoms tend to intensify at night and may interfere with sleep. Emotional stress stimulates the sympathetic nervous system, which causes vasoconstriction, elevated arterial pressure, and increased heart rate. This sympathetic response increases the cardiac workload. By decreasing anxiety, the patient's cardiac workload also is decreased. Oxygen may be administered during an acute event to diminish the work of breathing and to increase the patient's comfort.

When the patient exhibits anxiety, the nurse takes steps to promote physical comfort and provide psychological support. In many cases, a family member's presence provides reassurance. Pet visitation or animal-assisted therapy can also be beneficial (Cole, 2007).

Along with reassurance, the nurse can begin teaching the patient ways to control anxiety and avoid anxiety-provoking situations. The patient learns how to identify factors that contribute to anxiety and how to use relaxation techniques to control anxious feelings. As the patient's anxiety decreases, cardiac function may improve and symptoms of HF may decrease.

NURSING ALERT

In cases of confusion and anxiety reactions that affect the patient's safety, the use of restraints should be avoided. Restraints are likely to be resisted, and resistance inevitably increases the cardiac workload.

The patient who insists on getting out of bed at night can be seated comfortably in an armchair. As cerebral and systemic circulation improves, the degree of anxiety decreases and the quality of sleep improves.

In addition to anxiety, patients with HF have a high incidence of depression; depression is associated with

increased morbidity and mortality in patients with HF (Jiang, Kuchibhatia, Clary, et al., 2007). Patients with HF should be screened for this condition.

Minimizing Powerlessness

Patients need to recognize that they are not helpless and that they can influence the direction of their lives and the outcomes of treatment. The patient is assessed for factors that contribute to a sense of powerlessness. Contributing factors may include lack of knowledge and lack of opportunities to make decisions, particularly if health care providers and family members behave in controlling ways. If the patient is hospitalized, hospital policies may limit the patient's ability to make decisions (eg, what time to have meals or to take medications).

Taking time to listen actively to patients encourages them to express their concerns and ask questions. Other strategies include providing the patient with decision-making opportunities, such as when activities are to occur or encouraging food and fluid choices consistent with the dietary restrictions. Encouragement is provided, progress is identified, and the patient is assisted to differentiate between factors that can and cannot be controlled.

Monitoring and Managing Potential Complications

Many potential problems associated with HF therapy relate to the use of diuretics:

- Excessive and repeated diuresis can lead to hypokalemia (ie, potassium depletion). Signs include ventricular dysrhythmias, hypotension, muscle weakness, and generalized weakness. Hypokalemia poses problems for the patient with HF because it markedly weakens cardiac contractions. In patients receiving digoxin, hypokalemia can lead to digitalis toxicity. Digitalis toxicity and hypokalemia increase the likelihood of dangerous dysrhythmias (see Chart 30-3). Patients with HF may also develop low levels of magnesium, which can add to the risk of dysrhythmias.
- Hyperkalemia may occur, especially with the use of ACE inhibitors, ARBs, or spironolactone.
- Prolonged diuretic therapy may produce hyponatremia (deficiency of sodium in the blood), which results in disorientation, apprehension, weakness, fatigue, malaise, and muscle cramps.
- Volume depletion from excessive fluid loss may lead to dehydration and hypotension. ACE inhibitors and beta-blockers may contribute to the hypotension.
- Other problems associated with diuretics include increased serum creatinine and hyperuricemia (excessive uric acid in the blood), which leads to gout.

Promoting Home and Community-Based Care

TEACHING PATIENTS SELF-CARE. The nurse provides patient education and involves the patient in the therapeutic regimen to promote understanding and adherence to the plan. When the patient recognizes that the diagnosis of HF can be successfully managed with lifestyle changes and medications, recurrences of acute HF lessen, unnecessary hospitalizations decrease, and life expectancy increases. The Joint Commission and other agencies have established standards pertaining to the education of patients with HF.

Nurses teach patients and their families about medication management, low-sodium diets, activity and exercise recommendations, smoking cessation, learning to recognize the signs and symptoms of worsening HF, and when to contact a health care provider (Albert, 2006; Varughese, 2007). Although noncompliance is not well understood, interventions that may promote compliance include teaching to ensure accurate understanding. A basic home teaching plan for the patient with HF is presented in Chart 30-5.

The patient and family members are supported and encouraged to ask questions so that information can be clarified and understanding enhanced. It is important to be aware of cultural factors and adapt the teaching plan accordingly. Patients and their families need to be informed that the progression of the disease is influenced in part by choices made about health care and the decisions about following the treatment plan. They also need to be informed that health care providers are available to assist them in reaching their health care goals. Patients and family members need to make the decisions about the treatment plan and need to understand the possible outcomes of those

decisions. The treatment plan is based on the patient's goals rather than on what health care providers think is needed.

CONTINUING CARE. Success in management of HF requires a complex medical regimen and multiple lifestyle changes. Assistance may be provided through home health care, an HF clinic, or telehealth management.

Depending on the patient's physical status and the availability of family assistance, a home care referral may be indicated for a patient who has been hospitalized. Elderly patients and those who have long-standing heart disease with compromised physical stamina often require assistance with the transition to home after hospitalization for an acute episode of HF. The home care nurse assesses the physical environment of the home and makes suggestions for adapting the home environment to meet the patient's activity limitations. If stairs are a concern, the patient can plan the day's activities so that stair climbing is minimized; for some patients, a temporary bedroom may be set up on the main level of the home. The home care nurse works with the patient and family to maximize the benefits of these changes.

The home care nurse also reinforces and clarifies information about dietary changes and fluid restrictions, the

HOME CARE CHECKLIST *The Patient With Heart Failure*

At the completion of the home care instruction, the patient or caregiver will be able to:	PATIENT	CAREGIVER
• Identify heart failure as a chronic disease that can be managed with medications and specific self-management behaviors.	✓	✓
• Take or administer medications daily, exactly as prescribed.	✓	✓
• Monitor effects of medication such as changes in breathing and edema.	✓	✓
• Know signs and symptoms of orthostatic hypotension and how to prevent it.	✓	✓
• Weigh self daily at the same time with same clothes.	✓	
• Restrict sodium intake to 2000–3000 mg daily; adapt diet by examining nutrition labels to check sodium content per serving; avoid canned or processed foods; eat fresh or frozen foods; consult the written diet plan and the list of permitted and restricted foods; avoid salt use; and avoid excesses in eating and drinking.	✓	✓
• Review activity program. <ul style="list-style-type: none"> • Participate in a daily exercise program. • Increase walking and other activities gradually, provided they do not cause unusual fatigue or dyspnea. • Conserve energy by balancing activity with rest periods. • Avoid activity in extremes of heat and cold, which increase the work of the heart. • Recognize that air conditioning may be essential in a hot, humid environment. 	✓	
• Develop methods to manage and prevent stress. <ul style="list-style-type: none"> • Avoid tobacco. • Avoid alcohol. • Engage in diversional activities, meditation, guided imagery, or music therapy. 	✓	
• Keep regular appointments with physician or clinic.	✓	✓
• Be alert for symptoms that may indicate recurring heart failure. <ul style="list-style-type: none"> • Know how to contact health care provider. 	✓	✓
• Report immediately to the physician or clinic any of the following: <ul style="list-style-type: none"> • Gain in weight of 2–3 lb (0.9–1.4 kg) in 1 day, or 5 lb (2.3 kg) in 1 week. • Loss of appetite. • Unusual shortness of breath with activity. • Swelling of ankles, feet, or abdomen. • Persistent cough. • Development of restless sleep; increase in number of pillows needed to sleep. 	✓	✓

need to monitor symptoms and daily body weights, and the importance of obtaining follow-up health care. Assistance may be given in scheduling and keeping appointments as well. The patient is encouraged to gradually increase his or her self-care and responsibility for carrying out the therapeutic regimen. Assistance from home health nurses can result in fewer exacerbations of HF, lower costs, and improved quality of life (Anderson, 2007).

Disease management programs are important components in the successful management of HF (HFSA, 2006). HF clinics offer individualized disease management strategies. Referral to an HF clinic gives the patient access to education, professional staff, and timely adjustments to treatment regimens. Research has shown that patients managed through HF clinics have fewer exacerbations of HF, fewer hospitalizations, decreased costs of medical care, and increased quality of life (HFSA, 2006).

Telehealth management can provide the frequent contact necessary to manage HF without requiring frequent visits to health care providers. A variety of techniques ranging from simple telephone monitoring to sophisticated computer and video connections that monitor daily weight, vital signs, and symptoms may be used. Telehealth management can also decrease costs and hospitalizations for exacerbations of HF.

END-OF-LIFE CONSIDERATIONS. Because HF is a chronic and often progressive condition, patients and families need to consider issues related to the end of life. Although the prognosis in HF patients may be uncertain, issues often arise sooner or later related to the patient's thoughts and possible concerns about the use of complex treatment options (eg, ultrafiltration for fluid overload, implantation of a ventricular assist device). Discussions concerning the use of technology, preferences for end-of-life care, and advance directives should take place while the patient is able to participate and express preferences (Dougherty, Pyper, Au, et al., 2007).

Evaluation

Expected Patient Outcomes

1. Demonstrates tolerance for increased activity
 - a. Describes adaptive methods for usual activities
 - b. Schedules activities to conserve energy and reduce fatigue and dyspnea
 - c. Maintains heart rate, blood pressure, respiratory rate, and pulse oximetry within the targeted range
2. Maintains fluid balance
 - a. Exhibits decreased peripheral and sacral edema
 - b. Demonstrates methods for preventing edema
3. Is less anxious
 - a. Avoids situations that produce stress
 - b. Sleeps comfortably at night
 - c. Reports decreased stress and anxiety
 - d. Denies symptoms of depression
4. Makes sound decisions regarding care and treatment
 - a. Demonstrates ability to influence outcomes
5. Adheres to self-care regimen
 - a. Performs and records daily weights
 - b. Ensures dietary intake includes no more than 2 to 3 g of sodium per day
 - c. Takes medications as prescribed
 - d. Reports any unusual symptoms or side effects

Pulmonary Edema

Pulmonary edema is the abnormal accumulation of fluid in the interstitial spaces of the lungs that diffuses into the alveoli.

Pathophysiology

Pulmonary edema is an acute event that results from left ventricular failure. It can occur acutely, such as with MI, or it can occur as an exacerbation of chronic HF. Myocardial scarring can limit the distensibility of the ventricle and render it vulnerable to a sudden increase in workload. With increased resistance to left ventricular filling, blood backs up into the pulmonary circulation. The patient quickly develops pulmonary edema, sometimes called “flash pulmonary edema,” from the blood volume overload in the lungs. Pulmonary edema can also be caused by noncardiac disorders, such as renal failure, and other conditions that cause the body to retain fluid. The pathophysiology is similar to that seen in HF, in that the left ventricle cannot handle the volume overload and blood volume and pressure buildup in the left atrium. The rapid increase in atrial pressure results in an acute increase in pulmonary venous pressure, which produces an increase in hydrostatic pressure that forces fluid out of the pulmonary capillaries into the interstitial spaces and alveoli. Lymphatic drainage of the excess fluid is ineffective.

The fluid within the alveoli mixes with air, producing the classic symptom of pulmonary edema—frothy pink (blood-tinged) sputum. The fluid within the alveoli creates a diffusion block that severely impairs gas exchange. The result is hypoxemia, which is often severe. The onset may be preceded by premonitory symptoms of pulmonary congestion, but the condition also may develop quickly in the patient with a ventricle that has little reserve to meet increased oxygen needs.

Clinical Manifestations

As a result of decreased cerebral oxygenation, the patient becomes increasingly restless and anxious. Along with a sudden onset of breathlessness and a sense of suffocation, the patient's hands become cold and moist, the nail beds become cyanotic (bluish), and the skin turns ashen (gray). The pulse is weak and rapid, and the neck veins are distended. Incessant coughing may occur, producing increasing quantities of foamy sputum. As pulmonary edema progresses, the patient's anxiety and restlessness increase; the patient becomes confused, then stuporous. Breathing is rapid, noisy, and moist sounding. The patient's oxygen saturation is significantly decreased. The patient, nearly suffocated by the blood-tinged, frothy fluid filling the alveoli, is literally drowning in secretions. The situation demands emergent action.

Assessment and Diagnostic Findings

The diagnosis is made by evaluating the clinical manifestations resulting from pulmonary congestion. A chest x-ray may be obtained to confirm the extent of pulmonary vessel and tissue engorgement. Abrupt onset of signs of left-sided HF (eg, crackles on auscultation of the lungs) may occur without evidence of right-sided HF (eg, no JVD, no dependent edema).

Prevention

Like many emergent conditions, pulmonary edema is easier to prevent than to treat. To recognize it in its early stages, the nurse assesses the degree of dyspnea, auscultates the lung fields and heart sounds, and assesses the degree of peripheral edema. A hacking cough, fatigue, weight gain, development or worsening of edema, and decreased activity tolerance may be early indicators of developing pulmonary edema.

In its early stage, pulmonary edema may be alleviated by placing the patient in an upright position with the feet and legs dependent, eliminating overexertion, and minimizing emotional stress to reduce the left ventricular load. The treatment regimen and the patient's understanding of and adherence to it are assessed. The long-range approach to preventing pulmonary edema must be directed at identifying its precipitating factors.

Medical Management

Clinical management of a patient with acute pulmonary edema due to left ventricular failure is directed toward reducing volume overload, improving ventricular function, and increasing respiratory exchange (ICSI, 2006). These goals are accomplished through a combination of oxygen and ventilatory support, IV medications, and nursing interventions.

Oxygen Therapy

Oxygen is administered in concentrations adequate to relieve hypoxemia and dyspnea. A face mask is used initially. If respiratory failure is severe or persists, continuous positive airway pressure may be tried (see Chapter 25 for further discussion). For some patients, endotracheal intubation and mechanical ventilation are required. The ventilator can provide positive end-expiratory pressure, which is effective in reducing venous return, decreasing fluid movement from the pulmonary capillaries to the alveoli, and improving oxygenation. Oxygenation is monitored by pulse oximetry and by measurement of arterial blood gases.

Morphine

Morphine is titrated intravenously in small doses (2 to 5 mg) to reduce peripheral resistance and venous return so that blood can be redistributed from the pulmonary circulation to other parts of the body. This decreases pressure in the pulmonary capillaries and diffusion of fluid into the lung tissue. In addition, morphine reduces anxiety, which is also beneficial.

Diuretics

Diuretics promote the excretion of sodium and water by the kidneys. For example, furosemide is administered by IV push or as a continuous infusion to produce a rapid diuretic effect. Furosemide also causes vasodilation and pooling of blood in peripheral blood vessels, which reduces the amount of blood returned to the heart. Other diuretics such as metolazone may be administered as second-line therapy (ICSI, 2006).

Intravenous Infusions

Vasodilators such as IV nitroglycerin or nitroprusside (Nipride) may enhance symptom relief in pulmonary edema (HFSA, 2006). As described earlier in this chapter, a con-

tinuous infusion of nesiritide may also be prescribed for the patient with acute decompensated heart failure.

Nursing Management

Positioning the Patient to Promote Circulation

Proper positioning can help reduce venous return to the heart. The patient is positioned upright, preferably with the legs dangling over the side of the bed. This has the immediate effect of decreasing venous return, decreasing right ventricular stroke volume, and decreasing lung congestion.

Providing Psychological Support

As the ability to breathe decreases, the patient's fear and anxiety rise proportionately, making the condition more severe. Reassuring the patient and providing skillful anticipatory nursing care are integral parts of the therapy. Because the patient has an unstable condition, the nurse must remain with the patient. The nurse gives the patient simple, concise information in a reassuring voice about what is being done to treat the condition and the expected results.

Monitoring Medications

The patient receiving morphine is observed for respiratory depression, hypotension, and vomiting; a morphine antagonist, such as naloxone hydrochloride (Narcan), is kept available and given to the patient who exhibits serious respiratory depression.

The patient receiving diuretic therapy may excrete a large volume of urine within minutes after a potent diuretic is administered. A bedside commode may be used to decrease the energy required by the patient and to reduce the resultant increase in cardiac workload induced by getting on and off a bedpan. If necessary, an indwelling urinary catheter may be inserted.

The patient receiving continuous IV infusions of vasoactive medications requires ECG monitoring and frequent measurement of vital signs.

OTHER COMPLICATIONS

Cardiogenic Shock

Cardiogenic shock occurs when decreased CO leads to inadequate tissue perfusion and initiation of the shock syndrome. Cardiogenic shock may occur following MI when a large area of myocardium becomes ischemic and hypokinetic. It also can occur as a result of end-stage HF, cardiac tamponade, pulmonary embolism, cardiomyopathy, and dysrhythmias. Cardiogenic shock is a life-threatening condition with a high mortality rate. Chapter 15 provides detailed information about the pathophysiology and assessment of cardiogenic shock.

Medical Management

Goals in the treatment of cardiogenic shock include correcting the underlying problem, reducing any further demand on the heart, improving oxygenation, and restoring tissue perfusion. Chapter 15 discusses medical and pharmacologic management of cardiogenic shock; mechanical circulatory assistive devices are discussed below.

Mechanical Circulatory Assistive Devices

Therapeutic modalities for cardiogenic shock include the use of circulatory assist devices, such as the intra-aortic balloon pump (IABP). The IABP is a catheter with an inflatable balloon at the end. The catheter is usually inserted through the femoral artery, and the balloon is positioned in the descending thoracic aorta (Fig. 30-4). The IABP uses internal counterpulsation through the regular inflation and deflation of the balloon to augment the pumping action of the heart. It inflates during diastole, increasing the pressure in the aorta during diastole and therefore increasing blood flow through the coronary and peripheral arteries. It deflates just before systole, lessening the pressure within the aorta before left ventricular contraction, decreasing the amount of resistance the heart has to overcome to eject blood and therefore decreasing the amount of work the heart must put forth to eject blood. The device is connected to a console that synchronizes the inflation and deflation of the balloon with the ECG or the arterial pressure (as indicators for systole and diastole). Hemodynamic monitoring is often used to determine the patient's response to the IABP.

Other ventricular assist devices for long-term support of the failing heart are described in Chapter 29.

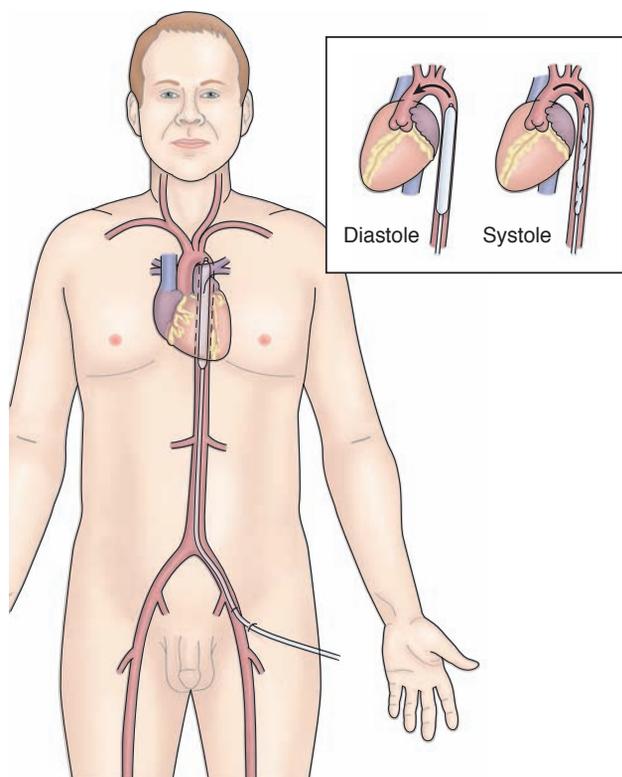

Figure 30-4 The intra-aortic balloon pump inflates at the beginning of diastole, which results in increased perfusion of the coronary and peripheral arteries. It deflates just before systole, which results in a decrease in afterload (resistance to ejection) and in the left ventricular workload.

Nursing Management

The patient in cardiogenic shock requires constant monitoring. Because of the frequency of nursing interventions and the technology required for effective patient management, the patient is treated in an intensive care unit. The critical care nurse must carefully assess the patient, observe the cardiac rhythm, monitor hemodynamic parameters, monitor fluid status, and adjust medications and therapies based on the assessment data. The patient is continuously evaluated for responses to the medical interventions and for the development of complications, so that problems can be addressed immediately.

Thromboembolism

The decreased mobility of the patient with cardiac disease and the impaired circulation that accompany these disorders contribute to the development of intracardiac and intravascular thrombosis. Intracardiac thrombi are especially common in patients with atrial fibrillation, because the atria do not contract forcefully and blood flows slowly and turbulently, increasing the likelihood of thrombus formation. Intracardiac thrombi are detected by an echocardiogram and treated with anticoagulants, such as heparin and warfarin (Coumadin). Adverse effects of thromboemboli are discussed in detail in Chapter 31.

Pulmonary Embolism

Pulmonary embolism is the most common thromboembolic problem among patients with HF. It poses a particular threat to people with cardiovascular disease (ICSI, 2006). Blood clots may form in the deep veins of the legs and embolize to the pulmonary vasculature, causing a life-threatening embolic event. Emboli mechanically obstruct the pulmonary vessels, cutting off the blood supply to sections of the lung (Fig. 30-5).

Clinical indicators of pulmonary embolism can vary but typically include dyspnea, tachypnea, chest pain, hemoptysis, tachycardia, and symptoms of deep venous thrombosis. Diagnostic tests often include a chest x-ray, ventilation-perfusion lung scan, or high-resolution helical computed tomography. A blood D-dimer assay is helpful to determine whether fibrinolysis of clots is taking place somewhere in the body.

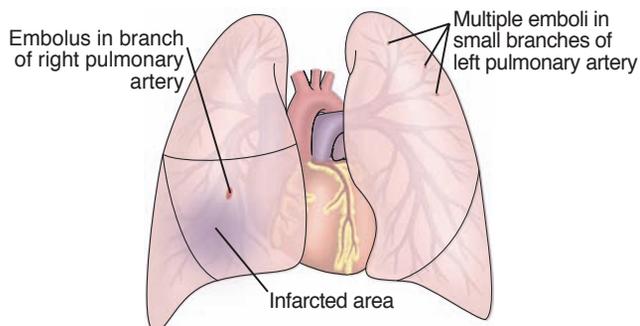

Figure 30-5 Pulmonary emboli may be single or multiple.

Patient management begins with cardiopulmonary assessment and intervention. Emboli can cause hypoxic vasoconstriction and the release of inflammatory mediators in the pulmonary vessels, which can ultimately lead to right heart failure and respiratory failure (Shaughnessy, 2007). Anticoagulant therapy with unfractionated heparin, low-molecular-weight heparin, or fondaparinux (Arixtra) is started when pulmonary embolism is suspected (Piazza & Goldhaber, 2006b). Thrombolytic therapy may be used in patients with massive pulmonary emboli accompanied by hypotension and shock. Following initial therapy, patients are placed on warfarin for at least 6 months. Prevention of deep vein thrombosis and pulmonary emboli is an important aspect of patient management. Both pharmacologic and mechanical means (eg, pneumatic compression devices) have proven effective in at-risk patients. Care for patients with pulmonary embolism is further discussed in Chapter 23.

Pericardial Effusion and Cardiac Tamponade

Pathophysiology

Pericardial effusion (accumulation of fluid in the pericardial sac) may accompany advanced HF, pericarditis, metastatic carcinoma, cardiac surgery, or trauma. Normally, the pericardial sac contains about 20 mL of fluid, which is needed to decrease friction for the beating heart. An increase in pericardial fluid raises the pressure within the pericardial sac and compresses the heart. This has the following effects:

- Elevated pressure in all cardiac chambers
- Decreased venous return due to atrial compression
- Inability of the ventricles to distend and fill adequately

Pericardial fluid may accumulate slowly without causing noticeable symptoms until a large amount accumulates. However, a rapidly developing effusion can stretch the pericardium to its maximum size and, because of increased pericardial pressure, reduce venous return to the heart and decrease CO. The result is cardiac tamponade (eg, compression of the heart).

Clinical Manifestations

The patient may report a feeling of fullness within the chest or may have substantial or ill-defined pain. The feeling of pressure in the chest may result from stretching of the pericardial sac. Because of increased pressure within the pericardium, venous pressure tends to increase, as evidenced by engorged neck veins. Other signs include shortness of breath and labile or low blood pressure (Humphreys, 2006). Systolic blood pressure that is markedly lower during inhalation is called **pulsus paradoxus**. Pulsus paradoxus is characterized by an abnormal difference of at least 10 mm Hg in systolic pressure between the point that it is heard during exhalation and the point that it is heard during inhalation. The cardinal signs of cardiac tamponade are falling systolic blood pressure, narrowing pulse pressure, rising venous pressure (increased JVD), and distant (muffled) heart sounds (Fig. 30-6).

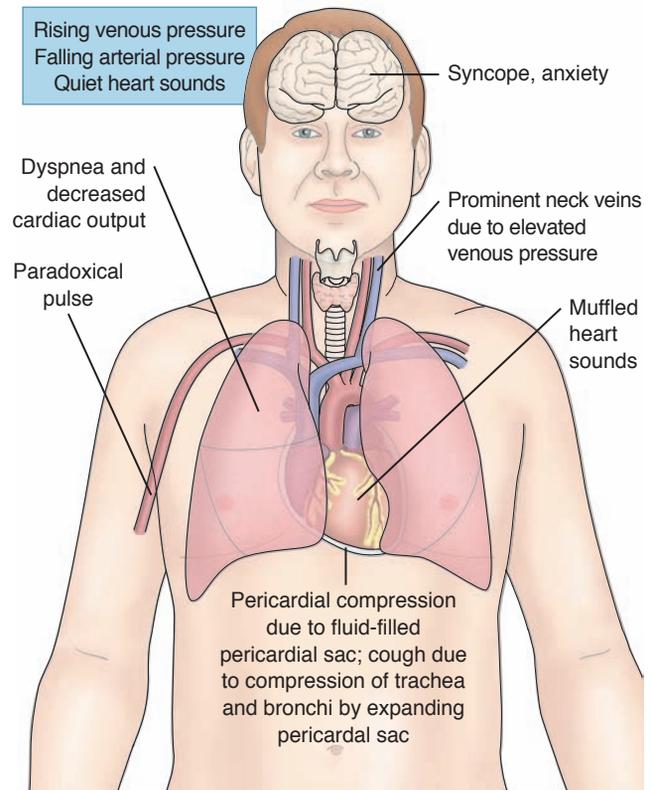

Figure 30-6 Assessment findings in cardiac tamponade resulting from pericardial effusion include feelings of faintness, shortness of breath, and anxiety from decreased cardiac output, cough from pressure created in the trachea from swelling of the pericardial sac, distended neck veins from rising venous pressure, paradoxical pulse, and muffled or distant heart sounds.

Assessment and Diagnostic Findings

An echocardiogram is performed to confirm the diagnosis and quantify the amount of pericardial fluid. A chest x-ray may also show a large pericardial effusion.

Medical Management

Pericardiocentesis

If cardiac function becomes seriously impaired, **pericardiocentesis** (puncture of the pericardial sac to aspirate pericardial fluid) is performed to remove fluid from the pericardial sac. During this procedure, the patient is monitored by continuous ECG and frequent vital signs. Emergency resuscitation equipment should be readily available. The head of the bed is elevated to 45 to 60 degrees, placing the heart in proximity to the chest wall so that the needle can be directly inserted into the pericardial sac. If a peripheral IV line is not already in place, one is inserted, and a slow IV infusion is started in case it becomes necessary to administer emergency medications or blood products.

The pericardial aspiration needle is attached to a 50-mL syringe by a three-way stopcock. Several possible sites are used for pericardial aspiration. Typically, ultrasound imaging is used to guide placement of the needle into the pericardial space. The needle is advanced slowly until it has entered the pericardium and fluid is obtained.

A resulting decrease in central venous pressure and an associated increase in blood pressure after withdrawal of

pericardial fluid indicate that the cardiac tamponade has been relieved. The patient almost always feels immediate relief. If there is a substantial amount of pericardial fluid, a small catheter may be left in place to drain recurrent accumulation of blood or fluid. Pericardial fluid is sent to the laboratory for examination for tumor cells, bacterial culture, chemical and serologic analysis, and differential blood cell count.

Complications of pericardiocentesis include coronary artery puncture, myocardial trauma, dysrhythmias, pleural laceration, and gastric puncture. After pericardiocentesis, the patient's heart rhythm, blood pressure, venous pressure, and heart sounds are monitored to detect possible recurrence of cardiac tamponade. If it recurs, repeated aspiration is necessary. Cardiac tamponade may require treatment by open pericardial drainage (pericardiectomy).

Pericardiectomy

Recurrent pericardial effusions, usually associated with neoplastic disease, may be treated by a **pericardiectomy** (pericardial window). Under general anesthesia, a portion of the pericardium is excised to permit the exudative pericardial fluid to drain into the lymphatic system. The nursing care is the same as that for other cardiac surgery (see Chapter 28).

Cardiac Arrest

Cardiac arrest occurs when the heart ceases to produce an effective pulse and circulate blood. It may be caused by a cardiac electrical event (ie, dysrhythmia) such as ventricular fibrillation, progressive profound bradycardia, or when there is no heart rhythm at all (asystole). Cardiac arrest may follow respiratory arrest; it may also occur when electrical activity is

present but there is ineffective cardiac contraction or circulating volume, which is called **pulseless electrical activity (PEA)**. PEA can be caused by hypovolemia (eg, with excessive bleeding), hypoxia, hypothermia, hyperkalemia, massive pulmonary embolism, myocardial infarction, and medication overdose (eg, beta-blockers, calcium channel blockers).

Clinical Manifestations

In cardiac arrest, consciousness, pulse, and blood pressure are lost immediately. Ineffective respiratory gasping may occur. The pupils of the eyes begin dilating within 45 seconds. Seizures may or may not occur.

The risk of irreversible brain damage and death increases with every minute from the time that circulation ceases. The interval varies with the age and underlying condition of the patient. During this period, the diagnosis of cardiac arrest must be made and measures must be taken immediately to restore circulation.

Emergency Management: Cardiopulmonary Resuscitation

Cardiopulmonary resuscitation (CPR) provides blood flow to vital organs until effective circulation can be reestablished. Following recognition of unresponsiveness, lack of pulse and respiration, the protocol for basic life support is initiated. Once loss of consciousness has been established, the resuscitation priority for the adult in most cases is placing a phone call to activate the code team or the emergency medical system (EMS). Exceptions to this include near drowning, drug or medication overdose, and respiratory arrest situations, for which 2 minutes of CPR should be performed before activating the EMS. Selected medications (Table 30-4) may be used during and after resuscitation.

Table 30-4  **MEDICATIONS USED IN CARDIOPULMONARY RESUSCITATION**

Agent and Action	Indications	Nursing Considerations
Oxygen—improves tissue oxygenation and corrects hypoxemia	Administered to all patients with acute cardiac ischemia or suspected hypoxemia, including those with COPD	<ul style="list-style-type: none"> • Use 100% FiO₂ during resuscitation. • Recognize that lung damage is unlikely when used for short time. • Monitor dose by pulse oximeter.
Epinephrine—increases systemic vascular resistance and BP; improves coronary and cerebral perfusion and myocardial contractility	Given to patients in cardiac arrest, especially caused by asystole or pulseless electrical activity; may be given if caused by ventricular tachycardia or ventricular fibrillation	<ul style="list-style-type: none"> • Administer 1 mg every 3–5 minutes by IV push or through endotracheal tube. • Avoid adding to IV lines that contain alkaline solution (eg, bicarbonate). • Give 40 U IV one time only.
Vasopressin (Pitressin)—increases systemic vascular resistance and BP	An alternative to epinephrine	
Atropine—blocks parasympathetic action; increases SA node automaticity and AV conduction	Given to patients with symptomatic bradycardia (hemodynamically unstable, frequent premature ventricular contractions, and symptoms of ischemia)	<ul style="list-style-type: none"> • Give rapidly as 0.5 mg IV push; may repeat to dose of 3 mg. • Be aware that less than 0.5 mg in adult can cause heart rate to decrease to a worse bradycardia. • Monitor patient for reflexive tachycardia.
Sodium bicarbonate (NaHCO ₃)—corrects metabolic acidosis	Given to correct metabolic acidosis that is refractory to standard advanced cardiac life-support interventions (cardiopulmonary resuscitation, intubation, and respiratory management)	<ul style="list-style-type: none"> • Administer initial dose of 1 mEq/kg IV; then administer dose based on base deficit calculated from arterial blood gas values. • Recognize that to prevent development of rebound metabolic alkalosis, complete correction of acidosis is not indicated.
Magnesium—promotes adequate functioning of cellular sodium–potassium pump	Given to patients with torsade de pointes	<ul style="list-style-type: none"> • May give 1–2 g diluted in 10 mL D₅W over 5–20 minutes. • Monitor for hypotension, asystole, bradycardia, and respiratory paralysis.

AV, atrioventricular; BP, blood pressure; COPD, chronic obstructive pulmonary disease; D₅W, dextrose 5% in water; FiO₂, fraction of inspired oxygen; IV, intravenous; SA, sinoatrial.

Assessment and intervention for the patient with cardiac arrest includes utilization of the ABCD protocol. The ABCDs of basic CPR include airway, breathing, circulation, and defibrillation (AHA, 2006):

1. Airway: opening and maintaining an airway
2. Breathing: providing artificial ventilation by rescue breathing if spontaneous respirations are absent or inadequate
3. Circulation: promoting artificial circulation by external cardiac compression when there is no pulse; administering medications (eg, epinephrine for asystole)
4. Defibrillation with standard defibrillator or automatic external defibrillator (AED) for ventricular tachycardia and ventricular fibrillation

If the patient is already being monitored or is immediately placed on the monitor using the multifunction pads (found on most defibrillators) and the ECG shows ventricular fibrillation or the patient is unresponsive with ventricular tachycardia, immediate defibrillation rather than CPR is the treatment of choice. In this scenario, CPR is performed initially only if the defibrillator is not immediately available. The survival rate decreases for every minute that defibrillation is delayed (AHA, 2006). If the patient has not been defibrillated within 10 minutes, there is little chance of survival. Survival after cardiac arrest has been improved by extensive education of health care providers and by the use of semiautomatic defibrillators (Peters & Boyde, 2007). More information on defibrillation can be found in Chapter 27. Chart 30-6 provides information related to family presence during CPR.

Maintaining Airway and Breathing

The first step in CPR is to establish an open airway. Any obvious material in the mouth or throat should be removed. The airway should be opened using a head-tilt

chin-lift maneuver. The rescuer looks, listens, and feels for air movement. An oropharyngeal airway is inserted if available. Two rescue ventilations are provided using a bag-mask or mouth-mask device. An obstructed airway should be suspected when the rescuer cannot give the initial ventilations, and the Heimlich maneuver or abdominal thrusts should be administered to relieve the obstruction (see Chapter 25, Chart 25-6).

If the first rescue ventilations meet little or no resistance, the patient is ventilated every 5 to 6 seconds. Each breath is delivered over 1 second. If the patient is in the hospital, endotracheal intubation is frequently performed by a physician, nurse anesthetist, or respiratory therapist during a resuscitation procedure (also called a code) to ensure an adequate airway and ventilation. The resuscitation bag device is then connected directly to the endotracheal tube (ET).

Because of the risk of unrecognized esophageal intubation or dislodgement of the ET, tracheal intubation must be confirmed by two different methods: a primary method (visualization of the ET through the vocal cords, auscultation of breath sounds in five areas on the chest, or bilateral chest expansion) and a secondary method (carbon dioxide detector). A chest x-ray, which is frequently obtained after ET placement, is helpful in determining whether the ET is too high or too low in the trachea. However, a chest x-ray cannot definitively confirm placement of an ET: an ET in the esophagus or the trachea may produce the same appearance on the x-ray. Arterial blood gas levels are measured to guide ventilation therapy.

Restoring Circulation

After performing ventilation, the carotid pulse is assessed, and external cardiac compressions are provided if no pulse is detected. If a defibrillator is not yet available but a process has been put into place to obtain one, chest compressions

NURSING RESEARCH PROFILE

Family Presence During Invasive Procedures and Cardiopulmonary Resuscitation

Duran, C. R., Oman, K. S., Abel, J. J., et al. (2007). Attitudes toward and beliefs about family presence: A survey of health-care providers, patients' families, and patients. *American Journal of Critical Care*, 16(3), 270–279.

Purpose

The presence of family members during invasive procedures and resuscitation is becoming accepted practice as the emphasis on family-centered care increases. Resistance to this change in practice has been expressed by some clinicians who identify concerns regarding issues such as family interference with care or increased performance anxiety in health care providers. The purpose of this study was to compare the attitudes and beliefs of clinicians, patients' families, and patients regarding the option of family presence during invasive procedures and cardiopulmonary resuscitation.

Design

Surveys were distributed to clinicians (nurses, physicians, and respiratory therapists), patients' family members, and patients in the emergency department and various intensive

care units of a large academic hospital. The surveys were completed by 202 clinicians, 72 family members, and 62 patients.

Findings

Health care providers had an overall positive attitude about family presence. Nurses were more open to family presence when compared to physicians. Residents, interns, and fellows were more open to the concept when compared with attending physicians, probably reflecting recent trends in exposure to family-centered care. Family members and patients had positive attitudes about family presence and found it beneficial. Some believed the family had a right to be present.

Nursing Implications

The results of this study confirm that family presence during invasive procedures and cardiopulmonary resuscitation is beneficial to patients and families. As this option becomes more accepted in practice, nurses and other providers need to plan for and accommodate families at the bedside.

Figure 30-7 Chest compressions in cardiopulmonary resuscitation (CPR) are performed by placing the heel of one hand in the center of the chest between the nipples and the other hand on top of the first hand. Elbows are kept straight and body weight is used to apply forceful compressions to the lower sternum. For the most effective hand placement and outcome, the patient's chest should be bare.

are initiated. Compressions are performed with the patient on a firm surface, such as the floor or a cardiac board. The rescuer (facing the patient's side) places the heel of one hand in the center of the chest between the nipples and positions the other hand on top of the first hand (Fig. 30-7). The fingers should not touch the chest wall (AHA, 2006).

Using the force of body weight while keeping the elbows straight, the rescuer presses quickly downward from the shoulder area to deliver a forceful compression to the victim's lower sternum about 3.8 to 5 cm (1.5 to 2 in) toward the spine. The chest compression rate is approximately 100 times per minute. A compression to ventilation ratio of 30 to 2 is recommended without pause for ventilations.

When the code team or emergency medical personnel arrive, the patient is quickly assessed to determine cardiac rhythm and respiratory status as well as possible causes of the arrest. The specific subsequent advanced life support interventions depend on the assessment results. For example, after the patient is placed on a cardiac monitor and ventricular fibrillation is detected, the patient is defibrillated, and then CPR is resumed. However, if asystole is detected on the monitor, CPR is resumed immediately while epinephrine is administered and an attempt is made to identify the underlying cause, such as hypovolemia, hypothermia, or hypoxia. CPR may be stopped when the patient responds and begins to breathe, rescuers are too exhausted or at risk (eg, a building is at risk of collapsing) to continue CPR, or signs of death are obvious. If the patient does not respond to therapies given during the arrest, the resuscitation effort may be stopped or "called" by the physician. Many factors are usually considered in the decision: the initiating dysrhythmia and potential etiologies, environmental causes (eg, water drowning, hypothermia, or electrocution), whether the arrest is witnessed, the presence of bystanders to initiate resuscitation efforts, the length of time for initiation of

advanced life support, and the patient's response to treatment. AHA guidelines state that resuscitation efforts should continue until death is inevitable (AHA, 2005).

Follow-Up Monitoring and Care

Once resuscitated, the patient is transferred to an intensive care unit for close monitoring. Continuous ECG monitoring and frequent blood pressure assessments are essential until hemodynamic stability is reestablished. Etiologic factors that precipitated the arrest, such as metabolic or rhythm abnormalities, must be identified and treated. Possible contributing factors, such as electrolyte or acid-base imbalances, need to be identified and corrected. Comatose patients may benefit from therapeutic hypothermia, which induces a drop in core body temperature to 32°C to 34°C (89.6°F to 93.2°F) for 12 to 24 hours postresuscitation, although the best method to induce hypothermia has yet to be determined through research (Neumar, Nolan, Adrie, et al., 2008).

CRITICAL THINKING EXERCISES

1 A 79-year-old woman is admitted to the cardiac care unit with a diagnosis of HF. As you start to fill out the admission database, the woman tells you that she is feeling very anxious and cannot catch her breath. What questions do you ask her? What are your assessment priorities? What interventions might need to occur immediately, and how should you act to provide these?

EBP 2 On an inpatient progressive care unit, you are assigned to care for a 60-year-old man who has been readmitted for the third time in the past 6 months with severe HF and generalized edema. According to the patient's chart, he has a history of noncompliance with diet and medications. What are your immediate priorities and short-term goals for this patient? What medical interventions are indicated for this patient at this point in time? Develop an evidence-based plan of care for this patient's transition from hospital to home. Describe your planned interaction with the patient (ie, communication technique, behaviors) that would encourage the patient to participate in the plan and comply with the plan.

EBP 3 A 62-year-old woman is recovering from an acute MI on the telemetry unit. During your assessment, she complains of mild chest pressure. Her vital signs are as follows: blood pressure 86/60 mm Hg, heart rate 104 bpm (beats per minute), respiratory rate 28 breaths/min, and SpO₂ 92%. What other parameters should be assessed? Describe your immediate interventions and communication with other key members of the multidisciplinary health care team. Identify the evidence that supports your interventions and expected outcomes. What complications might this patient be experiencing? What should you tell the patient and family about possible pending interventions that might be indicated?

chapter 31

Assessment and Management of Patients With Vascular Disorders and Problems of Peripheral Circulation

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

- 1 Identify anatomic and physiologic factors that affect peripheral blood flow and tissue oxygenation.
- 2 Use appropriate parameters for assessment of peripheral circulation.
- 3 Use the nursing process as a framework of care for patients with vascular insufficiency of the extremities.
- 4 Compare the various diseases of the arteries and their causes, pathophysiologic changes, clinical manifestations, management, and prevention.
- 5 Describe the prevention and management of venous thromboembolism.
- 6 Compare strategies to prevent venous insufficiency, leg ulcers, and varicose veins.
- 7 Use the nursing process as a framework of care for patients with leg ulcers.
- 8 Describe the relationship between lymphangitis and lymphedema.

GLOSSARY

- anastomosis:** junction of two vessels
- aneurysm:** a localized sac or dilation of an artery formed at a weak point in the vessel wall
- angioplasty:** an invasive procedure that uses a balloon-tipped catheter to dilate a stenotic area of a blood vessel
- ankle-brachial index (ABI) or ankle-arm index (AAI):** ratio of the ankle systolic pressure to the arm systolic pressure; an objective measurement of arterial disease that provides quantification of the degree of stenosis
- arteriosclerosis:** diffuse process whereby the muscle fibers and the endothelial lining of the walls of small arteries and arterioles thicken
- atherosclerosis:** inflammatory process involving the accumulation of lipids, calcium, blood components, carbohydrates, and fibrous tissue on the intimal layer of a large or medium-sized artery
- bruit:** sound produced by turbulent blood flow through an irregular, tortuous, stenotic, or dilated vessel
- dissection:** separation of the weakened elastic and fibromuscular elements in the medial layer of an artery
- duplex ultrasonography:** combines B-mode gray-scale imaging of tissue, organs, and blood vessels with capabilities of estimating velocity changes by use of a pulsed Doppler
- intermittent claudication:** a muscular, cramplike pain in the extremities consistently reproduced with the same degree of exercise or activity and relieved by rest
- ischemia:** deficient blood supply
- rest pain:** persistent pain in the foot or digits when the patient is resting, indicating a severe degree of arterial insufficiency
- rubor:** reddish blue discoloration of the extremities; indicative of severe peripheral arterial damage in vessels that remain dilated and unable to constrict
- stenosis:** narrowing or constriction of a vessel

Conditions of the vascular system include arterial disorders, venous disorders, lymphatic disorders, and cellulitis. Nursing management depends on an understanding of the vascular system.

ASSESSMENT OF VASCULAR FUNCTION

Adequate perfusion ensures oxygenation and nourishment of body tissues, and it depends in part on a properly functioning cardiovascular system. Adequate blood flow depends on the efficiency of the heart as a pump, the patency and responsiveness of the blood vessels, and the adequacy of circulating blood volume. Nervous system activity, blood viscosity, and the metabolic needs of tissues influence the rate and adequacy of blood flow.

Anatomic and Physiologic Overview

The vascular system consists of two interdependent systems. The right side of the heart pumps blood through the lungs to the pulmonary circulation, and the left side of the heart pumps blood to all other body tissues through the systemic circulation. The blood vessels in both systems channel the blood from the heart to the tissues and back to the heart (Fig. 31-1). Contraction of the ventricles is the driving force that moves blood through the vascular system.

Arteries distribute oxygenated blood from the left side of the heart to the tissues, whereas the veins carry deoxygenated blood from the tissues to the right side of the heart. Capillary vessels located within the tissues connect the arterial and venous systems. These vessels permit the exchange of nutrients and metabolic wastes between the circulatory system and the tissues. Arterioles and venules immediately adjacent to the capillaries, together with the capillaries, make up the microcirculation.

The lymphatic system complements the function of the circulatory system. Lymphatic vessels transport lymph (a fluid similar to plasma) and tissue fluids (containing proteins, cells, and cellular debris) from the interstitial space to systemic veins.

Anatomy of the Vascular System

Arteries and Arterioles

Arteries are thick-walled structures that carry blood from the heart to the tissues. The aorta, which has a diameter of approximately 25 mm (1 inch) in the average-sized adult, gives rise to numerous branches, which continue to divide into progressively smaller arteries that are 4 mm (0.16 inch) in diameter. The vessels divide further, diminishing in size to approximately 30 μm in diameter. These smallest arteries, called the arterioles, are generally embedded within the tissues.

The walls of the arteries and arterioles are composed of three layers: the intima, an inner endothelial cell layer; the media, a middle layer of smooth muscle and elastic tissue; and the adventitia, an outer layer of connective tissue. The intima, a very thin layer, provides a smooth surface for

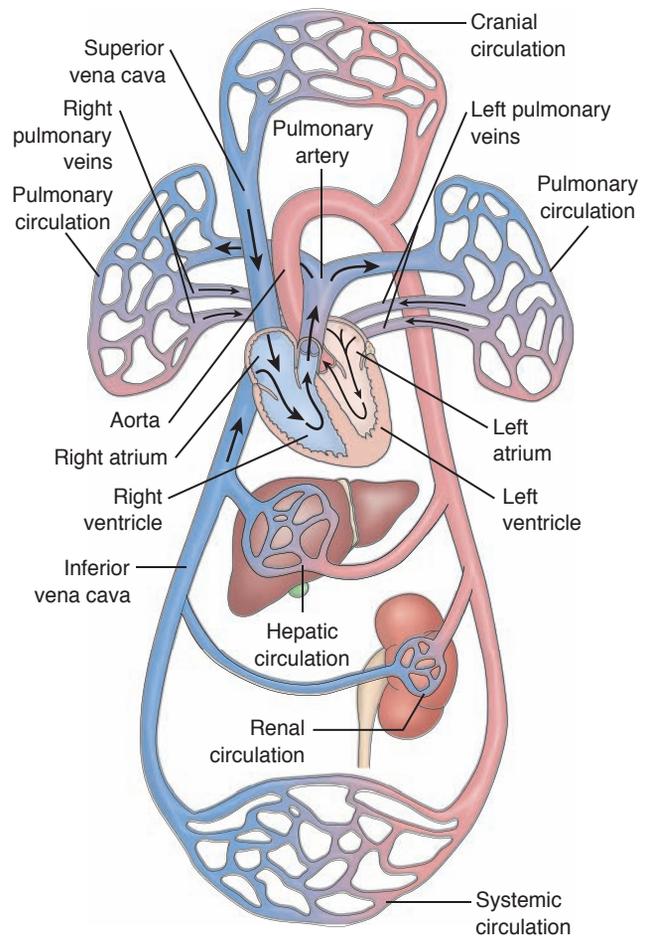

Figure 31-1 Systemic and pulmonary circulation. Oxygen-rich blood from the pulmonary circulation is pumped from the left heart into the aorta and the systemic arteries to the capillaries, where the exchange of nutrients and waste products takes place. The deoxygenated blood returns to the right heart by way of the systemic veins and is pumped into the pulmonary circulation.

contact with the flowing blood. The media makes up most of the vessel wall in the aorta and other large arteries of the body. This layer is composed chiefly of elastic and connective tissue fibers that give the vessels considerable strength and allow them to constrict and dilate to accommodate the blood ejected from the heart during each cardiac cycle (stroke volume) and maintain an even, steady flow of blood. The adventitia is a layer of connective tissue that anchors the vessel to its surroundings. There is much less elastic tissue in the smaller arteries and arterioles, and the media in these vessels is composed primarily of smooth muscle (Porth & Matfin, 2009). Smooth muscle controls the diameter of the vessels by contracting and relaxing. Chemical, hormonal, and neuronal factors influence the activity of smooth muscle. Because arterioles offer resistance to blood flow by altering their diameter, they are often referred to as *resistance vessels*. Arterioles regulate the volume and pressure in the arterial system and the rate of blood flow to the capillaries. Because of the large amount of smooth muscle in the media, the walls of the arteries are relatively thick, accounting for approximately 25% of the total diameter of the artery.

The intima and the inner third of the smooth muscle layer of the media are in such close contact with the blood that the blood vessels receive their nourishment by direct diffusion. The adventitia and the outer media layers have a limited vascular system for nourishment and require their own blood supply to meet metabolic needs.

Capillaries

The walls of the capillaries, which lack smooth muscle and adventitia, are composed of a single layer of endothelial cells. This thin-walled structure permits rapid and efficient transport of nutrients to the cells and removal of metabolic wastes. The diameter of capillaries ranges from 5 to 10 μm ; this means that red blood cells must alter their shape to pass through these vessels. Changes in a capillary's diameter are passive and are influenced by contractile changes in the blood vessels that carry blood to and from a capillary. The capillary's diameter also changes in response to chemical stimuli. In some tissues, a cuff of smooth muscle, called the precapillary sphincter, is located at the arteriolar end of the capillary and is responsible, along with the arteriole, for controlling capillary blood flow (Porth & Matfin, 2009).

Some capillary beds, such as those in the fingertips, contain arteriovenous anastomoses, through which blood passes directly from the arterial to the venous system. These vessels are believed to regulate heat exchange between the body and the external environment.

The distribution of capillaries varies with the type of tissue. For example, skeletal tissue, which has high metabolic requirements, has a denser capillary network than cartilage, which has low metabolic needs.

Veins and Venules

Capillaries join to form larger vessels called venules, which join to form veins. The venous system is therefore structurally analogous to the arterial system; venules correspond to arterioles, veins to arteries, and the vena cava to the aorta. Analogous types of vessels in the arterial and venous systems have approximately the same diameters (see Fig. 31-1).

The walls of the veins, in contrast to those of the arteries, are thinner and considerably less muscular. In most veins, the wall makes up only 10% of the diameter, in contrast to 25% in most arteries. In veins, the walls are composed of three layers, like those of arteries, although in veins, these layers are not as well defined.

The thin, less muscular structure of the vein wall allows these vessels to distend more than arteries. Greater distensibility and compliance permit large volumes of blood to remain in the veins under low pressure. For this reason, veins are referred to as *capacitance vessels*. Approximately 75% of total blood volume is contained in the veins. The sympathetic nervous system, which innervates the vein musculature, can stimulate the veins to constrict (venoconstriction), thereby reducing venous volume and increasing the volume of blood in the general circulation. Contraction of skeletal muscles in the extremities creates the primary pumping action to facilitate venous blood flow back to the heart (Porth & Matfin, 2009).

Some veins, unlike arteries, are equipped with valves. In general, veins that transport blood against the force of gravity, as in the lower extremities, have one-way bicuspid

valves that prevent blood from seeping backward as it is propelled toward the heart. Valves are composed of endothelial leaflets, the competency of which depends on the integrity of the vein wall.

Lymphatic Vessels

The lymphatic vessels are a complex network of thin-walled vessels similar to the blood capillaries. This network collects lymphatic fluid from tissues and organs and transports the fluid to the venous circulation. The lymphatic vessels converge into two main structures: the thoracic duct and the right lymphatic duct. These ducts empty into the junction of the subclavian and the internal jugular veins. The right lymphatic duct conveys lymph primarily from the right side of the head, neck, thorax, and upper arms. The thoracic duct conveys lymph from the remainder of the body. Peripheral lymphatic vessels join larger lymph vessels and pass through regional lymph nodes before entering the venous circulation. The lymph nodes play an important role in filtering foreign particles.

The lymphatic vessels are permeable to large molecules and provide the only means by which interstitial proteins can return to the venous system. With muscular contraction, lymph vessels become distorted to create spaces between the endothelial cells, allowing protein and particles to enter. Muscular contraction of the lymphatic walls and surrounding tissues aids in propelling the lymph toward the venous drainage points (Porth & Matfin, 2009).

Function of the Vascular System

Circulatory Needs of Tissues

The amount of blood flow needed by body tissues constantly changes. The percentage of blood flow received by individual organs or tissues is determined by the rate of tissue metabolism, the availability of oxygen, and the function of the tissues. When metabolic requirements increase, blood vessels dilate to increase the flow of oxygen and nutrients to the tissues. When metabolic needs decrease, vessels constrict and blood flow to the tissues decreases. Metabolic demands of tissues increase with physical activity or exercise, local heat application, fever, and infection. Reduced metabolic requirements of tissues accompany rest or decreased physical activity, local cold application, and cooling of the body. If the blood vessels fail to dilate in response to the need for increased blood flow, tissue **ischemia** (deficient blood supply to a body part) results. The mechanism by which blood vessels dilate and constrict to adjust for metabolic changes ensures that normal arterial pressure is maintained (Porth & Matfin, 2009).

As blood passes through tissue capillaries, oxygen is removed and carbon dioxide is added. The amount of oxygen extracted by each tissue differs. For example, the myocardium tends to extract about 50% of the oxygen from arterial blood in one pass through its capillary bed, whereas the kidneys extract only about 7% of the oxygen from the blood that passes through them. The average amount of oxygen removed collectively by all of the body tissues is about 25%. This means that the blood in the vena cava contains about 25% less oxygen than aortic blood. This is known as the *systemic arteriovenous oxygen difference* (Porth

& Matfin, 2009). This difference becomes greater when less oxygen is delivered to the tissues than they need.

Blood Flow

Blood flow through the cardiovascular system always proceeds in the same direction: left side of the heart to the aorta, arteries, arterioles, capillaries, venules, veins, vena cava, and right side of the heart. This unidirectional flow is caused by a pressure difference that exists between the arterial and venous systems. Because arterial pressure (approximately 100 mm Hg) is greater than venous pressure (approximately 40 mm Hg) and fluid always flows from an area of higher pressure to an area of lower pressure, blood flows from the arterial to the venous system.

The pressure difference (ΔP) between the two ends of the vessel propels the blood. Impediments to blood flow offer the opposing force, which is known as resistance (R). The rate of blood flow is determined by dividing the pressure difference by the resistance:

$$\text{Flow rate} = \Delta P/R$$

This equation clearly shows that when resistance increases, a greater driving pressure is required to maintain the same degree of flow (Porth & Matfin, 2009). In the body, an increase in driving pressure is accomplished by an increase in the force of contraction of the heart. If arterial resistance is chronically elevated, the myocardium hypertrophies (enlarges) to sustain the greater contractile force.

In most long smooth blood vessels, flow is laminar or streamlined, with blood in the center of the vessel moving slightly faster than the blood near the vessel walls. Laminar flow becomes turbulent when the blood flow rate increases, when blood viscosity increases, when the diameter of the vessel becomes greater than normal, or when segments of the vessel are narrowed or constricted (Porth & Matfin, 2009). Turbulent blood flow creates a sound, called a **bruit**, that can be heard with a stethoscope.

Blood Pressure

Chapter 32 provides more information on the physiology and measurement of blood pressure.

Capillary Filtration and Reabsorption

Fluid exchange across the capillary wall is continuous. This fluid, which has the same composition as plasma without the proteins, forms the interstitial fluid. The equilibrium between hydrostatic and osmotic forces of the blood and interstitium, as well as capillary permeability, determines the amount and direction of fluid movement across the capillary. Hydrostatic force is a driving pressure that is generated by the blood pressure. Osmotic pressure is the pulling force created by plasma proteins. Normally, the hydrostatic pressure at the arterial end of the capillary is relatively high compared with that at the venous end. This high pressure at the arterial end of the capillaries tends to drive fluid out of the capillary and into the tissue space. Osmotic pressure tends to pull fluid back into the capillary from the tissue space, but this osmotic force cannot overcome the high hydrostatic pressure at the arterial end of the capillary. However, at the venous end of the capillary, the osmotic force predom-

inates over the low hydrostatic pressure, and there is a net reabsorption of fluid from the tissue space back into the capillary (Porth & Matfin, 2009).

Except for a very small amount, fluid that is filtered out at the arterial end of the capillary bed is reabsorbed at the venous end. The excess filtered fluid enters the lymphatic circulation. These processes of filtration, reabsorption, and lymph formation aid in maintaining tissue fluid volume and removing tissue waste and debris. Under normal conditions, capillary permeability remains constant.

Under certain abnormal conditions, the fluid filtered out of the capillaries may greatly exceed the amounts reabsorbed and carried away by the lymphatic vessels. This imbalance can result from damage to capillary walls and subsequent increased permeability, obstruction of lymphatic drainage, elevation of venous pressure, or a decrease in plasma protein osmotic force. Accumulation of excess interstitial fluid that results from these processes is known as *edema*.

Hemodynamic Resistance

The most important factor that determines resistance in the vascular system is the vessel radius. Small changes in vessel radius lead to large changes in resistance. The predominant sites of change in the caliber or width of blood vessels, and therefore in resistance, are the arterioles and the precapillary sphincter. Peripheral vascular resistance is the opposition to blood flow provided by the blood vessels. This resistance is proportional to the viscosity or thickness of the blood and the length of the vessel and is influenced by the diameter of the vessels. Under normal conditions, blood viscosity and vessel length do not change significantly, and these factors do not usually play an important role in blood flow. However, a large increase in hematocrit may increase blood viscosity and reduce capillary blood flow.

Peripheral Vascular Regulating Mechanisms

Even at rest, the metabolic needs of body tissues are continuously changing. Therefore, an integrated and coordinated regulatory system is necessary so that blood flow to individual tissues is maintained in proportion to the needs of those tissues. This regulatory mechanism is complex and consists of central nervous system influences, circulating hormones and chemicals, and independent activity of the arterial wall itself.

Sympathetic (adrenergic) nervous system activity, mediated by the hypothalamus, is the most important factor in regulating the caliber and therefore the blood flow of peripheral blood vessels. All vessels are innervated by the sympathetic nervous system except the capillary and precapillary sphincters. Stimulation of the sympathetic nervous system causes vasoconstriction. The neurotransmitter responsible for sympathetic vasoconstriction is norepinephrine (Porth & Matfin, 2009). Sympathetic activation occurs in response to physiologic and psychological stressors. Diminution of sympathetic activity by medications or sympathectomy results in vasodilation.

Other hormones affect peripheral vascular resistance. Epinephrine, released from the adrenal medulla, acts like norepinephrine in constricting peripheral blood vessels in most tissue beds. However, in low concentrations, epinephrine

causes vasodilation in skeletal muscles, the heart, and the brain. Angiotensin I, which is formed from the interaction of renin (synthesized by the kidney) and angiotensinogen, a circulating serum protein, is then converted to angiotensin II by an enzyme secreted by the pulmonary vasculature, called angiotensin-converting enzyme (ACE). Angiotensin II is a potent vasoconstrictor, particularly of the arterioles. Although the amount of angiotensin II concentrated in the blood is usually small, its profound vasoconstrictive effects are important in certain abnormal states, such as heart failure and hypovolemia (Porth & Matfin, 2009).

Alterations in local blood flow are influenced by various circulating substances that have vasoactive properties. Potent vasodilators include nitric oxide, prostacyclin, histamine, bradykinin, prostaglandin, and certain muscle metabolites. A reduction in available oxygen and nutrients and changes in local pH also affect local blood flow. Thromboxane A₂ and serotonin are substances liberated from platelets that aggregate at the site of damaged vessels, causing arteriolar vasoconstriction and continued platelet aggregation at the site of injury (Mullenix, Anderson & Starnes, 2005).

Pathophysiology of the Vascular System

Reduced blood flow through peripheral blood vessels characterizes all peripheral vascular diseases. The physiologic effects of altered blood flow depend on the extent to which tissue demands exceed the supply of oxygen and nutrients available. If tissue needs are high, even modestly reduced blood flow may be inadequate to maintain tissue integrity. Tissues then fall prey to ischemia, become malnourished, and ultimately die unless adequate blood flow is restored.

Pump Failure

Inadequate peripheral blood flow occurs when the heart's pumping action becomes inefficient. Left-sided heart failure (left ventricular failure) causes an accumulation of blood in the lungs and a reduction in forward flow or cardiac output, which results in inadequate arterial blood flow to the tissues. Right-sided heart failure (right ventricular failure)

causes systemic venous congestion and a reduction in forward flow (see Chapter 30).

Alterations in Blood and Lymphatic Vessels

Intact, patent, and responsive blood vessels are necessary to deliver adequate amounts of oxygen to tissues and to remove metabolic wastes. Arteries can become damaged or obstructed as a result of atherosclerotic plaque, thromboemboli, chemical or mechanical trauma, infections or inflammatory processes, vasospastic disorders, and congenital malformations. A sudden arterial occlusion causes profound and often irreversible tissue ischemia and tissue death. When arterial occlusions develop gradually, there is less risk of sudden tissue death because collateral circulation may develop, giving that tissue the opportunity to adapt to gradually decreased blood flow.

Venous blood flow can be reduced by a thromboembolus obstructing the vein, by incompetent venous valves, or by a reduction in the effectiveness of the pumping action of surrounding muscles. Decreased venous blood flow results in increased venous pressure, a subsequent increase in capillary hydrostatic pressure, net filtration of fluid out of the capillaries into the interstitial space, and subsequent edema. Edematous tissues cannot receive adequate nutrition from the blood and consequently are more susceptible to breakdown, injury, and infection. Obstruction of lymphatic vessels also results in edema. Lymphatic vessels can become obstructed by a tumor or by damage from mechanical trauma or inflammatory processes.

Circulatory Insufficiency of the Extremities

Although many types of peripheral vascular diseases exist, most result in ischemia and produce some of the same symptoms: pain, skin changes, diminished pulse, and possible edema. The type and severity of symptoms depend in part on the type, stage, and extent of the disease process and on the speed with which the disorder develops. Table 31-1 highlights the distinguishing features of arterial and venous insufficiency. In this chapter, peripheral vascular disease is categorized as arterial, venous, or lymphatic.

Table 31-1 CHARACTERISTICS OF ARTERIAL AND VENOUS INSUFFICIENCY AND RESULTING ULCERS

Characteristic	Arterial	Venous
General Characteristics		
Pain	Intermittent claudication to sharp, unrelenting, constant	Aching, cramping
Pulses	Diminished or absent	Present, but may be difficult to palpate through edema
Skin characteristics	Dependent rubor—elevation pallor of foot; dry, shiny skin; cool-to-cold temperature; loss of hair over toes and dorsum of foot; nails thickened and ridged	Pigmentation in gaiter area (area of medial and lateral malleolus), skin thickened and tough, may be reddish blue, frequently with associated dermatitis
Ulcer Characteristics		
Location	Tip of toes, toe webs, heel or other pressure areas if confined to bed	Medial malleolus; infrequently lateral malleolus or anterior tibial area
Pain	Very painful	Minimal pain if superficial or may be very painful
Depth of ulcer	Deep, often involving joint space	Superficial
Shape	Circular	Irregular border
Ulcer base	Pale to black and dry gangrene	Granulation tissue—beefy red to yellow fibrinous in chronic long-term ulcer
Leg edema	Minimal unless extremity kept in dependent position constantly to relieve pain	Moderate to severe

Gerontologic Considerations

Aging produces changes in the walls of the blood vessels that affect the transport of oxygen and nutrients to the tissues. The intima thickens as a result of cellular proliferation and fibrosis. Elastin fibers of the media become calcified, thin, and fragmented, and collagen accumulates in the intima and the media. These changes cause the vessels to stiffen, which results in increased peripheral resistance, impaired blood flow, and increased left ventricular workload.

Assessment

Health History

The nurse obtains an in-depth description from the patient of any pain and its precipitating factors. A muscular, cramp-type pain in the extremities consistently reproduced with the same degree of exercise or activity and relieved by rest is experienced by patients with peripheral arterial insufficiency. Referred to as **intermittent claudication**, this pain is caused by the inability of the arterial system to provide adequate blood flow to the tissues in the face of increased demands for nutrients and oxygen during exercise. As the tissues are forced to complete the energy cycle without adequate nutrients and oxygen, muscle metabolites and lactic acid are produced. Pain is experienced as the metabolites aggravate the nerve endings of the surrounding tissue. Typically, about 50% of the arterial lumen or 75% of the cross-sectional area must be obstructed before intermittent claudication is experienced. When the patient rests and thereby decreases the metabolic needs of the muscles, the pain subsides. The progression of the arterial disease can be monitored by documenting the amount of exercise or the distance the patient can walk before pain is produced. Persistent pain in the forefoot (ie, the anterior portion of the foot) when the patient is resting indicates a severe degree of arterial insufficiency and a critical state of ischemia. Known as **rest pain**, this discomfort is often worse at night and may interfere with sleep. This pain frequently requires that the extremity be lowered to a dependent position to improve perfusion to the distal tissues.

The site of arterial disease can be deduced from the location of claudication, because pain occurs in muscle groups distal to the diseased vessel. Calf pain may accompany reduced blood flow through the superficial femoral or popliteal artery, whereas pain in the hip or buttock may result from reduced blood flow in the abdominal aorta or the common iliac or hypogastric arteries.

Physical Assessment

A thorough assessment of the patient's skin color and temperature and the character of the peripheral pulses is important in the diagnosis of arterial disorders.

Inspection of the Skin

Adequate blood flow warms the extremities and gives them a rosy coloring. Inadequate blood flow results in cool and pale extremities. Further reduction of blood flow to these tissues, which occurs when the extremity is elevated, for example,

results in an even whiter or more blanched appearance (eg, pallor). **Rubor**, a reddish-blue discoloration of the extremities, may be observed within 20 seconds to 2 minutes after the extremity is placed in the dependent position. Rubor suggests severe peripheral arterial damage in which vessels that cannot constrict remain dilated. Even with rubor, the extremity begins to turn pale with elevation. Cyanosis, a bluish tint of the skin, is manifested when the amount of oxygenated hemoglobin contained in the blood is reduced.

Additional changes resulting from a chronically reduced nutrient supply include loss of hair, brittle nails, dry or scaling skin, atrophy, and ulcerations. Edema may be apparent bilaterally or unilaterally and is related to the affected extremity's chronically dependent position because of severe rest pain. Gangrenous changes appear after prolonged, severe ischemia and represent tissue necrosis.

Palpation of Pulses

Determining the presence or absence, as well as the quality, of peripheral pulses is important in assessing the status of peripheral arterial circulation (Fig. 31-2). Palpation of pulses is subjective, and the examiner may mistake his or her own pulse for that of the patient. To prevent this, the examiner should use light touch and avoid using only the index finger for palpation because this finger has the strongest arterial pulsation of all the fingers. The thumb should not be used for the same reason. Absence of a pulse may indicate that the site of **stenosis** (narrowing or constriction) is proximal to that location. Occlusive arterial disease impairs blood flow and can reduce or obliterate palpable pulsations in the extremities. Pulses should be palpated bilaterally and simultaneously, comparing both sides for symmetry in rate, rhythm, and quality.

Gerontologic Considerations

In elderly people, symptoms of peripheral arterial disease may be more pronounced than in younger people. In elderly patients who are inactive, gangrene may be the first sign of disease. These patients may have adjusted their lifestyle to accommodate the limitations imposed by the disease and may not walk far enough to develop symptoms of claudication. Circulation is decreased, but this is not apparent to the patient until trauma occurs. At this point, gangrene develops when minimal arterial flow is impaired further by edema formation resulting from the traumatic event.

Intermittent claudication may occur after walking only one-half to one block or after walking up a slight incline. Any prolonged pressure on the foot can cause pressure areas that become ulcerated, infected, and gangrenous. The outcomes of arterial insufficiency can include reduced mobility and activity as well as a loss of independence. Older people with reduced mobility are less likely to remain in the community setting, have higher rates of hospitalizations, and experience a poorer quality of life (McDermott, Guralnik, Tian, et al., 2007).

Diagnostic Evaluation

Various tests may be performed to identify and diagnose abnormalities that can affect the vascular structures (arteries, veins, and lymphatics).

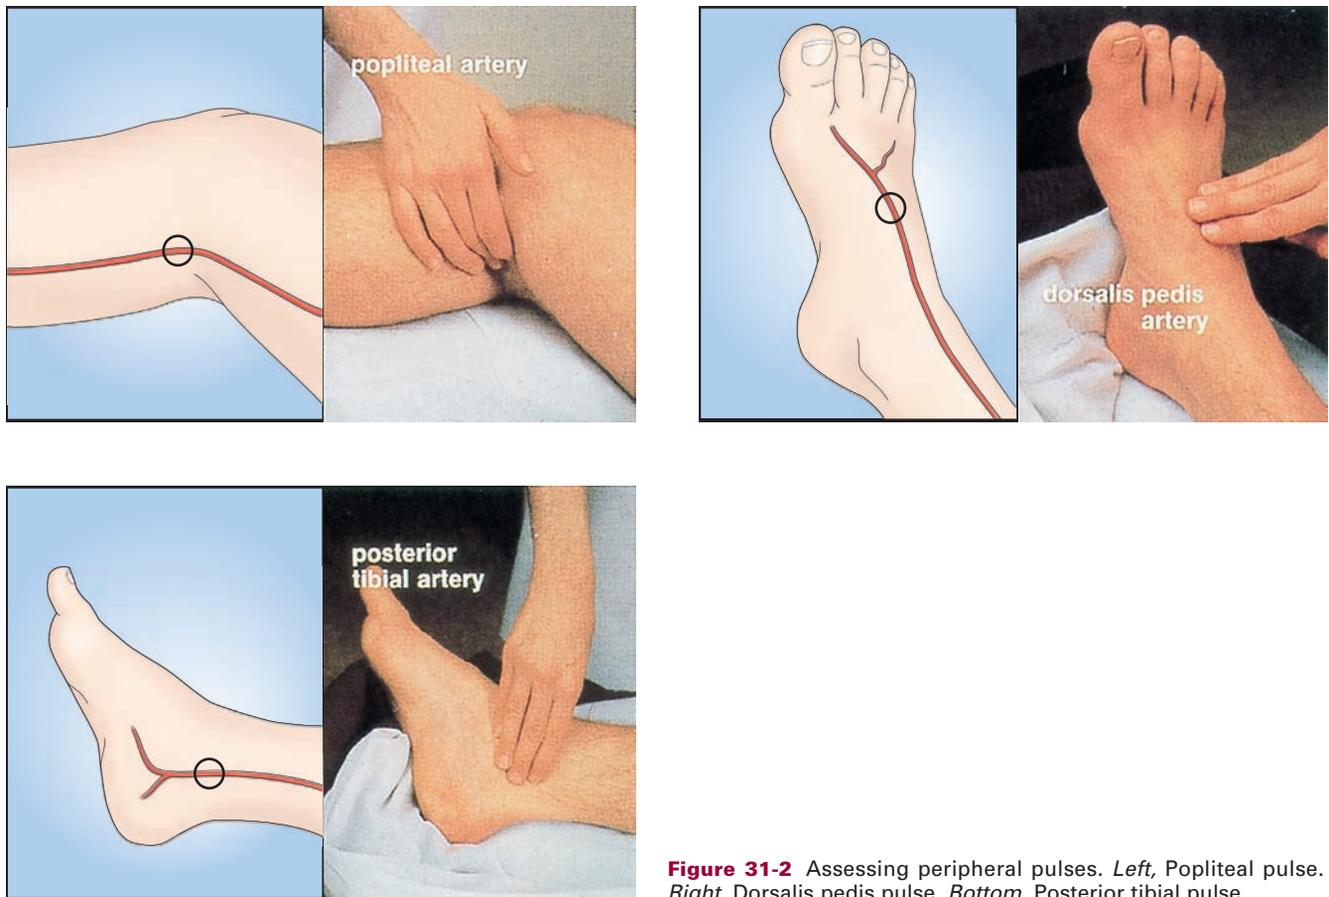

Figure 31-2 Assessing peripheral pulses. *Left*, Popliteal pulse. *Right*, Dorsalis pedis pulse. *Bottom*, Posterior tibial pulse.

Doppler Ultrasound Flow Studies

When pulses cannot be reliably palpated, a handheld continuous wave (CW) Doppler ultrasound device may be used to hear (insonate) the blood flow in vessels. This handheld device emits a continuous signal through the patient's tissues. The signals are reflected by ("echo off") the moving blood cells and are received by the device. The filtered-output Doppler signal is then transmitted to a loudspeaker or headphones, where it can be heard for interpretation. Because CW Doppler emits a continuous signal, all vascular structures in the path of the sound beam are insonated, and differentiating arterial from venous flow and detecting the site of a stenosis may be difficult. The depth at which blood flow can be detected by Doppler is determined by the frequency (in megahertz [MHz]) it generates. The lower the frequency, the deeper the tissue penetration; a 5- to 10-MHz probe may be used to evaluate the peripheral arteries.

To evaluate the lower extremities, the patient is placed in the supine position with the head of the bed elevated 20 to 30 degrees; the legs are externally rotated, if possible, to permit adequate access to the medial malleolus. Acoustic gel is applied to the patient's skin to permit uniform transmission of the ultrasound wave. The tip of the Doppler transducer is positioned at a 45- to 60-degree angle over the expected location of the artery and angled slowly to identify arterial blood flow. Excessive pressure is avoided because severely diseased arteries can collapse with even minimal pressure.

Because the transducer can detect blood flow in advanced arterial disease states, especially if collateral circulation has developed, identifying a signal documents only the presence of blood flow. The patient's provider must be notified of the absence of a signal if one had been detected previously.

CW Doppler is more useful as a clinical tool when combined with ankle blood pressures, which are used to determine the **ankle-brachial index (ABI)**, also called the **ankle-arm index (AAI)** (Fig. 31-3). The ABI is the ratio of the systolic blood pressure in the ankle to the systolic blood pressure in the arm. It is an objective indicator of arterial disease that allows the examiner to quantify the degree of stenosis. With increasing degrees of arterial narrowing, there is a progressive decrease in systolic pressure distal to the involved sites.

The first step in determining the ABI is to have the patient rest in a supine position (not seated) for approximately 5 minutes. An appropriate-sized blood pressure cuff (typically, a 10-cm cuff) is applied to the patient's ankle above the malleolus. After identifying an arterial signal at the posterior tibial and dorsalis pedis arteries, the systolic pressures are obtained in both ankles. Diastolic pressures in the ankles cannot be measured with a Doppler. If pressure in these arteries cannot be measured, pressure can be measured in the peroneal artery, which can also be assessed at the ankle (Fig. 31-4).

Doppler ultrasonography is used to measure brachial pressures in both arms. Both arms are evaluated because the

Figure 31-3 Continuous-wave (CW) Doppler ultrasound detects blood flow in peripheral vessels. Combined with computation of ankle or arm pressures, this diagnostic technique helps health care providers characterize the nature of peripheral vascular disease. Photograph reprinted with permission from Cantwell-Gab, K. (1996). Identifying chronic PAD. *American Journal of Nursing*, 96(7), 40–46.

patient may have an asymptomatic stenosis in the subclavian artery, causing brachial pressure on the affected side to be 20 mm Hg or more lower than systemic pressure. The abnormally low pressure should not be used for assessment.

To calculate ABI, the ankle systolic pressure for each foot is divided by the higher of the two brachial systolic pressures (Chart 31-1). The ABI can be computed for a patient with the following systolic pressures:

Right brachial: 160 mm Hg
 Left brachial: 120 mm Hg
 Right posterior tibial: 80 mm Hg
 Right dorsalis pedis: 60 mm Hg
 Left posterior tibial: 100 mm Hg
 Left dorsalis pedis: 120 mm Hg

The highest systolic pressure for each ankle (80 mm Hg for the right, 120 mm Hg for the left) would be divided by the highest brachial pressure (160 mm Hg):

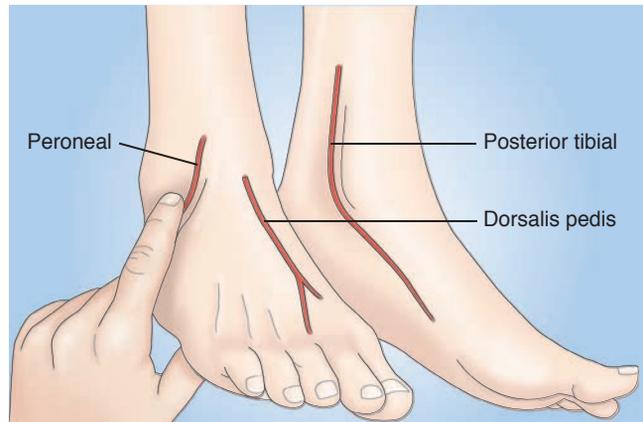

Figure 31-4 Location of peroneal artery; lateral malleolus.

Right: 80/160 mm Hg = 0.50 ABI

Left: 120/160 mm Hg = 0.75 ABI

In general, systolic pressure in the ankle of a healthy person is the same or slightly higher than the brachial systolic pressure, resulting in an ABI of about 1.0 (no arterial insufficiency). Patients with claudication usually have an ABI of 0.95 to 0.50 (mild to moderate insufficiency); patients with ischemic rest pain have an ABI of less than 0.50; and patients with severe ischemia or tissue loss have an ABI of 0.25 or less.

Exercise Testing

Exercise testing is used to determine how long a patient can walk and to measure the ankle systolic blood pressure in response to walking. The patient walks on a treadmill at 1.5 mph with a 10% incline for a maximum of 5 minutes. Most patients can complete the test unless they have severe cardiac, pulmonary, or orthopedic problems or a physical disability. A normal response to the test is little or no drop in ankle systolic pressure after exercise. However, in a patient with true vascular claudication, the ankle pressure drops. Combining this hemodynamic information with the

Chart 31-1 • Avoiding Common Errors in Calculating Ankle-Brachial Index (ABI)

Take the following precautions to ensure an accurate ABI calculation:

- *Use the correctly sized blood pressure (BP) cuffs.* To obtain accurate BP measurements, use a cuff with a bladder width at least 40% and length at least 80% of the limb circumference.
- *On the nursing plan of care, document the BP cuff sizes used* (eg, “12-cm BP cuff used for brachial pressures; 10-cm BP cuff used for ankle pressures”). This minimizes the risk of shift-to-shift discrepancies in ABIs.
- *Use sufficient BP cuff inflation.* To ensure complete closure of the artery and the most accurate measurements, inflate cuffs 20 to 30 mm Hg beyond the point at which the last arterial signal is detected.
- *Do not deflate BP cuffs too rapidly.* Try to maintain a deflation rate of 2 to 4 mm Hg/sec for patients without

dysrhythmias and 2 mm Hg/sec or slower for patients with dysrhythmias. Deflating the cuff more rapidly may miss the patient’s highest pressure and result in recording an erroneous (low) BP measurement.

- *Be suspicious of arterial pressures recorded at less than 40 mm Hg.* This may mean the venous signal has been mistaken for the arterial signal. If the arterial pressure, which is normally 120 mm Hg, is measured at less than 40 mm Hg, ask a colleague to double-check the findings before recording this as an arterial pressure.
- *Suspect medial calcific sclerosis anytime an ABI is 1.3 or greater or ankle pressure is more than 300 mm Hg.* Medial calcific sclerosis is associated with diabetes mellitus, chronic renal failure, and hyperparathyroidism. It produces falsely elevated ankle pressures by hardening the media of the arteries, making the vessels noncompressible.

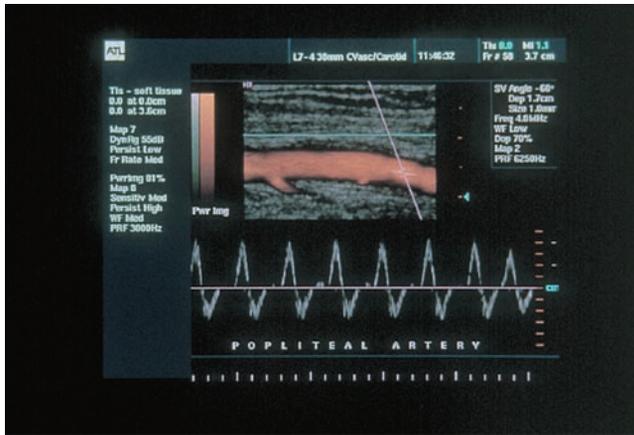

Figure 31-5 Color flow duplex image of popliteal artery with normal triphasic Doppler flow.

walking time helps the clinician determine whether intervention is necessary.

Duplex Ultrasonography

Duplex ultrasonography involves B-mode gray-scale imaging of the tissue, organs, and blood vessels (arterial and venous) and permits estimation of velocity changes by use of a pulsed Doppler (Fig. 31-5). Color flow techniques, which can identify vessels, may be used to shorten the examination time. The procedure primarily helps determine the level and extent of venous disease. The technique makes it possible to image and assess blood flow, evaluate flow of the distal vessels, locate the disease (stenosis versus occlusion), and determine anatomic morphology and the hemodynamic significance of plaque causing stenosis. Duplex ultrasound findings help in planning therapy and monitoring its outcomes. The test is noninvasive and usually requires no patient preparation. The equipment is portable, making it useful anywhere for initial diagnosis, screening, or follow-up evaluations.

Computed Tomography

Computed tomography (CT) provides cross-sectional images of soft tissue and visualizes the area of volume changes to an extremity and the compartment where changes take place. CT of a lymphedematous arm or leg, for example, demonstrates a characteristic honeycomb pattern in the subcutaneous tissue.

In spiral (also called helical) CT, the scan head moves circumferentially around the patient as the patient passes through the scanner, creating a series of overlapping images that are connected to one another in a continuous spiral. Currently, 64-“slice” scanners, which have 64 visual pictures per rotation, are available in most imaging centers; these provide improved volume coverage speed and/or longitudinal spatial resolution, resulting in improved images (Hallett & Fleischmann, 2006). Scan times are short. However, the patient is exposed to x-rays, and a contrast agent is usually injected to visualize the blood vessels. Using computer software, the slicelike images are reconstructed into three-dimensional images that can be rotated and viewed from multiple angles.

Computed Tomography Angiography

In computed tomography angiography (CTA), a spiral CT scanner and rapid intravenous (IV) infusion of contrast agent are used to image very thin sections of the target area, and the results are configured in three dimensions so that the image closely resembles an angiogram. A CTA of the thoracic or abdominal vasculature may be performed using 1.0- to 1.5-mm slices. However, thinner, 0.4- to 0.6-mm slices may be needed to evaluate small vessels such as those in the brain, kidney, upper extremity, or below-knee lower extremity. Achieving this increased resolution requires a higher radiation dose; therefore, this test is justified only if there is a potentially significant diagnostic gain (Hallett & Fleischmann, 2007). The high volume of contrast agent injected into a peripheral vein limits the usefulness of CTA in children and patients with significantly impaired renal function.

Angiography

An arteriogram produced by angiography may be used to confirm the diagnosis of occlusive arterial disease when surgery or other interventions are considered. It involves injecting a radiopaque contrast agent directly into the arterial system to visualize the vessels. The location of a vascular obstruction or an **aneurysm** (abnormal dilation of a blood vessel) and the collateral circulation can be demonstrated. Typically, the patient experiences a temporary sensation of warmth as the contrast agent is injected, and local irritation may occur at the injection site. Infrequently, a patient may have an immediate or delayed allergic reaction to the iodine contained in the contrast agent. Manifestations include dyspnea, nausea and vomiting, sweating, tachycardia, and numbness of the extremities. Any such reaction must be reported to the interventionalist at once; treatment may include the administration of epinephrine, antihistamines, or corticosteroids. Additional risks include vessel injury, acute arterial occlusion, bleeding, or contrast nephropathy.

Magnetic Resonance Angiography

Magnetic resonance angiography (MRA) is performed with a standard magnetic resonance imaging (MRI) scanner and special software programmed to isolate the blood vessels. The resulting images resemble a standard angiogram, but the images can be rotated and viewed from multiple angles.

Air Plethysmography

Air plethysmography is used to quantify venous reflux and calf muscle pump ejection. Changes in leg volumes are measured with the patient's legs elevated, with the patient supine and standing, and after the patient performs toe-ups (the patient extends the ankle while standing; stands on his or her toes) by an air-filled device wrapped around the feet and legs. Air plethysmography provides information about venous filling time, functional venous volume, ejected volume, and residual volume. It is useful in evaluating patients with suspected valvular incompetence or chronic venous insufficiency but is not used for diagnosis of deep vein thrombosis.

Contrast Phlebography (Venography)

Also known as venography, contrast phlebography involves injecting a radiopaque contrast agent into the venous system. If a thrombus exists, the x-ray image reveals an unfilled segment of vein in an otherwise completely filled vein. Injection of the contrast agent may cause brief but painful inflammation of the vein. The test is generally performed if the patient is to undergo thrombolytic therapy, but duplex ultrasonography is considered the standard for diagnosing lower extremity venous thrombosis.

Lymphangiography

Lymphangiography provides a way of detecting lymph node involvement resulting from metastatic carcinoma, lymphoma, or infection in sites that are otherwise inaccessible to the examiner except by surgery. In this test, a lymphatic vessel in each foot (or hand) is injected with contrast agent. A series of x-rays is taken at the conclusion of the injection, 24 hours later, and periodically thereafter, as indicated. The failure to identify subcutaneous lymphatic collection of contrast agent and the persistence of contrast agent in the tissue for days afterward help confirm a diagnosis of lymphedema.

Lymphoscintigraphy

Lymphoscintigraphy is a reliable alternative to lymphangiography. A radioactively labeled colloid is injected subcutaneously in the second interdigital space. The extremity is then exercised to facilitate the uptake of the colloid by the lymphatic system, and serial images are obtained at preset intervals.

ARTERIAL DISORDERS

Arteriosclerosis and Atherosclerosis

Arteriosclerosis is the most common disease of the arteries; the term means “hardening of the arteries.” It is a diffuse process whereby the muscle fibers and the endothelial lining of the walls of small arteries and arterioles become thickened. **Atherosclerosis** involves a different process, affecting the intima of the large and medium-sized arteries. These changes consist of the accumulation of lipids, calcium, blood components, carbohydrates, and fibrous tissue on the intimal layer of the artery. These accumulations are referred to as atheromas or plaques.

Although the pathologic processes of arteriosclerosis and atherosclerosis differ, rarely does one occur without the other, and the terms are often used interchangeably. Atherosclerosis is a generalized disease of the arteries, and when it is present in the extremities, it is usually present elsewhere in the body.

Pathophysiology

The most common direct results of atherosclerosis in arteries include narrowing (stenosis) of the lumen, obstruction by thrombosis, aneurysm, ulceration, and rupture. Its indirect results are malnutrition and the subsequent fibrosis of the organs that the sclerotic arteries supply with blood. All actively functioning tissue cells require an abundant supply

of nutrients and oxygen and are sensitive to any reduction in the supply of these nutrients. If such reductions are severe and permanent, the cells undergo ischemic necrosis (death of cells due to deficient blood flow) and are replaced by fibrous tissue, which requires much less blood flow.

Atherosclerosis can develop at any point in the body, but certain sites are more vulnerable, such as regions where arteries bifurcate or branch into smaller vessels. In the proximal lower extremity, these include the distal abdominal aorta, the common iliac arteries, the orifice of the superficial femoral and profunda femoris arteries, and the superficial femoral artery in the adductor canal, which is particularly narrow. Distal to the knee, atherosclerosis can occur anywhere along the artery.

Although many theories exist about the development of atherosclerosis, no single theory explains the pathogenesis completely; however, tenets of several theories are incorporated into the reaction-to-injury theory. According to this theory, vascular endothelial cell injury results from prolonged hemodynamic forces, such as shearing stresses and turbulent flow, irradiation, chemical exposure, or chronic hyperlipidemia. Injury to the endothelium increases the aggregation of platelets and monocytes at the site of the injury. Smooth muscle cells migrate and proliferate, allowing a matrix of collagen and elastic fibers to form (Guzman, 2007).

Atherosclerotic lesions are of two types: fatty streaks and fibrous plaque:

- Fatty streaks are yellow and smooth, protrude slightly into the lumen of the artery, and are composed of lipids and elongated smooth muscle cells. These lesions have been found in the arteries of people of all age groups, including infants. It is not clear whether fatty streaks predispose a person to the formation of fibrous plaques or whether they are reversible. They do not usually cause clinical symptoms.
- Fibrous plaques are composed of smooth muscle cells, collagen fibers, plasma components, and lipids. They are white to white-yellow and protrude in various degrees into the arterial lumen, sometimes completely obstructing it. These plaques are found predominantly in the abdominal aorta and the coronary, popliteal, and internal carotid arteries, and they are believed to be progressive lesions (Fig. 31-6).

Gradual narrowing of the arterial lumen stimulates the development of collateral circulation (Fig. 31-7). Collateral circulation arises from preexisting vessels that enlarge to reroute blood flow around a hemodynamically significant stenosis or occlusion. Collateral flow allows continued perfusion to the tissues, but it is often inadequate to meet increased metabolic demand, and ischemia results.

Risk Factors

Many risk factors are associated with atherosclerosis (Chart 31-2). Although it is not entirely clear whether modification of these risk factors prevents the development of cardiovascular disease, evidence indicates that it may slow the disease process (Ostchega, Dillon, Hughes, et al., 2007).

The use of tobacco products may be one of the most important risk factors in the development of atherosclerotic lesions. Nicotine in tobacco decreases blood flow to the extremities and increases heart rate and blood pressure by

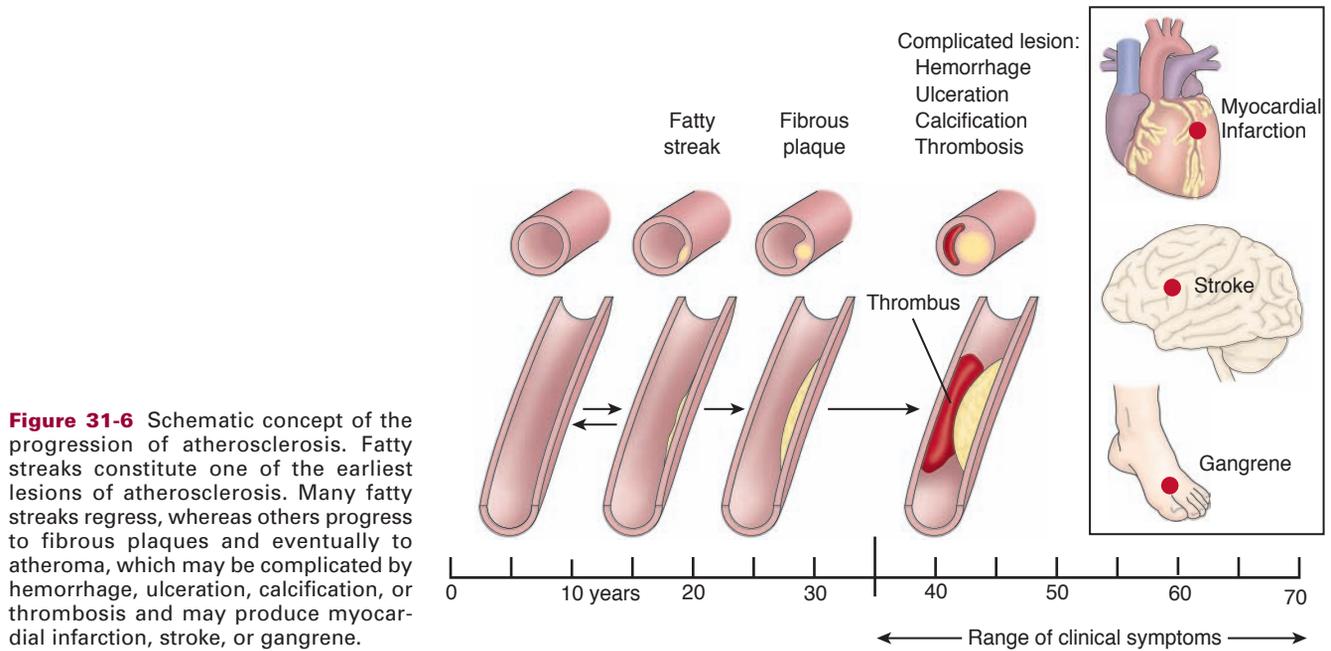

Figure 31-6 Schematic concept of the progression of atherosclerosis. Fatty streaks constitute one of the earliest lesions of atherosclerosis. Many fatty streaks regress, whereas others progress to fibrous plaques and eventually to atheroma, which may be complicated by hemorrhage, ulceration, calcification, or thrombosis and may produce myocardial infarction, stroke, or gangrene.

stimulating the sympathetic nervous system, causing vasoconstriction. It also increases the risk of clot formation by increasing the aggregation of platelets. Carbon monoxide, a toxin produced by burning tobacco, combines more readily with hemoglobin than oxygen, depriving the tissues of oxygen. The amount of tobacco used, inhaled or chewed, is directly related to the extent of the disease, and cessation of tobacco use reduces the risks. Many other factors, such as obesity, stress, and lack of exercise, have been identified as contributing to the disease process (Bakhrū & Erlinger, 2005).

C-reactive protein (CRP) is a sensitive marker of cardiovascular inflammation, both systemically and locally. Slight increases in serum CRP levels are associated with an increased risk of damage in the vasculature, especially if these increases are accompanied by other risk factors, including increasing age, female gender, hypertension, hypercholesterolemia, obesity, elevated blood glucose levels, smoking, or a positive family history of cardiovascular disease (Shankar, Li, Nieto, et al., 2007). There is also a positive association between peripheral arterial disease and the hemostatic or inflammatory markers fibrinogen and D-dimer (Reich, Heiss, Boland, et al., 2007).

Hyperhomocysteinemia has been positively correlated with the risk of peripheral, cerebrovascular, and coronary artery disease. Homocysteine is a protein that promotes coagulation by increasing factor V and factor XI activity

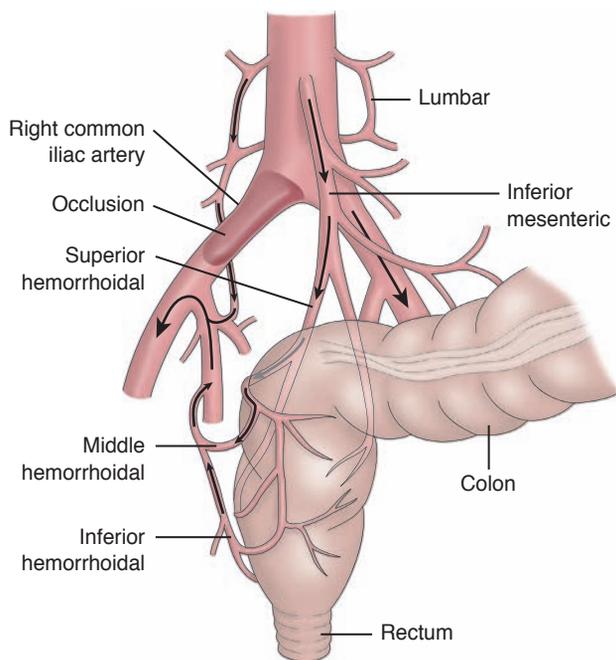

Figure 31-7 Development of channels for collateral blood flow in response to occlusion of the right common iliac artery and the terminal aortic bifurcation.

CHART 31-2 **Risk Factors for Atherosclerosis and Peripheral Arterial Disease**

Modifiable Risk Factors

- Nicotine use (ie, tobacco smoking or chewing)
- Diet (contributing to hyperlipidemia)
- Hypertension
- Diabetes mellitus (speeds the atherosclerotic process by thickening the basement membranes of both large and small vessels)
- Obesity
- Stress
- Sedentary lifestyle
- Elevated C-reactive protein
- Hyperhomocysteinemia

Nonmodifiable Risk Factors

- Age
- Gender
- Familial predisposition/genetics

while depressing protein C activation and increasing the binding of lipoprotein (a) in fibrin. These processes increase thrombin formation and the propensity for thrombosis. Folate therapy for hyperhomocysteinemia has not been shown to improve cardiovascular endpoints. However, National Cholesterol Education Program (NCEP) guidelines suggest that folic acid supplements of 0.5 to 1.0 mg daily be reserved for patients with a strong history of atherosclerosis that cannot be explained by their lipid profile (Rice & Lumsden, 2006).

Prevention

Intermittent claudication is a symptom of generalized atherosclerosis and may be a marker of occult coronary artery disease. Because it is suspected that a high-fat diet contributes to atherosclerosis, it is reasonable to measure serum cholesterol and to begin disease prevention efforts that include diet modification. The American Heart Association recommends reducing the amount of fat ingested in a healthy diet, substituting unsaturated fats for saturated fats, and decreasing cholesterol intake to reduce the risk of cardiovascular disease.

Certain medications that supplement dietary modification and exercise are used to reduce blood lipid levels. The NCEP has established guidelines for treating hyperlipidemia, with the primary goal of low-density lipoprotein (LDL) levels of less than 100 mg/dL. LDL levels of less than 70 mg/dL are recommended for patients with a history of diabetes, cigarette smoking, atherosclerosis, or hypertension (Federman, Ranani, Kirsner, et al., 2005). Secondary goals include achieving total cholesterol levels of less than 200 mg/dL and triglyceride levels less than 150 mg/dL. Medications classified as HMG-CoA reductase inhibitors or “statins,” including but not limited to atorvastatin (Lipitor), lovastatin (Mevacor), pravastatin (Pravachol), simvastatin (Zocor), fluvastatin (Lescol), and rosuvastatin (Crestor), are currently first-line treatment because they reduce the incidence of major cardiovascular events (Hankey, Norman & Eikelboom, 2006). Several other classes of medications used to reduce lipid levels include bile acid sequestrants (cholestyramine [Questran], colesevelam [WelChol], colestipol [Colestid]), nicotinic acid (niacin [Niacor, Niaspan]), fibric acid inhibitors (gemfibrozil [Lopid], fenofibrate [Tricor]), and cholesterol absorption inhibitors (ezetimibe [Zetia]). Patients receiving long-term therapy with these medications require close monitoring.

Hypertension, which may accelerate the rate at which atherosclerotic lesions form in high-pressure vessels, can lead to a cerebrovascular accident (CVA, brain attack, stroke), ischemic renal disease, severe peripheral arterial disease (PAD), or coronary artery disease. Hypertension is a major risk factor for the development of PAD, resulting in a twofold risk of development of claudication (Steg, Bhatt, Wilson, et al., 2007). All patients with PAD should achieve blood pressure control consistent with the Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation and Treatment of High Blood Pressure (JNC 7) guidelines (systolic blood pressure less than 130 mm Hg; diastolic blood pressure less than 90 mm Hg) (Ostchega, et al., 2007).

Although no single risk factor has been identified as the primary contributor to the development of atherosclerotic cardiovascular disease, it is clear that the greater the number of risk factors, the greater the risk of atherosclerosis. Elimination of all controllable risk factors, particularly the use of nicotine products, is strongly recommended.

Clinical Manifestations

The clinical signs and symptoms resulting from atherosclerosis depend on the organ or tissue affected. Coronary atherosclerosis (heart disease), angina, and acute myocardial infarction are discussed in Chapter 28. Cerebrovascular diseases, including transient cerebral ischemic attacks and stroke, are discussed in Chapter 62. Atherosclerosis of the aorta, including aneurysm, and atherosclerotic lesions of the extremities are discussed later in this chapter. Renovascular disease (renal artery stenosis and end-stage renal disease) is discussed in Chapter 45.

Medical Management

The management of atherosclerosis involves modification of risk factors, a controlled exercise program to improve circulation and its functioning capacity, medication therapy, and interventional or surgical graft procedures.

Surgical Management

Vascular surgical procedures are divided into two groups: inflow procedures, which improve blood supply from the aorta into the femoral artery, and outflow procedures, which provide blood supply to vessels below the femoral artery. Inflow surgical procedures are described with diseases of the aorta and outflow procedures with peripheral arterial occlusive disease.

Radiologic Interventions

Several interventional radiologic techniques are important adjunctive therapies to surgical procedures. If an isolated lesion or lesions are identified during the arteriogram, **angioplasty**, also called percutaneous transluminal angioplasty (PTA), may be performed. After the patient receives a local anesthetic agent, a balloon-tipped catheter is maneuvered across the area of stenosis. Although some clinicians theorize that PTA improves blood flow by overstretching (and thereby dilating) the elastic fibers of the nondiseased arterial segment, most believe that the procedure widens the arterial lumen by “cracking” and flattening the plaque against the vessel wall (see Chapter 28). Complications from PTA include hematoma formation, embolus, **dissection** (separation of the intima) of the vessel, acute arterial occlusion, and bleeding. To decrease the risk of reocclusion, stents (small, mesh tubes made of nitinol, titanium, or stainless steel) may be inserted to support the walls of blood vessels and prevent collapse immediately after balloon inflation (Fig. 31-8). A variety of stents and stent-grafts may be used for short-segment stenoses. Complications associated with stent or stent-graft use include distal embolization, intimal damage (dissection), and dislodgment. The advantage of angioplasty, stents, and stent-grafts is the decreased length of hospital stay required for the treatment; many of the procedures are performed on an outpatient basis.

Nursing Management of the Patient With Peripheral Arterial Insufficiency of the Extremities

An overview of the care of a patient with peripheral arterial problems is provided in the Plan of Nursing Care: The Patient With Peripheral Vascular Problems (Chart 31-3).

Improving Peripheral Arterial Circulation

Arterial blood supply to a body part can be enhanced by positioning the part below the level of the heart. For the lower extremities, this is accomplished by elevating the head of the patient's bed or by having the patient use a reclining chair or sit with the feet resting on the floor.

The nurse can assist the patient with walking or other moderate or graded isometric exercises that may be prescribed to promote blood flow and encourage the development of collateral circulation. The nurse instructs the patient to walk to the point of pain, rest until the pain subsides, and then resume walking so that endurance can be increased as collateral circulation develops. Pain can serve as a guide in determining the appropriate amount of exercise. The onset of pain indicates that the tissues are not receiving adequate oxygen, signaling the patient to rest before continuing activity. A regular exercise program can result in increased walking distance before the onset of claudication. The amount of exercise a patient can tolerate before the onset of pain is determined to provide a baseline for evaluation.

Not all patients with peripheral vascular disease should exercise. Before recommending any exercise program, the patient's primary health care provider should be consulted. Conditions that worsen with exercise include leg ulcers, cellulitis, gangrene, or acute thrombotic occlusions.

Promoting Vasodilation and Preventing Vascular Compression

Arterial dilation promotes increased blood flow to the extremities and is therefore a goal for patients with PAD. However, if the arteries are severely sclerosed, inelastic, or damaged, dilation is not possible. For this reason, measures to promote vasodilation, such as medications or surgery, may be only minimally effective.

Nursing interventions may involve applications of warmth to promote arterial flow and instructions to the patient to avoid exposure to cold temperatures, which causes vasoconstriction. Adequate clothing and warm temperatures protect the patient from chilling. If chilling occurs, a warm bath or drink is helpful. A hot water bottle or heating pad may be applied to the patient's abdomen, causing vasodilation throughout the lower extremities.

NURSING ALERT

Patients are instructed to test the temperature of bath water and to avoid using hot water bottles and heating pads on the extremities. It is safer to apply a hot water bottle or a heating pad to the abdomen; this can cause reflex vasodilation in the extremities.

In patients with vasospastic disorders (eg, Raynaud's disease), heat may be applied directly to ischemic extremities using a warmed or electric blanket; however, the temperature of the heat source must not exceed body temperature. Even at low temperatures, trauma to the tissues can occur in ischemic extremities.

NURSING ALERT

Excess heat may increase the metabolic rate of the extremities and increase the need for oxygen beyond that provided by the reduced arterial flow through the diseased artery. Heat must be used with great caution!

Nicotine from tobacco products causes vasospasm and can thereby dramatically reduce circulation to the extremities. Tobacco smoke also impairs transport and cellular use of oxygen and increases blood viscosity. Patients with arterial insufficiency who smoke or chew tobacco must be fully informed of the effects of nicotine on circulation and encouraged to stop.

Emotional upsets stimulate the sympathetic nervous system, resulting in peripheral vasoconstriction. Emotional stress can be minimized to some degree by avoiding stressful situations when possible or by consistently following a stress

CHART
31-3
PLAN OF NURSING CARE**The Patient With Peripheral Vascular Problems****NURSING DIAGNOSIS:** Ineffective peripheral tissue perfusion related to compromised circulation**GOAL:** Increased arterial blood supply to extremities**Nursing Interventions**

1. Lower the extremities below the level of the heart (if condition is arterial in nature).
2. Encourage moderate amount of walking or graded extremity exercises if no contraindications exist.

Rationale

1. Dependency of lower extremities enhances arterial blood supply.
2. Muscular exercise promotes blood flow and the development of collateral circulation.

Expected Outcomes

- Has extremities warm to touch
- Has extremities with improved color
- Experiences decreased muscle pain with exercise

GOAL: Decrease in venous congestion**Nursing Interventions**

1. Elevate extremities above heart level (if condition is venous in nature).
2. Discourage standing still or sitting for prolonged periods.
3. Encourage walking.

Rationale

1. Elevation of extremities counteracts gravity, promotes venous return, and prevents venous stasis.
2. Prolonged standing still or sitting promotes venous stasis.
3. Walking promotes venous return by activating the "muscle pump."

Expected Outcomes

- Elevates lower extremities as prescribed
- Has decreased edema of extremities
- Avoids prolonged standing still or sitting
- Gradually increases walking time daily

GOAL: Promotion of vasodilation and prevention of vascular compression**Nursing Interventions**

1. Maintain warm temperature and avoid chilling.
2. Discourage use of tobacco products.
3. Counsel in ways to avoid emotional upsets; stress management.
4. Encourage avoidance of constrictive clothing and accessories.
5. Encourage avoidance of crossing the legs.
6. Administer vasodilator medications and adrenergic blocking agents as prescribed, with appropriate nursing considerations.

Rationale

1. Warmth promotes arterial flow by preventing the vasoconstriction effects of chilling.
2. Nicotine in all tobacco products causes vasospasm, which impedes peripheral circulation.
3. Emotional stress causes peripheral vasoconstriction by stimulating the sympathetic nervous system.
4. Constrictive clothing and accessories impede circulation and promote venous stasis.
5. Crossing the legs causes compression of vessels with subsequent impediment of circulation, resulting in venous stasis.
6. Vasodilators relax smooth muscle; adrenergic blocking agents block the response to sympathetic nerve impulses or circulating catecholamines.

Expected Outcomes

- Protects extremities from exposure to cold
- Avoids all tobacco products
- Uses stress management program to minimize emotional upset
- Avoids constricting clothing and accessories
- Avoids crossing legs
- Takes medication as prescribed

NURSING DIAGNOSIS: Chronic pain related to impaired ability of peripheral vessels to supply tissues with oxygen**GOAL:** Relief of pain**Nursing Interventions**

1. Promote increased circulation.
2. Administer analgesic agents as prescribed, with appropriate nursing considerations.

Rationale

1. Enhancement of peripheral circulation increases the oxygen supplied to the muscle and decreases the accumulation of metabolites that cause muscle spasms.
2. Analgesic agents help reduce pain and allow the patient to participate in activities and exercises that promote circulation.

Expected Outcomes

- Uses measures to increase arterial blood supply to extremities
- Uses analgesic agents as prescribed

Continued

**CHART
31-3**
PLAN OF NURSING CARE**The Patient With Peripheral Vascular Problems (Continued)****NURSING DIAGNOSIS:** Risk for impaired skin integrity related to compromised circulation**GOAL:** Attainment/maintenance of tissue integrity**Nursing Interventions**

1. Instruct in ways to avoid trauma to extremities.
2. Encourage wearing protective shoes and padding for pressure areas; wear new shoes for short period of time and inspect feet for signs of injury.
3. Encourage meticulous hygiene: bathing with neutral soaps, applying lotions, and carefully trimming nails.
4. Caution to avoid scratching or vigorous rubbing.
5. Promote good nutrition; adequate intake of vitamins A and C, protein, and zinc; and control of obesity.

Rationale

1. Poorly nourished tissues are susceptible to trauma and bacterial invasion; healing of wounds is delayed or inhibited due to poor tissue perfusion.
2. Protective shoes and padding prevent foot injuries and blisters.
3. Neutral soaps and lotions prevent drying and cracking of skin; avoid lotion between toes as the increased moisture can lead to maceration of tissue.
4. Scratching and rubbing can cause skin abrasions and bacterial invasion.
5. Good nutrition promotes healing and prevents tissue breakdown.

Expected Outcomes

- Inspects skin daily for evidence of injury or ulceration
- Avoids trauma and irritation to skin
- Wears protective shoes
- Adheres to meticulous hygiene regimen
- Eats a healthy diet that contains adequate protein and vitamins A and C

NURSING DIAGNOSIS: Deficient knowledge regarding self-care activities**GOAL:** Adherence to the self-care program**Nursing Interventions**

1. Include family/significant others in teaching program.
2. Provide written instructions about foot care, leg care, and exercise program.
3. Assist to obtain properly fitting clothing, shoes, and stockings.
4. Refer to self-help groups as indicated, such as smoking cessation clinics or stress management, weight management, and exercise program.

Rationale

1. Adherence to the self-care program is enhanced when the patient receives support from family and from appropriate self-help groups and agencies.
2. Written instructions serve as reminder and reinforcement of information.
3. Constrictive clothing and accessories impede circulation and promote venous stasis.
4. Reducing risk factors may reduce symptoms or slow disease progression.

Expected Outcomes

- Practices frequent position changes as prescribed
- Practices postural exercises as prescribed
- Takes medications as prescribed
- Avoids vasoconstrictors
- Uses measures to prevent trauma
- Uses stress management program
- Accepts condition as chronic but amenable to therapies that will decrease symptoms

management program. Counseling services or relaxation training may be indicated for people who cannot cope effectively with situational stressors.

Constrictive clothing and accessories such as tight socks or shoelaces may impede circulation to the extremities and promote venous stasis and therefore should be avoided. Crossing the legs for more than 15 minutes at a time should be discouraged because it compresses vessels in the legs.

Relieving Pain

Frequently, the pain associated with peripheral arterial insufficiency is chronic, continuous, and disabling. It limits activities, affects work and responsibilities, disturbs sleep, and alters the patient's sense of well-being. Patients are often depressed, irritable, and unable to exert the energy necessary to execute prescribed therapies, making pain relief even

more difficult. Analgesic agents such as hydrocodone plus acetaminophen (Vicodin), oxycodone plus acetylsalicylic acid (Percodan), or oxycodone plus acetaminophen (Percocet) may be helpful in reducing pain so that the patient can participate in therapies that can increase circulation and ultimately relieve pain more effectively.

Maintaining Tissue Integrity

Poorly perfused tissues are susceptible to damage and infection. When lesions develop, healing may be delayed or inhibited because of the poor blood supply to the area. Infected, nonhealing ulcerations of the extremities can be debilitating and may require prolonged and often expensive treatments. Amputation of an ischemic limb may eventually be necessary. Measures to prevent these complications must be a high priority and vigorously implemented.

Trauma to the extremities must be avoided. Advising the patient to wear sturdy, well-fitting shoes or slippers to prevent foot injury and blisters may be helpful, and recommending neutral soaps and body lotions may prevent drying and cracking of skin. However, it is important to instruct the patient not to apply lotion between the toes because the increased moisture can lead to maceration of tissue. Scratching and vigorous rubbing can abrade skin and create sites for bacterial invasion; therefore, feet should be patted dry. Stockings should be clean and dry. Fingernails and toenails should be carefully trimmed straight across and sharp corners filed to follow the contour of the nail. If the nails cannot be trimmed safely, it is necessary to consult a podiatrist, who can also remove corns and calluses. Special shoe inserts may be needed to prevent calluses from recurring. All signs of blisters, ingrown toenails, infection, or other problems should be reported to health care professionals for treatment and follow-up. Patients with diminished vision and those with disabilities that limit mobility of the arms or legs may require assistance in periodically examining the lower extremities for trauma or evidence of inflammation or infection.

Good nutrition promotes healing and prevents tissue breakdown and is therefore included in the overall thera-

peutic program for patients with peripheral vascular disease. Eating a diet that contains adequate protein and vitamins is necessary for patients with arterial insufficiency. Key nutrients play specific roles in wound healing. Vitamin C is essential for collagen synthesis and capillary development. Vitamin A enhances epithelialization. Zinc is necessary for cell mitosis and cell proliferation. Obesity strains the heart, increases venous congestion, and reduces circulation; therefore, a weight reduction plan may be necessary for some patients. A diet low in lipids may be indicated for patients with atherosclerosis.

Promoting Home and Community-Based Care

The self-care program is planned with the patient so that activities that promote arterial and venous circulation, relieve pain, and promote tissue integrity are acceptable. The patient and family are helped to understand the reasons for each aspect of the program, the possible consequences of nonadherence, and the importance of keeping follow-up appointments. Long-term care of the feet and legs is of prime importance in the prevention of trauma, ulceration, and gangrene. Chart 31-4 provides detailed patient instructions for foot and leg care.

Peripheral Arterial Occlusive Disease

Arterial insufficiency of the extremities occurs most often in men and is a common cause of disability. The legs are most frequently affected; however, the upper extremities may be involved. The age of onset and the severity are influenced by the type and number of atherosclerotic risk factors (see Chart 31-2). In PAD, obstructive lesions are predominantly confined to segments of the arterial system extending from the aorta below the renal arteries to the popliteal artery (Fig. 31-9). Distal occlusive disease is frequently seen in patients with diabetes mellitus and in elderly patients (Chart 31-5).

Clinical Manifestations

The hallmark symptom is intermittent claudication. This pain may be described as aching, cramping, or inducing fatigue or weakness that occurs with the same degree of exercise or activity and is relieved with rest. The pain commonly occurs in muscle groups distal to the area of stenosis or occlusion. As the disease progresses, the patient may have a decreased ability to walk the same distance as previously or may notice increased pain with ambulation. When

the arterial insufficiency becomes severe, the patient has rest pain. This pain is associated with critical ischemia of the distal extremity and is persistent, aching, or boring; it may be so excruciating that it is unrelieved by opioids and is disabling. Ischemic rest pain is usually worse at night and often wakes the patient. Elevating the extremity or placing it in a horizontal position increases the pain, whereas placing the extremity in a dependent position reduces the pain. Some patients sleep with the affected leg hanging over the side of the bed. Some patients sleep in a reclining chair in an attempt to prevent or relieve the pain.

Assessment and Diagnostic Findings

A sensation of coldness or numbness in the extremities may accompany intermittent claudication and is a result of reduced arterial flow. The extremity is cool and pale when elevated or ruddy and cyanotic when placed in a dependent position. Skin and nail changes, ulcerations, gangrene, and muscle atrophy may be evident. Bruits may be auscultated with a stethoscope. Peripheral pulses may be diminished or absent.

Examination of the peripheral pulses is an important part of assessing arterial occlusive disease. Unequal pulses between extremities or the absence of a normally palpable pulse is a sign of PAD.

NURSING RESEARCH PROFILE

Long-Term Outcomes of Peripheral Arterial Disease in Patients With Diabetes in a Primary Care Setting

Khattab, D., Ali, I. S. & Rawlings, B. (2005). Peripheral arterial disease in diabetic patients selected from a primary care setting: Implications for nursing practice. *Journal of Vascular Nursing*, 23(4), 139–148.

Purpose

Patients diagnosed with diabetes have higher rates of peripheral arterial disease (PAD) than patients without diabetes. Few epidemiologic studies have examined long-term glycemic control and its association with PAD. Most of the care given to patients diagnosed with diabetes occurs in outpatient settings, yet there is limited information on the prevalence of diabetes and long-term progression of asymptomatic PAD in patients with PAD in primary care settings. The aims of this study were to investigate the prevalence and the progression of PAD in patients with diabetes compared to the progression of PAD in patients without diabetes over a 7-year period.

Design

This study included male and female patients ($n = 146$) with diabetes selected from a family practice clinic serving a population of 13,500 in southern England. They ranged in age from 17 to 94 years. The two endpoints were progression of PAD and death. The researchers compared mortality data from these patients with those of a control group of 113 patients without diabetes with similar demographics. They investigated the cohort group with diabetes in years 1, 3, and 7, obtaining a complete health history, body mass index (BMI) calculation, plasma glucose levels (fasting and 2 hours postprandial), Hb_{A1C}, and total cholesterol and triglyceride levels. In addition, researchers obtained Doppler pressures on the posterior tibial, dorsalis pedis, and peroneal arteries bilaterally and calculated individual ankle-brachial indices (ABIs) for each tibial artery. They noted the cause of death for patients from both cohorts who died during the 7-year course of the study.

Findings

The prevalence of PAD in the cohort group with diabetes by the seventh year of the study was 57.1% in males and 51.4% in females; PAD tended to affect both legs symmetrically. By the end of the 7-year study period, PAD had progressed in 50% of the 70 patients with diabetes who remained enrolled in the study. During these 7 years, 10 of these patients developed claudication, 13 developed rest pain, and 3 developed critical ischemia.

A comparison of risk factors between those who did and did not show progression of PAD found that increasing age, duration of diabetes, smoking, and BMI were not statistically significant risk factors. Multiple regression analysis at year 7 revealed a significant ($p \leq 0.05$) independent association between hyperglycemia measured by Hb_{A1C} and progression of PAD in the cohort with diabetes.

The overall mortality during the 7-year follow-up was 34.25% of the cohort group and 13.2% of the control group. This indicates a relative risk of mortality in the people with diabetes of 2.6-fold compared with controls.

Nursing Implications

Findings from this study are consistent with prevalence data concerning noninvasively diagnosed PAD in patients with diabetes. The prevalence of PAD among these participants with diabetes was higher than that in general population studies. Nurses in primary care settings need to know that identification of patients at high risk for death, followed by an aggressive approach to the correction of their atherosclerotic risk factors, may improve the survival in those with PAD. The findings of this study suggest that a low ABI value is strongly associated with increased mortality rate. Nurses may use Dopplers and obtain ABIs on patients at risk (ie, with diabetes) and, when appropriate, counsel and advise their patients about optimizing their health status. This may result in earlier detection of patients at risk for developing macrovascular complications.

The presence, location, and extent of arterial occlusive disease are determined by a careful history of the symptoms and by physical examination. The color and temperature of the extremity are noted and the pulses palpated. The nails may be thickened and opaque, and the skin may be shiny, atrophic, and dry, with sparse hair growth. The assessment includes comparison of the right and left extremities.

The diagnosis of peripheral arterial occlusive disease may be made using CW Doppler and ABIs, treadmill testing for claudication, duplex ultrasonography, or other imaging studies previously described.

Medical Management

Generally, patients feel better with some type of exercise program. Exercise therapy that centers around walking to a point that causes pain three times weekly has shown to increase maximal walking time (minutes) and results in an overall improvement in walking ability of approximately 150% (Leng, Fowler & Ernst, 2005). If this walking program is combined with weight reduction and cessation of tobacco use, patients often can improve their activity toler-

ance. Patients should not be promised that their symptoms will be relieved if they stop tobacco use, because claudication may persist, and they may lose their motivation to stop using tobacco.

Pharmacologic Therapy

Pentoxifylline (Trental) and cilostazol (Pletal) are approved for the treatment of symptomatic claudication. However, studies have found no consistent improvement with pentoxifylline compared to placebo (Robless, Mikhailidis & Stansby, 2008). Pentoxifylline increases erythrocyte flexibility, lowers blood fibrinogen concentrations, and has antiplatelet effects. Cilostazol, a phosphodiesterase III inhibitor, is a vasodilator that inhibits platelet aggregation. This agent is contraindicated in patients with a history of congestive heart failure (Rice & Lumsden, 2006).

Antiplatelet agents such as aspirin or clopidogrel (Plavix) prevent the formation of thromboemboli, which can lead to myocardial infarction and stroke. Aspirin has been shown to reduce the risk of cardiovascular events (eg, myocardial infarction, stroke, and cardiovascular death) in patients

with vascular disease; however, adverse events associated with aspirin use include gastrointestinal upset or bleeding. In a study conducted with a large, international registry of outpatients with known PAD, the 1-year rate for a cardiovascular event was high. The rate depended on whether the patient had risk factors (2.2%) alone or also symptomatic coronary or cerebrovascular disease (9.2%), suggesting that atherothrombosis is a type of global arterial disease (Steg, et al., 2007).

Statin therapy reduces the incidence of new intermittent claudication symptoms in patients with prior myocardial infarctions or anginal symptoms and improves pain-free walking time in patients with PAD. These medications also have beneficial effects on vascular inflammation, plaque stabilization, endothelial dysfunction, and thrombosis (Rice & Lumsden, 2006).

Surgical Management

Surgery is reserved for treatment of severe and disabling claudication or when the limb is at risk for amputation because of tissue necrosis. The choice of the surgical procedure depends on the degree and location of the stenosis or occlusion. Other important considerations are the overall health of the patient and the length of the procedure that can be tolerated. For patients whose overall health is so compromised that they cannot tolerate an extensive vascular surgical procedure, it is sometimes necessary to provide the palliative therapy of primary amputation rather than arterial bypass. If endarterectomy is performed, an incision is made into the artery and the atheromatous obstruction is removed (Fig. 31-10).

Bypass grafts are performed to reroute the blood flow around the stenosis or occlusion. Before bypass grafting, the surgeon determines where the distal **anastomosis** (site where the vessels are surgically joined) will be placed. The distal outflow vessel must be at least 50% patent for the graft to remain patent. If the atherosclerotic occlusion is below the inguinal ligament in the superficial femoral artery, the surgical procedure of choice is the femoral-to-popliteal graft. This procedure is further classified as above-knee and below-knee grafts, referring to the location of the distal anastomosis.

Lower leg or ankle vessels with occlusions may also require grafts. Occasionally, the popliteal artery is completely occluded and only collateral vessels maintain perfusion.

The distal anastomosis may be made onto any of the tibial arteries (posterior tibial, anterior tibial, or peroneal arteries) or the dorsalis pedis or plantar artery. The distal anastomosis site is determined by the ease of exposure of the vessel in surgery and by which vessel provides the best flow to the distal limb. These grafts require the use of native vein (ie, autologous; the patient's own vein) to ensure patency. The greater or lesser saphenous vein or a combination of one of the saphenous veins and an upper extremity vein such as the cephalic vein is used to provide the required length.

How long the graft remains patent is determined by several factors, including the size of the graft, graft location, and development of intimal hyperplasia at anastomosis sites. Bypass grafts may be synthetic or use autologous vein. Several synthetic materials are available for use as a peripheral bypass graft: woven or knitted Dacron or expanded polytetrafluoroethylene (ePTFE, such as Gore-Tex or Impra). Cryopreserved saphenous veins and umbilical veins are also available. Infection can be a problem that threatens survival of the graft and almost always requires its removal.

If a vein graft is the surgical choice, care must be taken in the operating room not to damage the vein after harvesting (removing the vein from the patient's body). The vein is occluded at one end and inflated with a heparinized solution to check for leakage and competency. The graft is then placed in a heparinized solution to keep it from becoming dry and brittle.

Nursing Management

Maintaining Circulation

The primary objective in the postoperative period is to maintain adequate circulation through the arterial repair. Pulses, Doppler assessment, color and temperature, capillary refill, and sensory and motor function of the affected extremity are checked and compared with those of the other extremity; these values are recorded initially every 15 minutes and then at progressively longer intervals if the patient's status remains stable. Doppler evaluation of the vessels distal to the bypass graft should be performed for all postoperative vascular patients because it is more sensitive than palpation for pulses. The ABI is monitored at least once every 8 hours for the first 24 hours and then once each day until discharge (not usually assessed with pedal artery bypasses). An adequate circulating blood volume should be

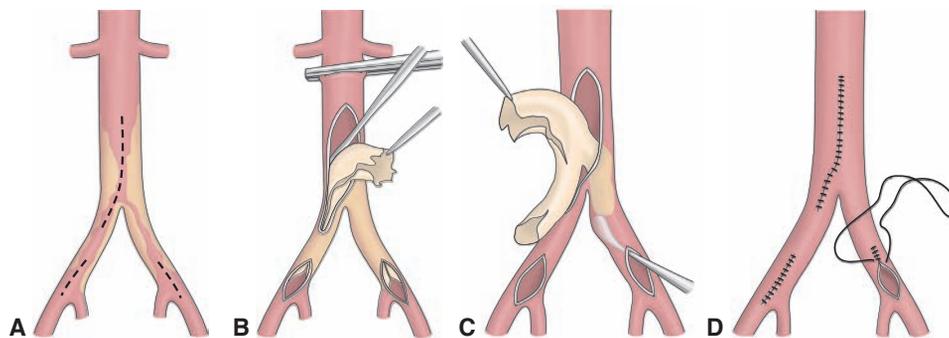

Figure 31-10 In an aortoiliac endarterectomy, the vascular surgeon (A) identifies the diseased area, (B) clamps off the blood supply to the vessel, (C) removes the plaque, and (D) sutures the vessel shut, after which blood flow is restored. Adapted with permission from Rutherford, R. B. (2005). *Vascular surgery* (6th ed., Vols. I and II). Philadelphia: Elsevier.

established and maintained. Disappearance of a pulse that was present may indicate thrombotic occlusion of the graft; the surgeon is immediately notified.

Monitoring and Managing Potential Complications

Continuous monitoring of urine output, central venous pressure, mental status, and pulse rate and volume permits early recognition and treatment of fluid imbalances. Bleeding can result from the heparin administered during surgery or from an anastomotic leak. A hematoma may form as well.

Leg crossing and prolonged extremity dependency are avoided to prevent thrombosis. Edema is a normal postoperative finding; however, elevating the extremities and encouraging the patient to exercise the extremities while in bed reduces edema. Graduated compression or anti-embolism stockings may be prescribed for some patients, but care must be taken to avoid compressing distal vessel bypass grafts. Severe edema of the extremity, pain, and decreased sensation of toes or fingers can be an indication of compartment syndrome (see Chapter 69).

Promoting Home and Community-Based Care

Discharge planning includes assessing the patient's ability to manage activities of daily living (ADLs) independently. The nurse determines whether the patient has a network of family and friends to assist with ADLs. The patient is encouraged to make the lifestyle changes necessitated by the onset of a chronic disease, including pain management and modifications in diet, activity, and hygiene (skin care). The nurse ensures that the patient has the knowledge and ability to assess for any postoperative complications such as infection, occlusion of the artery or graft, and decreased blood flow. The nurse assists the patient in developing and implementing a plan to stop using tobacco.

Nursing care for patients with peripheral vascular disease is reviewed in Chart 31-3.

Upper Extremity Arterial Occlusive Disease

Arterial occlusions occur less frequently in the upper extremities (arms) than in the legs and cause less severe symptoms because the collateral circulation is significantly better in the arms. The arms also have less muscle mass and are not subjected to the workload of the legs.

Clinical Manifestations

Stenosis and occlusions in the upper extremity result from atherosclerosis or trauma. The stenosis usually occurs at the origin of the vessel proximal to the vertebral artery, setting up the vertebral artery as the major contributor of flow. The patient typically complains of arm fatigue and pain with exercise (forearm claudication), inability to hold or grasp objects (eg, combing hair, placing objects on shelves above the head), and occasionally difficulty driving.

The patient may develop a "subclavian steal" syndrome characterized by reverse flow in the vertebral and basilar artery to provide blood flow to the arm. This syndrome may cause vertebrobasilar (cerebral) symptoms, including vertigo, ataxia, syncope, or bilateral visual changes.

Assessment and Diagnostic Findings

Assessment findings include coolness and pallor of the affected extremity, decreased capillary refill, and a difference in arm blood pressures of more than 20 mm Hg. Noninvasive studies performed to evaluate for upper extremity arterial occlusions include upper and forearm blood pressure determinations and duplex ultrasonography to identify the anatomic location of the lesion and to evaluate the hemodynamics of the blood flow. Transcranial Doppler evaluation is performed to evaluate the intracranial circulation and to detect any siphoning of blood flow from the posterior circulation to provide blood flow to the affected arm. If a surgical or interventional procedure is planned, a diagnostic arteriogram may be necessary.

Medical Management

If a short, focal lesion is identified in an upper extremity artery, a PTA with possible stent or stent-graft placement may be performed. If the lesion involves the subclavian artery with documented siphoning of blood flow from the intracranial circulation and an interventional radiologic procedure is not possible, a surgical bypass may be performed.

Nursing Management

Nursing assessment involves bilateral comparison of upper arm blood pressures (obtained by stethoscope and Doppler); radial, ulnar, and brachial pulses; motor and sensory function; temperature; color changes; and capillary refill every 2 hours. Disappearance of a pulse or Doppler flow that had been present may indicate an acute occlusion of the vessel, and the physician is notified immediately.

After surgery, the arm is kept at heart level or elevated, with the fingers at the highest level. Pulses are monitored with Doppler assessment of the arterial flow every hour for 4 hours and then every shift. Blood pressure (obtained by stethoscope and Doppler) is also assessed every hour for 4 hours and then every shift. Motor and sensory function, warmth, color, and capillary refill are monitored with each arterial flow (pulse) assessment.

NURSING ALERT

Before and for 24 hours after surgery, the patient's arm is kept at heart level and protected from cold, venipunctures or arterial sticks, tape, and constrictive dressings.

Discharge planning is similar to that for the patient with peripheral arterial occlusive disease. Chart 31-3 describes nursing care for patients with peripheral vascular disease.

Thromboangiitis Obliterans (Buerger's Disease)

Buerger's disease is characterized by recurring inflammation of the intermediate and small arteries and veins of the lower and upper extremities. It results in thrombus formation and segmental occlusion of the vessels. It is differentiated from other vessel diseases by its microscopic appearance. In contrast

to atherosclerosis, Buerger's disease is believed to be an autoimmune vasculitis that results in occlusion of distal vessels.

Buerger's disease occurs most often in men between 20 and 35 years of age, and it has been reported in all races and in many areas of the world. There is considerable evidence that heavy smoking or chewing of tobacco is a causative or an aggravating factor (Puechal & Fiessinger, 2007).

Clinical Manifestations

Pain is the outstanding symptom of Buerger's disease, which is generally bilateral and symmetric with focal lesions. Superficial thrombophlebitis may be present. The patient complains of foot cramps, especially of the arch (instep claudication), after exercise. The pain is relieved by rest; often, a burning pain is aggravated by emotional disturbances, nicotine, or chilling. Cold sensitivity of the Raynaud type is found in half the patients and is frequently confined to the hands. Digital rest pain is constant, and the characteristics of the pain do not change between activity and rest.

Physical signs include intense rubor (reddish-blue discoloration) of the foot and absence of the pedal pulse, but with normal femoral and popliteal pulses. If the upper extremities are involved, the radial and ulnar artery pulses are absent or diminished. Various types of paresthesias may develop.

As the disease progresses, definite redness or cyanosis of the part appears when the extremity is in a dependent position. Involvement is generally bilateral, but color changes may affect only one extremity or only certain digits. Color changes may progress to ulceration, and ulceration with gangrene eventually occurs.

Assessment and Diagnostic Findings

Segmental limb blood pressures are taken to demonstrate the distal location of the lesions or occlusions. Duplex ultrasonography is used to document patency of the proximal vessels and to visualize the extent of distal disease. Contrast angiography is used to identify the diseased portion of the anatomy.

Although Buerger's disease is different from atherosclerosis, it may be accompanied by atherosclerosis of the larger vessels. The patient's ability to walk may be severely limited. Patients are at higher risk for nonhealing wounds because of impaired circulation.

Medical Management

The treatment of Buerger's disease is essentially the same as that for atherosclerotic PAD. The main objectives are to improve circulation to the extremities, prevent the progression of the disease, and protect the extremities from trauma and infection. Treatment of ulceration and gangrene is directed toward minimizing infection and conservative débridement of necrotic tissue. Tobacco use is highly detrimental, and patients are strongly advised to completely stop using tobacco. Symptoms are often relieved by cessation of tobacco use.

Vasodilators are rarely prescribed because these medications cause dilation of only healthy vessels; vasodilators may divert blood away from the partially occluded vessels, thus exacerbating the manifestations of the disease. A regional sympathetic block or ganglionectomy may be useful

in some instances to produce vasodilation and increase blood flow.

If gangrene of a toe develops as a result of arterial occlusive disease in the leg, it is unlikely that toe amputation or even transmetatarsal amputation will be sufficient; often, a below-knee amputation or occasionally an above-knee amputation is necessary. The indications for amputation include gangrene, especially if the infected area is moist; severe rest pain; or severe sepsis.

Nursing Management

The patient is assisted in developing and implementing a plan to stop using tobacco and to manage pain. The patient may need to be encouraged to make the lifestyle changes necessary to adequately manage a chronic disease, including modifications in diet, activity, and hygiene (skin care). The nurse determines whether the patient has a network of family and friends to assist with ADLs. The nurse ensures that the patient has the knowledge and ability to assess for any postoperative complications such as infection and decreased blood flow. Chart 31-3 describes nursing care for patients with peripheral vascular disease. Nursing management during the immediate postoperative phase after amputation and through the rehabilitation phase is described in Chapter 69.

Aortoiliac Disease

If collateral circulation has developed, patients with a stenosis or occlusion of the aortoiliac segment may be asymptomatic, or they may complain of buttock or low back discomfort associated with walking. Men may experience impotence. These patients may have decreased or absent femoral pulses.

Medical Management

The treatment of aortoiliac disease is essentially the same as that for atherosclerotic peripheral arterial occlusive disease. The surgical procedure of choice is the aortoiliac graft. If possible, the distal graft is anastomosed to the iliac artery, and the entire surgical procedure is performed within the abdomen. If the iliac vessels are diseased, the distal anastomosis is made to the femoral arteries (aortobifemoral graft). Bifurcated woven or knitted Dacron grafts are preferred for this surgical procedure.

Nursing Management

Preoperative assessment, in addition to the standard parameters (see Chapter 18), includes evaluating the brachial, radial, ulnar, femoral, posterior tibial, and dorsalis pedis pulses to establish a baseline for follow-up after arterial lines are placed and postoperatively. Patient teaching includes an overview of the procedure to be performed, the preparation for surgery, and the anticipated postoperative plan of care. Sights, sounds, and sensations that the patient may experience are discussed.

Postoperative care includes monitoring for signs of thrombosis in arteries distal to the surgical site. The nurse assesses color and temperature of the extremity, capillary refill time, sensory and motor function, and pulses by palpation and Doppler initially every 15 minutes and then at progressively

longer intervals if the patient's status remains stable. Any dusky or bluish discoloration, coldness, decrease in sensory or motor function, or decrease in pulse quality is reported immediately to the physician.

Postoperative care also includes monitoring urine output and ensuring that output is at least 30 mL/h. Renal function may be impaired as a result of hypoperfusion from hypotension, ischemia to the renal arteries during the surgical procedure, hypovolemia, or embolization of the renal artery or renal parenchyma. Vital signs, pain, and intake and output are monitored with the pulse and extremity assessments. Results of laboratory tests are monitored and reported to the physician. Abdominal assessment for bowel sounds and paralytic ileus is performed at least every 8 hours. Bowel sounds may not return before the third postoperative day. The absence of bowel sounds, absence of flatus, and abdominal distention are indications of paralytic ileus. Manual manipulation of the bowel during surgery may have caused bruising, resulting in decreased peristalsis. Nasogastric suction may be necessary to decompress the bowel until peristalsis returns. A liquid bowel movement before the third postoperative day may indicate bowel ischemia, which may occur when the mesenteric blood supply (celiac, superior mesenteric, or inferior mesenteric arteries) is occluded. Ischemic bowel usually causes increased pain and a markedly elevated white blood cell count (20,000 to 30,000 cells/mm³).

Aneurysms

An aneurysm is a localized sac or dilation formed at a weak point in the wall of the artery (Fig. 31-11). It may be classified by its shape or form. The most common forms of aneurysms are saccular and fusiform. A saccular aneurysm projects from only one side of the vessel. If an entire arterial segment becomes dilated, a fusiform aneurysm develops. Very small aneurysms due to localized infection are called mycotic aneurysms.

Historically, the cause of abdominal aortic aneurysm, the most common type of degenerative aneurysm, has been attributed to atherosclerotic changes in the aorta. Other causes of aneurysm formation are listed in Chart 31-6. Aneurysms are serious because they can rupture, leading to hemorrhage and death.

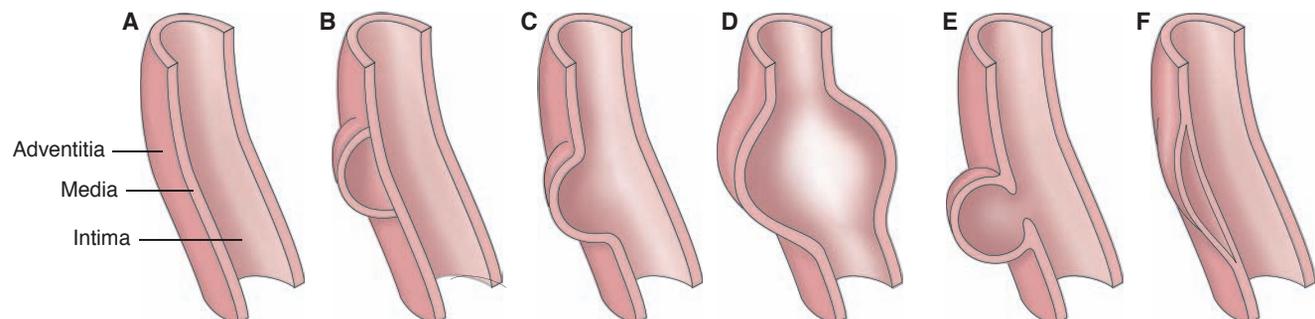

Figure 31-11 Characteristics of arterial aneurysm. **A**, Normal artery. **B**, False aneurysm—actually a pulsating hematoma. The clot and connective tissue are outside the arterial wall. **C**, True aneurysm. One, two, or all three layers of the artery may be involved. **D**, Fusiform aneurysm—symmetric, spindle-shaped expansion of entire circumference of involved vessel. **E**, Saccular aneurysm—a bulbous protrusion of one side of the arterial wall. **F**, Dissecting aneurysm—this usually is a hematoma that splits the layers of the arterial wall.

Chart 31-6 • Etiologic Classification of Arterial Aneurysms

Congenital: Primary connective tissue disorders (Marfan's syndrome, Ehlers-Danlos syndrome) and other diseases (focal medial agenesis, tuberous sclerosis, Turner's syndrome, Menkes' syndrome)

Mechanical (hemodynamic): Poststenotic and arteriovenous fistula and amputation related

Traumatic (pseudoaneurysms): Penetrating arterial injuries, blunt arterial injuries, pseudoaneurysms

Inflammatory (noninfectious): Associated with arteritis (Takayasu's disease, giant cell arteritis, systemic lupus erythematosus, Behçet's syndrome, Kawasaki's disease) and periarterial inflammation (ie, pancreatitis)

Infectious (mycotic): Bacterial, fungal, spirochetal infections

Pregnancy-related degenerative: Nonspecific, inflammatory variant

Anastomotic (postarteriotomy) and graft aneurysms: Infection, arterial wall failure, suture failure, graft failure

Adapted with permission from Rutherford, R. B. (2005). *Vascular surgery* (6th ed., Vols. 1 and 2). Philadelphia: W. B. Saunders.

THORACIC AORTIC ANEURYSM

Approximately 85% of all cases of thoracic aortic aneurysm are caused by atherosclerosis. They occur most frequently in men between the ages of 40 and 70 years. The thoracic area is the most common site for a dissecting aneurysm. About one third of patients with thoracic aneurysms die of rupture of the aneurysm (Rutherford, 2005).

Clinical Manifestations

Symptoms are variable and depend on how rapidly the aneurysm dilates and how the pulsating mass affects surrounding intrathoracic structures. Some patients are asymptomatic. In most cases, pain is the most prominent symptom. The pain is usually constant and boring but may occur only when the person is supine. Other conspicuous symptoms are dyspnea, the result of pressure of the aneurysm sac against the trachea, a main bronchus, or the lung itself; cough, frequently paroxysmal and with a brassy quality; hoarseness, stridor, or weakness or complete loss of the

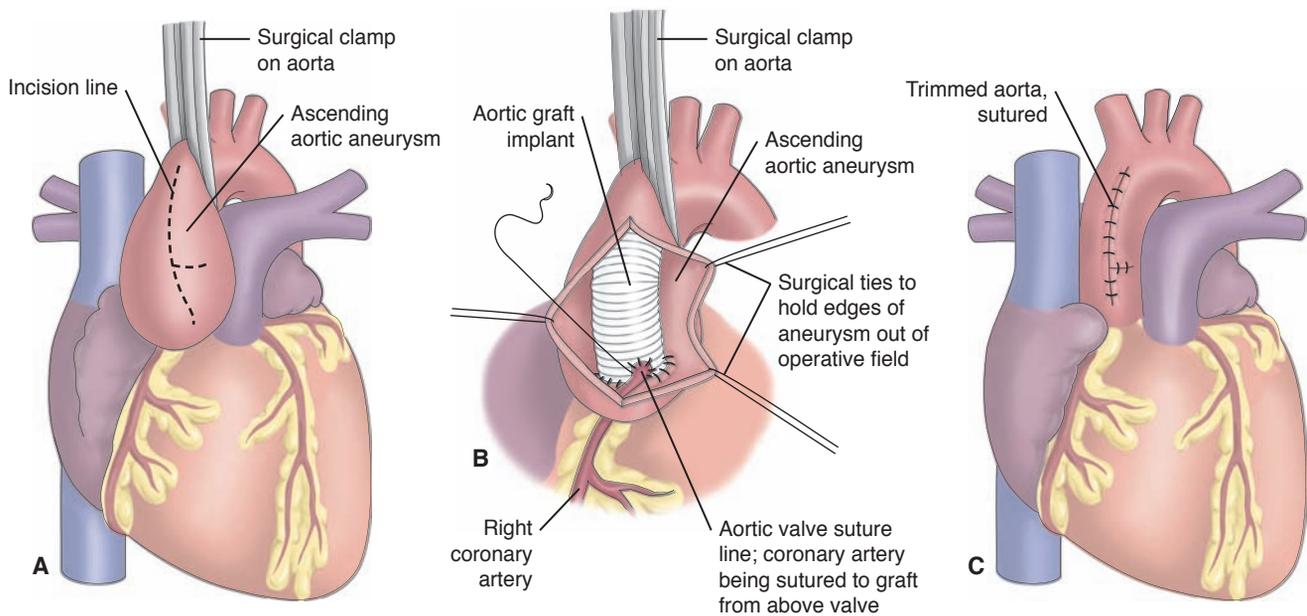

Figure 31-12 Repair of an ascending aortic aneurysm and aortic valve replacement. **A**, Incision into aortic aneurysm. **B**, Aortic valve replacement with aortic graft implant to repair ascending aortic aneurysm. **C**, Aortic aneurysm trimmed and closed over graft.

voice (aphonia), resulting from pressure against the laryngeal nerve; and dysphagia (difficulty in swallowing) due to impingement on the esophagus by the aneurysm.

Assessment and Diagnostic Findings

When large veins in the chest are compressed by the aneurysm, the superficial veins of the chest, neck, or arms become dilated, and edematous areas on the chest wall and cyanosis are often evident. Pressure against the cervical sympathetic chain can result in unequal pupils. Diagnosis of a thoracic aortic aneurysm is principally made by chest x-ray, CTA, and transesophageal echocardiography (TEE).

Medical Management

Treatment is based on whether the aneurysm is symptomatic, is expanding in size, is caused by an iatrogenic injury, contains a dissection, and involves branch vessels. General measures such as controlling blood pressure and correcting risk factors may be helpful. It is important to control blood pressure in patients with dissecting aneurysms. Preoperatively, the systolic pressure is maintained at approximately 100 to 120 mm Hg with a beta-blocker such as esmolol (Brevibloc) or metoprolol (Lopressor). Occasionally, antihypertensives such as hydralazine (Apresoline) are used for this purpose. Sodium nitroprusside (Nipride) may be used by continuous IV drip to emergently lower the blood pressure. The goal of surgery is to repair the aneurysm and restore vascular continuity with a vascular graft (Fig. 31-12). Intensive monitoring is usually required after this type of surgery, and the patient is cared for in the critical care unit. The morbidity and mortality rate with open surgical repair of thoracic aneurysms is 20%, and patients have a 4% chance of developing paraplegia (Rodriguez, Olsen, Shtutman, et al., 2007).

Repair of thoracic aneurysms using endovascular grafts placed percutaneously in an interventional suite (eg, interventional radiology, cardiac catheterization laboratory) or

an operating room may decrease postoperative recovery time and decrease complications compared with traditional surgical techniques. Thoracic endografts are made of similar materials as aortic endografts, such as Gore-Tex or PTFE material reinforced with nitinol or titanium stents. These endovascular grafts are inserted into the thoracic aorta via various vascular access routes, usually the brachial or femoral artery. Because a large surgical incision is not necessary to gain vascular access, the overall patient recovery time tends to be shorter than with open surgical repair. There is a 2.2% chance of perioperative paraplegia and a 2.7% chance of an intracranial CVA (Buth, Harris, Hobo, et al., 2007). To decrease the chances of paraplegia, spinal drains are usually placed in patients undergoing an endovascular repair of thoracic aortic aneurysms. Cerebral spinal drainage is performed to decrease the arterial to cerebral spinal fluid gradient, thereby improving spinal perfusion. What appears to be most important in preventing neurologic deficit is to maintain the blood pressure 20 mm Hg above baseline and to keep the mean arterial pressure greater than 90 mm Hg for the first 48 hours postoperatively (Sullivan & Sundt, 2006).

ABDOMINAL AORTIC ANEURYSM

The most common cause of abdominal aortic aneurysm is atherosclerosis. The condition, which is more common among Caucasians, affects men four times more often than women and is most prevalent in elderly patients (Rutherford, 2005). Most of these aneurysms occur below the renal arteries (infrarenal aneurysms). Untreated, the eventual outcome may be rupture and death.

Pathophysiology

All aneurysms involve a damaged media layer of the vessel. This may be caused by congenital weakness, trauma, or disease. After an aneurysm develops, it tends to enlarge.

Risk factors include genetic predisposition, tobacco use, and hypertension; more than half of patients with aneurysms have hypertension.

Clinical Manifestations

Only about 40% of patients with abdominal aortic aneurysms have symptoms. Some patients complain that they can feel their heart beating in their abdomen when lying down, or they may say they feel an abdominal mass or abdominal throbbing. If the abdominal aortic aneurysm is associated with thrombus, a major vessel may be occluded or smaller distal occlusions may result from emboli. Small cholesterol, platelet, or fibrin emboli may lodge in the interosseous or digital arteries, causing cyanosis and mottling of the toes.

Assessment and Diagnostic Findings

The most important diagnostic indication of an abdominal aortic aneurysm is a pulsatile mass in the middle and upper abdomen. About 80% of these aneurysms can be palpated. A systolic bruit may be heard over the mass. Duplex ultrasonography or CTA is used to determine the size, length, and location of the aneurysm. When the aneurysm is small, ultrasonography is conducted at 6-month intervals until the aneurysm reaches a size so that surgery to prevent rupture is of more benefit than the possible complications of a surgical procedure. Some aneurysms remain stable over many years of monitoring.

Gerontologic Considerations

Most abdominal aortic aneurysms occur in patients between 60 and 90 years of age. Rupture is likely with coexisting hypertension and with aneurysms more than 6 cm wide. In most cases at this point, the chances of rupture are greater than the chance of death during surgical repair. If the elderly patient is considered at moderate risk of complications related to surgery or anesthesia, the aneurysm is not repaired until it is at least 5.5 cm (2 inches) wide.

Medical Management

Pharmacologic Therapy

If the aneurysm is stable in size based on serial duplex ultrasound scans, the blood pressure is closely monitored over time, because there is an association between increased diastolic blood pressure (above 100 mm Hg) and aneurysm rupture (Rutherford, 2005). Antihypertensive agents, including diuretics, beta-blockers, ACE inhibitors, angiotensin II receptor antagonists, and calcium channel blockers, are frequently prescribed to maintain the patient's blood pressure within acceptable limits (see Chapter 32).

Surgical Management

An expanding or enlarging abdominal aortic aneurysm is likely to rupture. Surgery is the treatment of choice for abdominal aortic aneurysms more than 5.5 cm (2 inches) wide or those that are enlarging; the standard treatment has been open surgical repair of the aneurysm by resecting the vessel and sewing a bypass graft in place. The mortality rate associated with elective aneurysm repair, a major surgical procedure, is reported to be 1% to 4%. The prognosis for a pa-

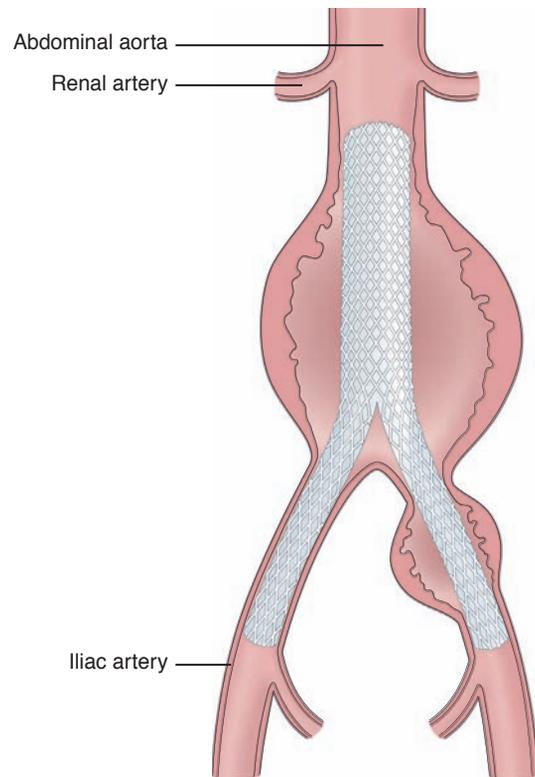

Figure 31-13 AneuRx Endograft repair of an abdominal aortic aneurysm (Medtronic).

tient with a ruptured aneurysm is poor, and surgery is performed immediately (Rutherford, 2005).

An alternative for treating an infrarenal abdominal aortic aneurysm is endovascular grafting, which involves the transluminal placement and attachment of a sutureless aortic graft prosthesis across an aneurysm (Fig. 31-13). This procedure can be performed under local or regional anesthesia. Endovascular grafting of abdominal aortic aneurysms may be performed if the patient's abdominal aorta and iliac arteries are not extremely tortuous, small, calcified, or filled with thrombi. Results from studies suggest comparable mortality rates between patients with aneurysms treated by endovascular grafting and those treated with surgical repair (O'Donnell, Sun, Winder, et al., 2007; Semmens, Lawrence-Brown, Hartley, et al., 2006). Potential complications include bleeding, hematoma, or wound infection at the arterial insertion site; distal ischemia or embolization; dissection or perforation of the aorta; graft thrombosis or infection; break of the attachment system; graft migration; proximal or distal graft leaks; delayed rupture; and bowel ischemia.

Nursing Management

Before surgery, nursing assessment is guided by anticipating a rupture and by recognizing that the patient may have cardiovascular, cerebral, pulmonary, and renal impairment from atherosclerosis. The functional capacity of all organ systems should be assessed. Medical therapies designed to stabilize physiologic function should be promptly implemented.

Signs of impending rupture include severe back or abdominal pain, which may be persistent or intermittent. Abdominal

pain is often localized in the middle or lower abdomen to the left of the midline. Low back pain may be present because of pressure of the aneurysm on the lumbar nerves. Indications of a rupturing abdominal aortic aneurysm include constant, intense back pain; falling blood pressure; and decreasing hematocrit. Rupture into the peritoneal cavity is rapidly fatal. A retroperitoneal rupture of an aneurysm may result in hematomas in the scrotum, perineum, flank, or penis. Signs of heart failure or a loud bruit may suggest a rupture into the vena cava. If the aneurysm adheres to the adjacent vena cava, the vena cava may become damaged when rupture or leak of the aneurysm occurs. Rupture into the vena cava results in higher-pressure arterial blood entering the lower-pressure venous system and causing turbulence, which is heard as a bruit. The high blood pressure and increased blood volume returning to the right side of the heart from the vena cava may cause right-sided heart failure.

Postoperative care requires frequent monitoring of pulmonary, cardiovascular, renal, and neurologic status. Possible complications of surgery include arterial occlusion, hemorrhage, infection, ischemic bowel, renal failure, and impotence.

Other Aneurysms

Aneurysms may also arise in the peripheral vessels, most often as a result of atherosclerosis. These may involve such vessels as the subclavian artery, renal artery, femoral artery, or (most frequently) popliteal artery. Between 50% and 60% of popliteal aneurysms are bilateral and may be associated with abdominal aortic aneurysms.

The aneurysm produces a pulsating mass and disturbs peripheral circulation distal to it. Pain and swelling develop because of pressure on adjacent nerves and veins. Diagnosis is made by duplex ultrasonography and CTA to determine the size, length, and extent of the aneurysm. Arteriography may be performed to evaluate the level of proximal and distal involvement.

Medical Management

Surgical repair is performed with replacement grafts or endovascular repair using a stent-graft or wall graft, which is a Dacron or PTFE graft with external structures made from a variety of materials (eg, nitinol, titanium, stainless steel) for additional support.

Nursing Management

The patient who has had an endovascular repair must lie supine for 6 hours; the head of the bed may be elevated up to 45 degrees after 2 hours. The patient needs to use a bedpan or urinal while on bed rest, or an indwelling urinary catheter may be used. Vital signs and Doppler assessment of peripheral pulses are performed initially every 15 minutes and then at progressively longer intervals if the patient's status remains stable. The access site (usually the femoral or iliac artery) is assessed when vital signs and pulses are monitored. The nurse assesses for bleeding, pulsation, swelling, pain, and hematoma formation. Skin changes of the lower extremity, lumbar area, or buttocks that might indicate signs of embolization, such as extremely tender, irregularly

shaped, cyanotic areas, as well as any changes in vital signs, pulse quality, bleeding, swelling, pain, or hematoma, are immediately reported to the physician.

The patient's temperature should be monitored every 4 hours, and any signs of postimplantation syndrome should be reported. Postimplantation syndrome typically begins within 24 hours of stent-graft placement and consists of a spontaneously occurring fever, leukocytosis, and, occasionally, transient thrombocytopenia. This condition has been attributed to complex immunologic changes, although the exact etiology is unknown. The symptoms are thought to be related to the activation of cytokines (Akowuah, Wilde, Angelini, et al., 2007). They can be managed with mild analgesic or anti-inflammatory agents, such as acetaminophen (Tylenol) or ibuprofen (Motrin) and usually subside within a week.

Because of the increased risk of hemorrhage, the physician is also notified of persistent coughing, sneezing, vomiting, or systolic blood pressure greater than 180 mm Hg. Most patients can resume their preprocedure diet and are encouraged to drink fluids. An IV infusion may be continued until the patient can drink normally. Fluids are important to maintain blood flow through the arterial repair site and to assist the kidneys with excreting IV contrast agent and other medications used during the procedure. Six hours after the procedure, the patient may be able to roll from side to side and may be able to ambulate with assistance to the bathroom. Once the patient can take adequate fluids orally, the IV infusion may be discontinued and the IV access converted to a saline lock.

Dissecting Aorta

Occasionally, in an aorta diseased by arteriosclerosis, a tear develops in the intima or the media degenerates, resulting in a dissection (see Fig. 31-11). Arterial dissections are three times more common in men than in women and occur most commonly in the 50- to 70-year-old age group (Rutherford, 2005).

Pathophysiology

Arterial dissections (separations) are commonly associated with poorly controlled hypertension, blunt chest trauma, and cocaine use. The profound increase in sympathetic response caused by cocaine use creates an increase in the force of left ventricular contraction that causes heightened shear forces upon the aortic wall (Rutherford, 2005). Dissection is caused by rupture in the intimal layer. A rupture may occur through adventitia or into the lumen through the intima, allowing blood to reenter the main channel and resulting in chronic dissection (eg, pseudoaneurysm) or occlusion of branches of the aorta.

As the separation progresses, the arteries branching from the involved area of the aorta shear and occlude. The tear occurs most commonly in the region of the aortic arch, with the highest mortality rate associated with ascending aortic dissection. The dissection of the aorta may progress backward in the direction of the heart, obstructing the openings to the coronary arteries or producing hemopericardium (effusion of blood into the pericardial sac) or aortic insufficiency, or it may extend in the opposite direction, causing occlusion

of the arteries supplying the gastrointestinal tract, kidneys, spinal cord, and legs.

Clinical Manifestations

Onset of symptoms is usually sudden. Severe and persistent pain, described as tearing or ripping, may be reported. The pain is in the anterior chest or back and extends to the shoulders, epigastric area, or abdomen. Aortic dissection may be mistaken for an acute myocardial infarction, which could confuse the clinical picture and initial treatment. Cardiovascular, neurologic, and gastrointestinal symptoms are responsible for other clinical manifestations, depending on the location and extent of the dissection. The patient may appear pale. Sweating and tachycardia may be detected. Blood pressure may be elevated or markedly different from one arm to the other if dissection involves the orifice of the subclavian artery on one side. Because of the variable clinical picture associated with this condition, early diagnosis is usually difficult.

Assessment and Diagnostic Findings

Arteriography, CTA, transesophageal echocardiography, duplex ultrasonography, and MRA aid in the diagnosis.

Medical Management

The medical or surgical treatment of a dissecting aorta depends on the type of dissection present and follows the general principles outlined for the treatment of thoracic aortic aneurysms.

Nursing Management

A patient with a dissecting aorta requires the same nursing care as a patient with an aortic aneurysm requiring surgical intervention, as described earlier in this chapter. Interventions described in Chart 31-3 are also appropriate.

Arterial Embolism and Arterial Thrombosis

Acute vascular occlusion may be caused by an embolus or acute thrombosis. Acute arterial occlusions may result from iatrogenic injury, which can occur during insertion of invasive catheters such as those used for arteriography, PTA or stent placement, or an intra-aortic balloon pump, or it may occur as a result of IV drug abuse. Other causes include trauma from a fracture, crush injury, and penetrating wounds that disrupt the arterial intima. The accurate diagnosis of an arterial occlusion as embolic or thrombotic in origin is necessary to initiate appropriate treatment.

Pathophysiology

Arterial emboli arise most commonly from thrombi that develop in the chambers of the heart as a result of atrial fibrillation, myocardial infarction, infective endocarditis, or chronic heart failure. These thrombi become detached and are carried from the left side of the heart into the arterial system, where they lodge in and obstruct an artery that is smaller than the embolus. Emboli may also develop in advanced aortic atherosclerosis because the atheromatous plaques ulcerate or become rough. Acute thrombosis frequently occurs in patients with preexisting ischemic symptoms.

Clinical Manifestations

The symptoms of arterial emboli depend primarily on the size of the embolus, the organ involved, and the state of the collateral vessels. The immediate effect is cessation of distal blood flow. The blockage can progress distal and proximal to the site of the obstruction. Secondary vasospasm can contribute to the ischemia. The embolus can fragment or break apart, resulting in occlusion of distal vessels. Emboli tend to lodge at arterial bifurcations and areas narrowed by atherosclerosis. Cerebral, mesenteric, renal, and coronary arteries are often involved in addition to the large arteries of the extremities.

The symptoms of acute arterial embolism in extremities with poor collateral flow are acute, severe pain and a gradual loss of sensory and motor function. The six *Ps* associated with acute arterial embolism are *pain*, *pallor*, *pulselessness*, *paresthesia*, *poikilothermia* (coldness), and *paralysis*. Eventually, superficial veins may collapse because of decreased blood flow to the extremity. Because of ischemia, the part of the extremity distal to the occlusion is markedly colder and paler than the part proximal to the occlusion.

Arterial thrombosis can also acutely occlude an artery. A thrombosis is a slowly developing clot that usually occurs where the arterial wall has become damaged, generally as a result of atherosclerosis. Thrombi may also develop in an arterial aneurysm. The manifestations of an acute thrombotic arterial occlusion are similar to those described for embolic occlusion. However, treatment is more difficult with a thrombus because the arterial occlusion has occurred in a degenerated vessel and requires more extensive reconstructive surgery to restore flow than is required with an embolic event.

Assessment and Diagnostic Findings

An arterial embolus is usually diagnosed on the basis of the sudden nature of the onset of symptoms and an apparent source for the embolus. Two-dimensional transthoracic echocardiography or TEE, chest x-ray, and electrocardiography (ECG) may reveal underlying cardiac disease. Non-invasive duplex and Doppler ultrasonography can determine the presence and extent of underlying atherosclerosis, and arteriography may be performed.

Medical Management

Management of arterial thrombosis depends on its cause. Management of acute embolic occlusion usually requires surgery because time is of the essence. Because the onset of the event is acute, collateral circulation has not developed, and the patient quickly moves through the list of six *Ps* to paralysis, the most advanced stage. Heparin therapy is initiated immediately to prevent further development of emboli and to prevent the extension of existing thrombi. Typically, an initial IV bolus of 5000 units or 60 units/kg body weight is administered, followed by a continuous infusion of 12 units/kg/h until the patient undergoes surgery.

Surgical Management

Emergency embolectomy is the procedure of choice if the involved extremity is viable (Fig. 31-14). Arterial emboli are usually treated by insertion of an embolectomy catheter. The

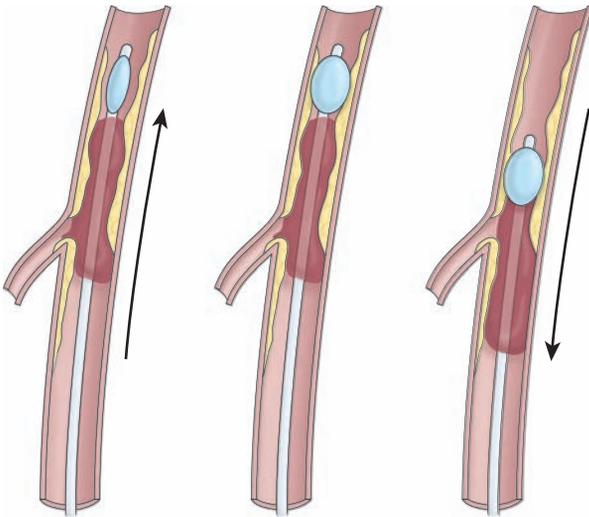

Figure 31-14 Extraction of an embolus by balloon-tipped embolectomy catheter. The deflated balloon-tipped catheter is advanced past the embolus, inflated, and then gently withdrawn, carrying the embolic material with it. Adapted with permission from Rutherford, R. B. (2005). *Vascular surgery* (6th ed., Vols. I and II). Philadelphia: Elsevier.

catheter is passed through a groin incision into the affected artery and advanced past the occlusion. The catheter balloon is inflated with sterile saline solution, and the thrombus is extracted as the catheter is withdrawn. This procedure involves incising the vessel and removing the clot.

Endovascular Management

Percutaneous mechanical thrombectomy devices may also be used for the treatment of an acute thrombosis. All endovascular devices necessitate obtaining access to the patient's arterial system and inserting a catheter into the patient's artery to obtain access to the thrombus. The approach is similar to that used for angiograms in that it is made through the groin to the femoral artery. Some devices require that a small incision be made into the patient's artery. These devices may use (1) a jet of fluid to disrupt the thrombus and then aspirate the particles; (2) a rotating, sinusoidal-shaped wire that mixes a thrombolytic agent that simultaneously dissolves the clot; or (3) high-frequency, low-energy ultrasound to dissolve an occlusive thrombus. Complications arising from the use of any of the endovascular devices may include arterial dissection or distal artery embolization.

Pharmacologic Therapy

When the patient has collateral circulation, treatment may include IV anticoagulation with heparin, which can prevent the thrombus from spreading and reduce muscle necrosis. Intra-arterial thrombolytic medications are used to dissolve the embolus. Fibrin-specific thrombolytic medications (eg, tissue plasminogen activator [t-PA, alteplase, Activase] and single-chain urokinase-type plasminogen activator [scu-PA, prourokinase]) do not deplete circulating fibrinogen and plasminogen, which prevents the development of systemic fibrinolysis. Other thrombolytic medications are reteplase (r-PA, Retavase), tenecteplase (TNKase), and

staphylokinase (Moore, 2006). Although these agents differ in their pharmacokinetics, they are administered in a similar manner: A catheter is advanced under x-ray visualization to the clot, and the thrombolytic agent is infused.

Thrombolytic therapy should not be used when there are known contraindications to therapy or when the extremity cannot tolerate the several additional hours of ischemia that it takes for the agent to lyse (disintegrate) the clot. Contraindications to peripheral thrombolytic therapy include active internal bleeding, cerebrovascular hemorrhage, recent major surgery, uncontrolled hypertension, and pregnancy.

Nursing Management

Before surgery, the patient remains on bed rest with the affected extremity level or slightly dependent (15 degrees). The affected part is kept at room temperature and protected from trauma. Heating and cooling pads are contraindicated because ischemic extremities are easily traumatized by alterations in temperature. If possible, tape and ECG electrodes should not be used on the extremity; sheepskin and foot cradles are used to protect an affected leg from mechanical trauma.

If the patient is treated with thrombolytic therapy, the dose is based on the patient's weight. The patient is admitted to a critical care unit for continuous monitoring. Vital signs are taken initially every 15 minutes and then at progressively longer intervals if the patient's status remains stable. The patient is closely monitored for bleeding. The nurse minimizes the number of punctures for inserting IV lines and obtaining blood samples, avoids intramuscular injections, prevents any possible tissue trauma, and applies pressure at least twice as long as usual after any puncture is performed. If t-PA is used for the treatment, heparin is usually administered to prevent another thrombus from forming at the site of the lesion. The t-PA activates plasminogen on the thrombus, but it does not decrease the clotting factors as much as other thrombolytic therapies, so patients receiving t-PA can make new thrombi more readily than if they receive other thrombolytics.

During the postoperative period, the nurse collaborates with the surgeon about the patient's appropriate activity level based on the patient's condition. Generally, every effort is made to encourage the patient to move the extremity to stimulate circulation and prevent stasis. Anticoagulant therapy may be continued after surgery to prevent thrombosis of the affected artery and to diminish the development of subsequent thrombi at the initiating site. The nurse assesses for evidence of local and systemic hemorrhage, including mental status changes, which can occur when anticoagulants are administered. Pulses, Doppler signals, ABI, and motor and sensory function are assessed every hour for the first 24 hours, because significant changes may indicate reocclusion. Metabolic abnormalities, renal failure, and compartment syndrome may be complications after an acute arterial occlusion.

Raynaud's Phenomenon

Raynaud's phenomenon is a form of intermittent arteriolar vasoconstriction that results in coldness, pain, and pallor of the fingertips or toes. There are two forms of this disorder.

Primary or idiopathic Raynaud's (Raynaud's disease) occurs in the absence of an underlying disease. Secondary Raynaud's (Raynaud's syndrome) occurs in association with an underlying disease, usually a connective tissue disorder, such as systemic lupus erythematosus, rheumatoid arthritis, or scleroderma; trauma; or obstructive arterial lesions. Symptoms may result from a defect in basal heat production that eventually decreases the ability of cutaneous vessels to dilate. Episodes may be triggered by emotional factors or by unusual sensitivity to cold. Raynaud's phenomenon is most common in women between 16 and 40 years of age, and it occurs more frequently in cold climates and during the winter (Pope, 2007).

The prognosis for patients with Raynaud's phenomenon varies; some slowly improve, some become progressively worse, and others show no change. Raynaud's symptoms may be mild so that treatment is not required. However, secondary Raynaud's is characterized by vasospasm and fixed blood vessel obstructions that may lead to ischemia, ulceration, and gangrene.

Clinical Manifestations

The classic clinical picture reveals pallor brought on by sudden vasoconstriction. The skin then becomes bluish (cyanotic) because of pooling of deoxygenated blood during vasospasm. As a result of exaggerated reflow (hyperemia) due to vasodilation, a red color (rubor) is produced when oxygenated blood returns to the digits after the vasospasm stops. The characteristic sequence of color change of Raynaud's phenomenon is described as white, blue, and red. Numbness, tingling, and burning pain occur as the color changes. The manifestations tend to be bilateral and symmetric and may involve toes and fingers.

Medical Management

Avoiding the particular stimuli (eg, cold, tobacco) that provoke vasoconstriction is a primary factor in controlling Raynaud's phenomenon. Calcium channel blockers (nifedipine [Procardia], amlodipine [Norvasc]) may be effective in relieving symptoms. Sympathectomy (interrupting the sympathetic nerves by removing the sympathetic ganglia or dividing their branches) may help some patients.

Nursing Management

The nurse teaches the patient to avoid situations that may be stressful or unsafe. Stress management classes may be helpful. Exposure to cold must be minimized, and in areas where the fall and winter months are cold, the patient should wear layers of clothing when outdoors. Hats and mittens or gloves should be worn at all times when outside. Fabrics specially designed for cold climates (eg, Thinsulate) are recommended. Patients should warm up their vehicles before getting in so that they can avoid touching a cold steering wheel or door handle, which could elicit an attack. During summer, a sweater should be available when entering air-conditioned rooms.

Patients are often concerned about serious complications, such as gangrene and amputation, but these complications are uncommon unless the patient has another underlying disease causing arterial occlusions. Patients should avoid all forms of nicotine; nicotine gum or patches used to help people quit smoking may induce attacks.

Patients should be cautioned to handle sharp objects carefully to avoid injuring their fingers. Patients should be informed about the postural hypotension that may result from medications, such as calcium channel blockers, used to treat Raynaud's phenomenon.

VENOUS DISORDERS

Venous Thromboembolism

Deep vein thrombosis (DVT) and pulmonary embolism (PE) collectively make up the condition known as venous thromboembolism (VTE). The incidence of VTE is 10% to 20% in general medical patients, 20% to 50% in patients who have had a stroke, and up to 80% in critically ill patients (Morrison, 2006). The extent of the problem is underestimated, possibly because DVT and PE are often clinically silent. It is estimated that as many as 30% of patients hospitalized with VTE develop long-term postthrombotic complications. Hospital stays are shorter, which means that the majority of symptomatic thromboembolic complications in surgical patients occur after hospital discharge.

Pathophysiology

Superficial veins, such as the greater saphenous, lesser saphenous, cephalic, basilic, and external jugular veins, are thick-walled muscular structures that lie just under the skin. Deep veins are thin walled and have less muscle in the media. They run parallel to arteries and bear the same names as the arteries. Deep and superficial veins have valves that permit unidirectional flow back to the heart. The valves lie at the base of a segment of the vein that is expanded into a sinus. This arrangement permits the valves to open without coming into contact with the wall of the vein, permitting rapid closure when the blood starts to flow backward. Other kinds of veins are known as perforating veins. These vessels have valves that allow one-way blood flow from the superficial system to the deep system.

Although the exact cause of VTE remains unclear, three factors, known as Virchow's triad, are believed to play a significant role in its development: stasis of blood (venous stasis), vessel wall injury, and altered blood coagulation (Chart 31-7). Venous stasis occurs when blood flow is reduced, as in heart failure or shock; when veins are dilated, as with some medication therapies; and when skeletal muscle contraction is reduced, as in immobility, paralysis of the extremities, or anesthesia. Moreover, bed rest reduces blood flow in the legs by at least 50% (Porth & Matfin, 2009). Damage to the intimal lining of blood vessels creates a site for clot formation. Direct trauma to the vessels, as with fractures or dislocation, diseases of the veins, and chemical irritation of the vein from IV medications or solutions, can damage veins. Increased blood coagulability occurs most commonly in patients for whom anticoagulant medications have been abruptly withdrawn. Oral contraceptive use and several blood dyscrasias (abnormalities) also can lead to hypercoagulability (Yang, 2005). In addition, normal pregnancy is accompanied by an increase in clotting factors that may not return to baseline until longer than 8 weeks postpartum, increasing the risk of thrombosis (James, 2007).

CHART
31-7

Risk Factors for Deep Vein Thrombosis (DVT) and Pulmonary Embolism (PE)

Endothelial Damage

- Trauma
- Surgery
- Pacing wires
- Central venous catheters
- Dialysis access catheters
- Local vein damage
- Repetitive motion injury

Venous Stasis

- Bed rest or immobilization
- Obesity
- History of varicosities
- Spinal cord injury
- Age (greater than 65 years)

Altered Coagulation

- Cancer
- Pregnancy
- Oral contraceptive use
- Protein C deficiency
- Protein S deficiency
- Antiphospholipid antibody syndrome
- Factor V Leiden defect
- Prothrombin 20210A defect
- Hyperhomocysteinemia
- Elevated factors II, VIII, IX, XI
- Antithrombin III deficiency
- Polycythemia
- Septicemia

Formation of a thrombus frequently accompanies phlebitis, which is an inflammation of the vein walls. When a thrombus develops initially in the veins as a result of stasis or hypercoagulability but without inflammation, the process is referred to as phlebothrombosis. Venous thrombosis can occur in any vein, but it occurs more often in the veins of the lower extremities. The superficial and deep veins of the extremities may be affected.

Upper extremity venous thrombosis is not as common as lower extremity thrombosis. Upper extremity venous thrombosis is more common in patients with IV catheters or in patients with an underlying disease that causes hypercoagulability. Internal trauma to the vessels may result from pacemaker leads, chemotherapy ports, dialysis catheters, or parenteral nutrition lines. The lumen of the vein may be decreased as a result of the catheter or from external compression, such as by neoplasms or an extra cervical rib. Effort thrombosis of the upper extremity is caused by repetitive motion (eg, in competitive swimmers, tennis players, and construction workers) that irritates the vessel wall, causing inflammation and subsequent thrombosis.

Venous thrombi are aggregates of platelets attached to the vein wall that have a tail-like appendage containing fibrin, white blood cells, and many red blood cells. The “tail” can grow or can propagate in the direction of blood flow as successive layers of the thrombus form. A propagating venous thrombosis is dangerous because parts of the thrombus can break off and occlude the pulmonary blood vessels. Fragmentation of the thrombus can occur spontaneously as it dissolves naturally, or it can occur with an elevated venous pressure, such as when a person stands suddenly or engages in muscular activity after prolonged inactivity. After an episode of acute DVT, recanalization (ie, reestablishment of the lumen of the vessel) typically occurs. The time required for complete recanalization is an important determinant of venous valvular incompetence, which is one complication of venous thrombosis (Labropoulos, Patel, Tiongson, et al., 2007). Other complications of venous thrombosis are listed in Chart 31-8.

Clinical Manifestations

A major problem associated with recognizing DVT is that the signs and symptoms are nonspecific. The exception is phlegmasia cerulea dolens (massive iliofemoral venous thrombosis), in which the entire extremity becomes massively swollen, tense, painful, and cool to the touch.

Deep Veins

With obstruction of the deep veins comes edema and swelling of the extremity because the outflow of venous blood is inhibited. The amount of swelling can be determined by measuring the circumference of the affected extremity at various levels with a tape measure and comparing one extremity with the other at the same level to determine size differences. If both extremities are swollen, a size difference may be difficult to detect. The affected extremity may feel warmer than the unaffected extremity, and the superficial veins may appear more prominent.

Tenderness, which usually occurs later, is produced by inflammation of the vein wall and can be detected by gently palpating the affected extremity. Homans' sign (pain in the calf after the foot is sharply dorsiflexed) is not a reliable sign

Chart 31-8 • Complications of Venous Thrombosis

- Chronic venous occlusion**
- Pulmonary emboli from dislodged thrombi**
- Valvular destruction**
 - Chronic venous insufficiency
 - Increased venous pressure
 - Varicosities

- Venous obstruction**
 - Increased distal pressure
 - Fluid stasis
 - Edema
 - Venous gangrene

for DVT because it can be elicited in any painful condition of the calf and has no clinical value in assessment for DVT. In some cases, signs and symptoms of a pulmonary embolus are the first indication of DVT.

Superficial Veins

Thrombosis of superficial veins produces pain or tenderness, redness, and warmth in the involved area. The risk of the superficial venous thrombi becoming dislodged or fragmenting into emboli is very low because most of them dissolve spontaneously. This condition can be treated at home with bed rest, elevation of the leg, analgesic agents, and possibly anti-inflammatory medication.

Assessment and Diagnostic Findings

Careful assessment is invaluable in detecting early signs of venous disorders of the lower extremities. Patients with a history of varicose veins, hypercoagulation, neoplastic disease, cardiovascular disease, or recent major surgery or injury are at high risk. Other patients at high risk include those who are obese or elderly and women taking oral contraceptives.

When performing the nursing assessment, key concerns include limb pain, a feeling of heaviness, functional impairment, ankle engorgement, and edema; differences in leg circumference bilaterally from thigh to ankle; increase in the surface temperature of the leg, particularly the calf or ankle; and areas of tenderness or superficial thrombosis (ie, cord-like venous segment).

Prevention

VTE can be prevented, especially if patients who are considered at high risk are identified and preventive measures are instituted without delay. Preventive measures include the application of graduated compression stockings, the use of intermittent pneumatic compression devices, and encourage-

ment of early mobilization and leg exercises. An additional method to prevent venous thrombosis in surgical patients is administration of subcutaneous unfractionated or low-molecular-weight heparin (LMWH). Patients should be advised to make lifestyle changes as appropriate, which may include weight loss, smoking cessation, and regular exercise.

Medical Management

The objectives of treatment for DVT are to prevent the thrombus from growing and fragmenting (thus risking PE), recurrent thromboemboli, and postthrombotic syndrome (discussed later in the chapter) (Yang, 2005). Anticoagulant therapy (administration of a medication to delay the clotting time of blood, prevent the formation of a thrombus in postoperative patients, and forestall the extension of a thrombus after it has formed) can meet these objectives. However, anticoagulants cannot dissolve a thrombus that has already formed. Combining anticoagulation therapy with thrombolytic therapy may eliminate venous obstruction, maintain venous patency, and prevent postthrombotic syndrome caused by early removal of the thrombus (Vedantham, Millward, Cardella, et al., 2006).

Pharmacologic Therapy

Measures for preventing or reducing blood clotting within the vascular system are indicated in patients with thrombophlebitis, recurrent embolus formation, and persistent leg edema from heart failure (Table 31-2). They are also indicated in elderly patients with a hip fracture that may result in lengthy immobilization. Contraindications for anticoagulant therapy are noted in Chart 31-9.

Unfractionated Heparin

Unfractionated heparin is administered subcutaneously to prevent development of DVT, or by intermittent or

Table 31-2  **SUMMARY OF ANTICOAGULANTS AND THROMBOLYTICS USED TO TREAT VENOUS THROMBOEMBOLI**

Medication	Major Indications
Unfractionated Heparin Heparin	Anticoagulation in patients with current VTE or VTE prophylaxis in patients at risk
Low-Molecular-Weight Heparin (LMWH) Dalteparin (Fragmin) Enoxaparin (Lovenox)	Prophylaxis in patients at risk for VTE or at risk for extension of current VTE
Oral Anticoagulant Warfarin (Coumadin)	Anticoagulation in patients with current VTE or VTE prophylaxis in patients at risk
Factor Xa Inhibitor Fondaparinux (Arixtra)	Prophylaxis in surgical patients at risk for VTE
Thrombolytic Alteplase (Activase, t-PA) Retepase (Retavase) Tenecteplase (TNKase) Urokinase (Abbokinase) Streptokinase (Streptase)	Fibrinolysis/dissolution of existing VTE
Direct Thrombin Inhibitor Lepirudin (Refludan) Argatroban (Novastan)	Treatment of heparin-induced thrombocytopenia

VTE, venous thromboembolism.

CHART

PHARMACOLOGY

Contraindications to Anticoagulant Therapy

- Lack of patient cooperation
- Bleeding from the following systems:
 - Gastrointestinal
 - Genitourinary
 - Respiratory
 - Reproductive
- Hemorrhagic blood dyscrasias
- Aneurysms
- Severe trauma
- Alcoholism
- Recent or impending surgery of the eye, spinal cord, or brain
- Severe hepatic or renal disease
- Recent cerebrovascular hemorrhage
- Infections
- Open ulcerative wounds
- Occupations that involve a significant hazard for injury
- Recent childbirth

continuous IV infusion for 5 days to prevent the extension of a thrombus and the development of new thrombi. Oral anticoagulants, such as warfarin, are administered with heparin therapy. Medication dosage is regulated by monitoring the activated partial thromboplastin time (aPTT), the international normalized ratio (INR), and the platelet count.

Low-Molecular-Weight Heparin

Subcutaneous LMWHs that may include medications such as dalteparin and enoxaparin are effective treatments for some cases of DVT. These agents have longer half-lives than unfractionated heparin, so doses can be given in one or two subcutaneous injections each day. Doses are adjusted according to weight. LMWHs prevent the extension of a thrombus and development of new thrombi, and they are associated with fewer bleeding complications and lower risks of heparin-induced thrombocytopenia (HIT) than unfractionated heparin. Because there are several preparations, the dosing schedule must be based on the product used and the protocol at each institution. The cost of LMWH is higher than that of unfractionated heparin; however, LMWH may be used safely in pregnant women, and patients who take it may be more mobile and have an improved quality of life.

Oral Anticoagulants

Warfarin is a vitamin K antagonist that is indicated for extended anticoagulant therapy. Routine coagulation monitoring is essential to ensure that a therapeutic response is obtained and maintained over time. Interactions with a range of other medications can reduce or enhance the anticoagulant effects of warfarin, as can variable intake of foods containing vitamin K (see Chart 33-15). Warfarin has a narrow therapeutic window, and there is a slow onset of action. Treatment is initially supported with concomitant parenteral anticoagulation with heparin until the warfarin demonstrates anticoagulant effectiveness.

Factor Xa Inhibitor

Fondaparinux selectively inhibits factor Xa. This agent is given daily subcutaneously at a fixed dose, has a half-life of 17 hours, and is excreted unchanged via the kidneys (and therefore must be used with caution in patients with renal insufficiency). It has no effect on routine tests of coagulation, such as the aPTT or activated clotting time (ACT), so

routine coagulation monitoring is unnecessary. Fondaparinux is approved for prophylaxis during major orthopedic surgery, such as hip or knee arthroplasties. Recent data suggest that fondaparinux, in conjunction with warfarin, is also effective for treatment of VTE (Nutescu, Wittkowsky, Dobesh, et al., 2006).

Thrombolytic Therapy

Unlike the heparins, catheter-directed thrombolytic (fibrinolytic) therapy lyses and dissolves thrombi in at least 50% of patients. Thrombolytic therapy (eg, alteplase) is given within the first 3 days after acute thrombosis. Therapy initiated beyond 14 days after the onset of symptoms is significantly less effective. The advantages of thrombolytic therapy include less long-term damage to the venous valves and a reduced incidence of postthrombotic syndrome and chronic venous insufficiency. However, thrombolytic therapy results in a threefold greater incidence of bleeding than heparin. If bleeding occurs and cannot be stopped, the thrombolytic agent is discontinued (Vedantham, et al., 2006).

Endovascular Management

Endovascular management is necessary for DVT when anticoagulant or thrombolytic therapy is contraindicated (see Chart 31-9), the danger of pulmonary embolism is extreme, or venous drainage is so severely compromised that permanent damage to the extremity is likely. A thrombectomy may be necessary. This mechanical method of clot removal may involve using intraluminal catheters with a balloon or other devices. Some of these spin to break the clot, and others use oscillation to break up the clot to facilitate removal. A vena cava filter may be placed at the time of the thrombectomy; this filter traps large emboli and prevents pulmonary emboli (see Chapter 23). Some retrievable caval filters can be left in place and then retrieved for up to several months. In patients with chronic iliac vein compression, balloon angioplasty with stent placement may successfully treat the patient's chronic leg symptoms (Shebel & Whalen, 2005).

Nursing Management

If the patient is receiving anticoagulant therapy, the nurse must frequently monitor the aPTT, prothrombin time (PT), INR, ACT, hemoglobin and hematocrit values, platelet count, and fibrinogen level, depending on which medication is being given. Close observation is also required to

detect bleeding; if bleeding occurs, it must be reported immediately and anticoagulant therapy discontinued.

Assessing and Monitoring Anticoagulant Therapy

To prevent inadvertent infusion of large volumes of unfractionated heparin, which could cause hemorrhage, unfractionated heparin is administered by continuous IV infusion using an electronic infusion device. Dosage calculations are based on the patient's weight, and any possible bleeding tendencies are detected by a pretreatment clotting profile. If renal insufficiency exists, lower doses of heparin are required. Periodic coagulation tests and hematocrit levels are obtained. Heparin is in the effective, or therapeutic, range when the aPTT is 1.5 times the control.

Oral anticoagulants, such as warfarin, are monitored by the PT or the INR. Because the full anticoagulant effect of warfarin is delayed for 3 to 5 days, it is usually administered concurrently with heparin until desired anticoagulation has been achieved (ie, when the PT is 1.5 to 2 times normal or the INR is 2.0 to 3.0).

Monitoring and Managing Potential Complications

Bleeding

The principal complication of anticoagulant therapy is spontaneous bleeding. Bleeding from the kidneys is detected by microscopic examination of the urine and is often the first sign of excessive dosage. Bruises, nosebleeds, and bleeding gums are also early signs. To promptly reverse the effects of heparin, IV injections of protamine sulfate may be administered. Risks of protamine administration include bradycardia and hypotension, which can be minimized by slow administration. Protamine sulfate can be used to reverse the effects of LMWH, but it is less effective with LMWH than with unfractionated heparin. Reversing the anticoagulation effects of warfarin is more difficult, but effective measures that may be prescribed include administration of vitamin K and/or infusion of fresh-frozen plasma or prothrombin concentrate. Oral and low-dose IV vitamin K significantly reduces the INR within 24 hours.

Thrombocytopenia

A complication of heparin therapy may be heparin-induced thrombocytopenia (HIT), which is defined as a sudden decrease in the platelet count by at least 30% of baseline levels. Patients at greatest risk are those who receive unfractionated heparin for a long period of time (ie, several days or weeks). Therefore, it is preferable not to use unfractionated heparin over the long term. The administration of LMWH is less frequently associated with HIT. Beginning warfarin concomitantly with unfractionated heparin can provide a stable INR or PT by day 5 of heparin treatment, at which time the heparin may be discontinued.

The thrombocytopenia associated with HIT is thought to result from an autoimmune mechanism that causes destruction of platelets. If the process is not arrested, platelets may aggregate, initiating inappropriate clotting, and thrombosis may occur. This serious complication results in thromboembolic manifestations known as HIT with thrombosis (HITT), and the prognosis is extremely guarded.

Prevention of thrombocytopenia depends on regular monitoring of platelet counts. Early signs include a decreasing platelet count, the need for increasing doses of heparin to maintain the therapeutic level, and thromboembolic or hemorrhagic complications (appearance of skin necrosis, either at the site of injection or at distal sites where thromboses occur; skin discoloration consisting of large hemorrhagic areas; hematomas; purpura; and blistering) (Arepally & Ortel, 2006). If thrombocytopenia does occur, platelet aggregation studies are performed, the heparin is discontinued, and alternate anticoagulant therapy is rapidly initiated because the continued prothrombotic state poses an ongoing threat of continuous clot development.

Lepirudin (Refludan) and argatroban (Novastan) are direct thrombin inhibitors approved for treatment of HIT. Lepirudin has a half-life of 1.3 hours, is excreted by the kidneys, and can be monitored using the aPTT. An initial IV bolus infusion followed by a continuous infusion with subsequent adjustments to maintain the aPTT between 1.5 and 2.5 times baseline is recommended. Strict dosage adjustment in renal failure is required, because the clearance of lepirudin is proportional to the patient's creatinine clearance. Argatroban has a half-life of 30 to 45 minutes, is metabolized by the liver, and is unaffected by renal function. The anticoagulant effect of argatroban is predictable, with low variability between patients, but it is dose dependent and requires monitoring with either the aPTT or ACT.

There is no safe, rapidly acting antidote if the patient develops bleeding complications from direct thrombin inhibitors. Recombinant factor VIIa may reverse the anticoagulant effects of direct thrombin inhibitors but may not be available in all hospitals, and it is costly (Nutescu, et al., 2006).

Drug Interactions

Because oral anticoagulants (ie, warfarin) interact with many other medications and herbal and nutritional supplements, close monitoring of the patient's medication schedule is necessary. Many medications and supplements potentiate or inhibit oral anticoagulants; it is always wise to check to see if any medications or supplements are contraindicated with warfarin (see Chart 33-15). Contraindications to anticoagulant therapy are summarized in Chart 31-9.

Providing Comfort

Elevation of the affected extremity, graduated compression stockings, and analgesic agents for pain relief are adjuncts to therapy. They help improve circulation and increase comfort. Warm, moist packs applied to the affected extremity reduce the discomfort associated with DVT. The patient is encouraged to walk once anticoagulation therapy has been initiated. The nurse should instruct the patient that walking is better than standing or sitting for long periods. Bed exercises, such as repetitive dorsiflexion of the foot, are also recommended.

Compression Therapy

Stockings

Graduated compression stockings usually are prescribed for patients with venous insufficiency. The amount of pressure gradient is determined by the amount and severity of

venous disease. For example, a 20- to 30-mm Hg pressure gradient is prescribed for patients with asymptomatic varicose veins, whereas at least a 40-mm Hg pressure gradient is prescribed for patients with venous stasis ulceration. These stockings should not be confused with anti-embolism stockings (ie, TED stockings) that provide less compression (12 to 20 mm Hg). Graduated compression stockings are designed to apply 100% of the prescribed pressure gradient at the ankle and pressure that decreases as the stocking approaches the thigh, reducing the caliber of the superficial veins in the leg and increasing flow in the deep veins. These stockings may be knee high, thigh high, or pantyhose.

NURSING ALERT

Any type of stocking can inadvertently become a tourniquet if applied incorrectly (ie, rolled tightly at the top). In such instances, the stockings produce rather than prevent stasis. For ambulatory patients, graduated compression stockings are removed at night and reapplied before the legs are lowered from the bed to the floor in the morning.

When the stockings are off, the skin is inspected for signs of irritation, and the calves are examined for tenderness. Any skin changes or signs of tenderness are reported. Stockings are contraindicated in patients with severe pitting edema because they can produce severe pitting at the knee.

Gerontologic Considerations. Because of decreased strength and manual dexterity, elderly patients may be unable to apply graduated compression stockings properly. If this is the case, a family member or friend should be taught to assist the patient to apply the stockings so that they do not cause undue pressure on any part of the feet or legs. Frames have been designed to assist patients with applying stockings, and if there is any concern regarding patients' physical abilities, they should be referred to a stocking vendor that can provide examples and training of stocking assistance devices.

External Compression Devices and Wraps

Short stretch elastic wraps may be applied from the toes to the knee in a 50% spiral overlap. These wraps are available in a two-layer system, which includes an inner layer of soft padding. These wraps are rectangular and become squares on stretching, indicating the appropriate degree of stretch and reducing the possibility of wrapping a leg too loosely or too tightly. Three- and four-layer systems are also available (eg, Profore, Dyna-Care), but these may be used only once compared with the two-layer system, which can be used multiple times.

Other types of compression are available. The Unna boot, which consists of a paste bandage impregnated with zinc oxide, glycerin, gelatin, and sometimes calamine, is applied without tension in a circular fashion from the base of the toes to the tibial tuberosity with a 50% spiral overlap. It is important to keep the foot dorsiflexed at a 90-degree an-

gle to the leg, thus avoiding excess pressure or trauma to the anterior ankle area. Once the bandage dries, it provides a constant and consistent compression of the venous system. This type of compression may remain in place for as long as 1 week, although it may be too heavy for debilitated patients to handle.

The CircAid, a nonelastic leg wrap with a series of overlapping, interlocking Velcro straps, augments the effect of muscle while the patient is walking. The CircAid is usually worn during the day. Patients may find the CircAid easier to apply and wear than the Unna boot because it is lighter; they can remove it to shower, and it is adjustable. This readily adjustable feature may also be problematic; patients may be tempted to loosen the straps, and the compression achieved may not be adequate.

Intermittent Pneumatic Compression Devices

These devices can be used with elastic or graduated compression stockings to prevent DVT. They consist of an electric controller that is attached by air hoses to plastic knee-high or thigh-high sleeves. The leg sleeves are divided into compartments, which sequentially fill to apply pressure to the ankle, calf, and thigh at 35 to 55 mm Hg of pressure. These devices can increase blood velocity beyond that produced by the stockings. Nursing measures include ensuring that prescribed pressures are not exceeded, assessing for patient comfort, and ensuring compliance to therapy.

Positioning the Body and Encouraging Exercise

When the patient is on bed rest, the feet and lower legs should be elevated periodically above the level of the heart. This position allows the superficial and tibial veins to empty rapidly and to remain collapsed. Active and passive leg exercises, particularly those involving calf muscles, should be performed to increase venous flow. Early ambulation is most effective in preventing venous stasis. Deep-breathing exercises are beneficial because they produce increased negative pressure in the thorax, which assists in emptying the large veins. Once ambulatory, the patient is instructed to avoid sitting for more than an hour at a time. The goal is to walk at least 10 minutes every 1 to 2 hours. The patient is also instructed to perform active and passive leg exercises as frequently as necessary when he or she cannot ambulate, such as during long car, bus, train, and plane trips.

Promoting Home and Community-Based Care

In addition to teaching the patient how to apply graduated compression stockings and explaining the importance of elevating the legs and exercising adequately, the nurse teaches about the prescribed anticoagulant, its purpose, and the need to take the correct amount at the specific times prescribed (Chart 31-10). The patient should also be aware that periodic blood tests are necessary to determine if a change in medication or dosage is required. If the patient fails to adhere to the therapeutic regimen, continuation of the medication therapy should be questioned. A person who refuses to discontinue the use of alcohol should not receive anticoagulants because chronic alcohol use decreases their effectiveness. In patients with liver disease, the potential for bleeding may be exacerbated by anticoagulant therapy.

CHART
31-10

PATIENT EDUCATION

Taking Anticoagulant Medications

- Take the anticoagulant medication at the same time each day, usually between 8:00 and 9:00 am.
- Wear or carry identification indicating the anticoagulant medication being taken.
- Keep all appointments for blood tests.
- Because other medications affect the action of the anticoagulant medication do not take any of the following medications or supplements without consulting with the primary health care provider: vitamins, cold medicines, antibiotics, aspirin, mineral oil, and anti-inflammatory agents, such as ibuprofen (Motrin) and similar medications or herbal or nutritional supplements. The primary health care provider should be contacted before taking any over-the-counter drugs.
- Avoid alcohol, because it may change the body's response to an anticoagulant medication.
- Avoid food fads, crash diets, or marked changes in eating habits.
- Do not take warfarin (Coumadin) unless directed.
- Do not stop taking warfarin (when prescribed) unless directed.
- When seeking treatment from a physician, dentist, podiatrist, or another health care provider, be sure to inform the caregiver that you are taking an anticoagulant medication.
- Contact your primary health care provider before having dental work or elective surgery.
- If any of the following signs appear, report them immediately to the primary health care provider:
 - Faintness, dizziness, or increased weakness
 - Severe headaches or abdominal pain
 - Reddish or brownish urine
 - Any bleeding—for example, cuts that do not stop bleeding
 - Bruises that enlarge, nosebleeds, or unusual bleeding from any part of the body
 - Red or black bowel movements
 - Rash
- Avoid injury that can cause bleeding.
- For women: Notify the primary health care provider if you suspect pregnancy.

Chronic Venous Insufficiency/ Postthrombotic Syndrome

Venous insufficiency results from obstruction of the venous valves in the legs or a reflux of blood through the valves. Superficial and deep leg veins can be involved. Resultant venous hypertension can occur whenever there has been a prolonged increase in venous pressure, such as occurs with DVT. Because the walls of veins are thinner and more elastic than the walls of arteries, they distend readily when venous pressure is consistently elevated. In this state, leaflets of the venous valves are stretched and prevented from closing completely, causing a backflow or reflux of blood in the veins. Duplex ultrasonography confirms the obstruction and identifies the level of valvular incompetence. From 20% to 50% of patients who are post-DVT when the valves in the deep veins become incompetent suffer from postthrombotic syndrome (Fig. 31-15) (Marr, 2006).

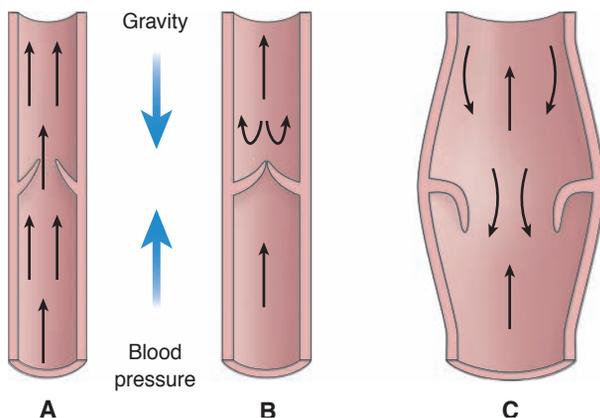

Figure 31-15 Competent valves showing blood flow patterns when the valve is open (A) and closed (B), allowing blood to flow against gravity. C, With faulty or incompetent valves, the blood cannot move toward the heart.

Clinical Manifestations

Postthrombotic syndrome is characterized by chronic venous stasis, resulting in edema, altered pigmentation, pain, and stasis dermatitis. The patient may notice the symptoms less in the morning and more in the evening. Obstruction or poor calf muscle pumping in addition to valvular reflux must be present for the development of severe postthrombotic syndrome and stasis ulcers. Superficial veins may be dilated. The disorder is long-standing, difficult to treat, and often disabling (Gohel, Barwell, Taylor, et al., 2007).

Stasis ulcers develop as a result of the rupture of small skin veins and subsequent ulcerations. When these vessels rupture, red blood cells escape into surrounding tissues and then degenerate, leaving a brownish discoloration of the tissues. The pigmentation and ulcerations usually occur in the lower part of the extremity, in the area of the medial malleolus of the ankle. The skin becomes dry, cracks, and itches; subcutaneous tissues fibrose and atrophy. The risk of injury and infection of the extremities is increased.

Complications

Venous ulceration is the most serious complication of chronic venous insufficiency and can be associated with other conditions affecting the circulation of the lower extremities. Cellulitis or dermatitis may complicate the care of chronic venous insufficiency and venous ulcerations.

Management

Management of the patient with venous insufficiency is directed at reducing venous stasis and preventing ulcerations. Measures that increase venous blood flow are antigravity activities, such as elevating the leg, and compression of superficial veins with graduated compression stockings.

Elevating the legs decreases edema, promotes venous return, and provides symptomatic relief. The legs should be elevated frequently throughout the day (at least 15 to 30 minutes every 2 hours). At night, the patient should sleep

with the foot of the bed elevated about 15 cm (6 inches). Prolonged sitting or standing in one position is detrimental; walking should be encouraged. When sitting, the patient should avoid placing pressure on the popliteal spaces, as occurs when crossing the legs or sitting with the legs dangling over the side of the bed. Constricting garments, especially socks that are too tight at the top or that leave marks on the skin, should be avoided.

Compression of the legs with graduated compression stockings reduces the pooling of venous blood, enhances venous return to the heart, and is recommended for people with venous insufficiency. It is recommended that stockings with 30 to 40 mm Hg pressure be used during the first year post-DVT (Marr, 2006). Each stocking should fit so that pressure is greater at the foot and ankle and then gradually declines to a lesser pressure at the knee or groin. If the top of the stocking is too tight or becomes twisted, a tourniquet effect is created, which worsens venous pooling. Stockings should be applied after the legs have been elevated for a period, when the amount of blood in the leg veins is at its lowest.

Extremities with venous insufficiency must be carefully protected from trauma; the skin is kept clean, dry, and soft. Signs of ulceration are immediately reported to the health care provider for treatment and follow-up.

Leg Ulcers

A leg ulcer is an excavation of the skin surface that occurs when inflamed necrotic tissue sloughs off. About 75% of all leg ulcers result from chronic venous insufficiency. Lesions due to arterial insufficiency account for approximately 20%; the remaining 5% are caused by burns, sickle cell anemia, and other factors (Humphreys, Stewart, Gohel, et al., 2007).

Pathophysiology

Inadequate exchange of oxygen and other nutrients in the tissue is the metabolic abnormality that underlies the development of leg ulcers. When cellular metabolism cannot maintain energy balance, cell death (necrosis) results. Alterations in blood vessels at the arterial, capillary, and venous levels may affect cellular processes and lead to the formation of ulcers.

Clinical Manifestations

The characteristics of leg ulcers are determined by the cause of the ulcer. Most ulcers, especially in elderly patients, have more than one cause. The symptoms depend on whether the problem is arterial or venous in origin (see Table 31-1). The severity of the symptoms depends on the extent and duration of the vascular insufficiency. The ulcer itself appears as an open, inflamed sore. The area may be draining or covered by eschar (dark, hard crust).

Arterial Ulcers

Chronic arterial disease is characterized by intermittent claudication, which is pain caused by activity and relieved after a few minutes of rest. The patient may also complain of digital or forefoot pain at rest. If the onset of arterial occlusion is acute, ischemic pain is unrelenting and rarely relieved even with opioids. Typically, arterial ulcers are small,

Figure 31-16 A, Ulcers resulting from arterial emboli. B, Gangrene of the toes resulting from severe arterial ischemia. C, Ulcer from venous stasis.

circular, deep ulcerations on the tips of toes or in the web spaces between the toes. Ulcers often occur on the medial side of the hallux or lateral fifth toe and may be caused by a combination of ischemia and pressure (Fig. 31-16).

Arterial insufficiency may result in gangrene of the toe (digital gangrene), which usually is caused by trauma. The toe is stubbed and then turns black (see Fig. 31-16). Usually, patients with this problem are elderly people without adequate circulation to provide revascularization. Débridement is contraindicated in these instances. Although the toe is gangrenous, it is dry. Managing dry gangrene is preferable to debriding the toe and causing an open wound that will not heal because of insufficient circulation. If the toe were to be amputated, the lack of adequate circulation would prevent healing and might make further amputation necessary—a below-knee or an above-knee amputation. A higher-level amputation in an elderly person could result in a loss of independence and possibly the need for institutional care. Dry gangrene of the toe in an elderly person with poor circulation is usually left undisturbed. The nurse keeps the toe clean and dry until it separates (without creating an open wound).

Venous Ulcers

Chronic venous insufficiency is characterized by pain described as aching or heavy. The foot and ankle may be edematous. Ulcerations are in the area of the medial or lateral

malleolus (gaiter area) and are typically large, superficial, and highly exudative. Venous hypertension causes extravasation of blood, which discolors the area (see Fig. 31-16). Patients with neuropathy frequently have ulcerations on the side of the foot over the metatarsal heads. These ulcers are painless and are described in further detail in Chapter 41.

Assessment and Diagnostic Findings

Because ulcers have many causes, the cause of each ulcer needs to be identified so appropriate therapy can be prescribed. The history of the condition is important in determining venous or arterial insufficiency. The pulses of the lower extremities (femoral, popliteal, posterior tibial, and dorsalis pedis) are carefully examined. More conclusive diagnostic aids are Doppler and duplex ultrasound studies, arteriography, and venography. Cultures of the ulcer bed may be necessary to determine whether an infecting agent is the primary cause of the ulcer.

Medical Management

Patients with ulcers can be effectively managed by advanced practice nurses or wound-ostomy-contenance nurses in collaboration with physicians. All ulcers have the potential to become infected.

Pharmacologic Therapy

Antibiotic therapy is prescribed when the ulcer is infected; the specific antibiotic agent is based on culture and sensitivity test results. Oral antibiotics usually are prescribed because topical antibiotics have not proven to be effective for leg ulcers.

Compression Therapy

Adequate compression therapy involves the application of external or counter pressure to the lower extremity to facilitate venous return to the heart. The pressure should be applied in a gradient or graduated fashion with the pressure being somewhat higher at the ankle. Graduated compression stockings are one option; some of these are custom-made to the patient's anatomic specifications. The patient should be instructed to wear the stockings at all times except at night and to reapply the stockings in the morning before getting out of bed. Short stretch elastic wraps, Unna boots, and CircAids may be other effective options. (See Venous Thromboembolism, Compression Therapy.)

Débridement

To promote healing, the wound is kept clean of drainage and necrotic tissue. The usual method is to flush the area with normal saline solution or clean it with a noncytotoxic wound-cleansing agent (Saf-Clens, Biolex, Restore). If this is unsuccessful, débridement may be necessary. Débridement is the removal of nonviable tissue from wounds. Removing the dead tissue is important, particularly in instances of infection. Débridement can be accomplished by several different methods:

- Surgical débridement is the fastest method and can be performed by a physician, skilled advanced practice nurse, or wound-ostomy-contenance nurse in collaboration with the physician.
- Nonselective débridement can be accomplished by applying isotonic saline dressings of fine-mesh gauze to the ulcer. When the dressing dries, it is removed (dry), along with the debris adhering to the gauze. Pain management is usually necessary.
- Enzymatic débridement with the application of enzyme ointments may be prescribed to treat the ulcer. The ointment is applied to the lesion but not to normal surrounding skin. Most enzymatic ointments are covered with saline-soaked gauze that has been thoroughly wrung out. A dry gauze dressing and a loose bandage are then applied. The enzymatic ointment is discontinued when the necrotic tissue has been débrided, and an appropriate wound dressing is applied.
- Calcium alginate dressings (eg, Kaltostat, Sorbsan, Aquacel Hydrofiber) may be used for débridement when absorption of exudate is needed. These dressings are changed when the exudate seeps through the cover dressing or at least every 7 days. The dressing can also be used on areas that are bleeding, because the material helps stop the bleeding. As the dry fibers absorb exudate, they become a gel that can be painlessly removed from the ulcer bed. Calcium alginate dressings should not be used on dry or nonexudative wounds.
- Foam dressings (eg, Lyofoam, Allevyn, Cavicare) may be an option for exudative wounds because they absorb exudate into the foam, keeping the wound moist.

Topical Therapy

A variety of topical agents can be used in conjunction with cleansing and débridement therapies to promote healing of leg ulcers. The goals of treatment are to remove devitalized tissue and to keep the ulcer clean and moist while healing takes place. The treatment should not destroy developing tissue. For topical treatments to be successful, adequate nutritional therapy must be maintained.

Wound Dressing

After the circulatory status has been assessed and determined to be adequate for healing (ABI of more than 0.5), surgical dressings can be used to promote a moist environment. Semioclusive or occlusive wound dressings prevent evaporative water loss from the wound and retain warmth; these factors favor healing. When determining the appropriate dressing to apply, the following should be considered: simplicity of application, frequency of required dressing changes, ability to absorb wound drainage, expense, and patient comfort. Available options that promote the growth of granulation tissue and re-epithelialization include the hydrocolloids (eg, Comfeel, DuoDERM CGF, Restore, Tegaderm). These materials also provide a barrier for protection because they adhere to the wound bed and surrounding tissue. Semipermeable film dressings (eg, Bioclusive, OpSite, Tegaderm) may be selected because they keep the wound moist and are impervious to bacteria while allowing some gas exchange. However, they may not be effective treatment for deep wounds and infected wounds.

Growth factor dressings (eg, OASIS, becaplermin [Regranex], keratinocyte lysate) may directly provide a growth factor or they may stimulate important growth substances within the wound. Some studies of these dressings have

shown a statistically significant improvement in the number of ulcers healed and a reduced time to wound closure (O'Donnell & Lau, 2006).

Knowledge deficit, frustration, fear, and depression can decrease the patient's and family's compliance with the prescribed therapy; therefore, patient and family education is necessary before beginning and throughout the wound care program.

Stimulated Healing

Tissue-engineered human skin equivalent (eg, Apligraf [Graftskin]) is a skin product cultured from human dermal fibroblasts and keratinocytes used in combination with therapeutic compression. When applied, it interacts with the patient's cells within the wound to stimulate the production of growth factors. Application is not difficult, no suturing is involved, and the procedure is painless.

Hyperbaric Oxygenation

Hyperbaric oxygenation (HBO) may be beneficial as an adjunct treatment in patients with diabetes with no signs of wound healing after 30 days of standard wound treatment. HBO is accomplished by placing the patient into a chamber that increases barometric pressure while the patient is breathing 100% oxygen. The process by which HBO is thought to work involves several factors. The edema in the wound area is decreased because high oxygen tension facilitates vasoconstriction and enhances the ability of leukocytes to phagocytize and kill bacteria. In addition, HBO is thought to increase diffusion of oxygen to the hypoxic wound, thereby enhancing epithelial migration and improving collagen production. The two most common adverse effects of HBO are middle ear barotrauma and confinement anxiety (Mechem & Manaker, 2005).

Negative Pressure Wound Therapy

Research findings suggest that negative pressure wound therapy using vacuum-assisted closure (VAC) devices decreases time to healing in complex wounds that have not healed in a 3-week period (Brem, Sheehan, Rosenberg, et al., 2006). Ambulatory patients may be given the small, portable VAC devices that can be strapped around the waist, giving patients the freedom to perform their ADLs.

NURSING PROCESS

THE PATIENT WITH LEG ULCERS

Assessment

A careful nursing history and assessment are important. The extent and type of pain are carefully assessed, as are the appearance and temperature of the skin of both legs. The quality of all peripheral pulses is assessed, and the pulses in both legs are compared. The legs are checked for edema. If the extremity is edematous, the degree of edema is determined. Any limitation of mobility and activity that results from vascular insufficiency is identified. The patient's nutritional status is assessed, and a history of diabetes, collagen disease, or varicose veins is obtained.

Diagnosis

Nursing Diagnoses

Based on the assessment data, major nursing diagnoses for the patient may include:

- Impaired skin integrity related to vascular insufficiency
- Impaired physical mobility related to activity restrictions of the therapeutic regimen and pain
- Imbalanced nutrition: less than body requirements, related to increased need for nutrients that promote wound healing

Collaborative Problems/Potential Complications

Based on the assessment data, potential complications that may develop include:

- Infection
- Gangrene

Planning and Goals

The major goals for the patient may include restoration of skin integrity, improved physical mobility, adequate nutrition, and absence of complications.

Nursing Interventions

The nursing challenge in caring for these patients is great, whether the patient is in the hospital, in a long-term care facility, or at home. The physical problem is often a long-term and disabling one that causes a substantial drain on the patient's physical, emotional, and economic resources.

Restoring Skin Integrity

To promote wound healing, measures are used to keep the area clean. Cleansing requires very gentle handling, a mild soap, and lukewarm water. Positioning of the legs depends on whether the ulcer is of arterial or venous origin. If there is arterial insufficiency, the patient should be referred for evaluation for vascular reconstruction. If there is venous insufficiency, dependent edema can be avoided by elevating the lower extremities. A decrease in edema promotes the exchange of cellular nutrients and waste products in the area of the ulcer, promoting healing.

Avoiding trauma to the lower extremities is imperative in promoting skin integrity. Protective boots may be used (eg, Rooke Vascular boot); they are soft and provide warmth and protection from injury and displace tissue pressure to prevent ulcer formation. If the patient is on bed rest, it is important to relieve pressure on the heels to prevent pressure ulcerations. When the patient is in bed, a bed cradle can be used to relieve pressure from bed linens and to prevent anything from touching the legs. When the patient is ambulatory, all obstacles are moved from the patient's path so that the patient's legs are not bumped. Heating pads, hot water bottles, or hot baths are avoided, because they increase the oxygen demands and thus the blood flow demands of the already compromised tissue. The patient with diabetes mellitus suffers from neuropathy with decreased sensation, and heating pads may produce injury before the patient is aware of being burned.

Improving Physical Mobility

Generally, physical activity is initially restricted to promote healing. When infection resolves and healing begins, ambulation should resume gradually and progressively. Activity promotes arterial flow and venous return and is encouraged after the acute phase of the ulcer process. Until full activity is resumed, the patient is encouraged to move about when in bed, to turn from side to side frequently, and to exercise the upper extremities to maintain muscle tone and strength. Meanwhile, diversional activities are encouraged. Consultation with an occupational therapist may be helpful if prolonged immobility and inactivity are anticipated.

If pain limits the patient's activity, analgesic agents may be prescribed. The pain of peripheral vascular disease is typically chronic and often disabling. Analgesic agents may be taken before scheduled activities to help the patient participate more comfortably.

Promoting Adequate Nutrition

Nutritional deficiencies are common, requiring dietary alterations to remedy deficiencies. A diet that is high in protein, vitamins C and A, iron, and zinc is encouraged to promote healing. Many patients with peripheral vascular disease are elderly. Particular consideration should be given to their iron intake, because many elderly people are anemic. After a dietary plan has been developed that meets the patient's nutritional needs and promotes healing, diet instruction is provided to the patient and family.

Promoting Home and Community-Based Care

The self-care program is planned with the patient so that activities that promote arterial and venous circulation, relieve pain, and promote tissue integrity are encouraged. Reasons for each aspect of the program are explained to the patient and family. Leg ulcers are often chronic and difficult to heal; they frequently recur, even when the patient rigorously follows the plan of care. Long-term care of the feet and legs to promote healing of wounds and prevent recurrence of ulcerations is the primary goal. Leg ulcers increase the patient's risk of infection, may be painful, and may limit mobility, necessitating lifestyle changes. Participation of family members and home health care providers may be necessary for treatments such as dressing changes, reassessments, reinforcement of instruction, and evaluation of the effectiveness of the plan of care. Regular follow-up with a primary health care provider is necessary.

Evaluation

Expected Patient Outcomes

Expected patient outcomes may include:

1. Demonstrates restored skin integrity
 - a. Exhibits absence of inflammation
 - b. Exhibits absence of drainage; negative wound culture
 - c. Avoids trauma to the legs
2. Increases physical mobility
 - a. Progresses gradually to optimal level of activity
 - b. Reports that pain does not impede activity
3. Attains adequate nutrition
 - a. Selects foods high in protein, vitamins, iron, and zinc
 - b. Discusses with family members dietary modifications that need to be made at home
 - c. Plans, with the family, a diet that is nutritionally sound

Varicose Veins

Varicose veins (varicosities) are abnormally dilated, tortuous, superficial veins caused by incompetent venous valves (see Fig. 31-15). Most commonly, this condition occurs in the lower extremities, the saphenous veins, or the lower trunk, but it can occur elsewhere in the body, such as the esophagus (eg, esophageal varices; see Chapter 39).

It is estimated that varicose veins occur in up to 60% of the adult population in the United States, with an increased incidence correlated with increased age (Beebe-Dimmer, Pfeifer, Engle, et al., 2005). The condition is most common in women and in people whose occupations require prolonged standing, such as salespeople, hair stylists, teachers, nurses and ancillary medical personnel, and construction workers. A hereditary weakness of the vein wall may contribute to the development of varicosities, and it commonly occurs in several members of the same family. Varicose veins are rare before puberty. Pregnancy may cause varicosities because of hormonal effects related to decreased venous outflow, increased pressure by the gravid uterus, and increased blood volume (James, 2007).

Pathophysiology

Varicose veins may be primary (without involvement of deep veins) or secondary (resulting from obstruction of deep veins). A reflux of venous blood in the veins results in venous stasis. If only the superficial veins are affected, the person may have no symptoms but may be troubled by their appearance.

Clinical Manifestations

Symptoms, if present, may include dull aches, muscle cramps, increased muscle fatigue in the lower legs, ankle edema, and a feeling of heaviness of the legs. Nocturnal cramps are common. When deep venous obstruction results in varicose veins, the patient may develop the signs and symptoms of chronic venous insufficiency: edema, pain, pigmentation, and ulcerations. Susceptibility to injury and infection is increased.

Assessment and Diagnostic Findings

Diagnostic tests for varicose veins include the duplex ultrasound scan, which documents the anatomic site of reflux and provides a quantitative measure of the severity of valvular reflux. Air plethysmography measures the changes in venous blood volume. Venography is not routinely performed to evaluate for valvular reflux. However, when it is used, it involves injecting a radiopaque contrast agent into the leg veins so that the vein anatomy can be visualized by x-ray studies during various leg movements.

Prevention

The patient should avoid activities that cause venous stasis, such as wearing socks that are too tight at the top or that leave marks on the skin, crossing the legs at the thighs, and sitting or standing for long periods. Changing position frequently, elevating the legs when they are tired, and getting up to walk for several minutes of every hour promote circulation. The patient is encouraged to walk 1 or 2 miles each day if there are no contraindications. Walking up the stairs rather than using the elevator or escalator is helpful, and swimming is good exercise.

Graduated compression stockings, especially knee-high stockings, are useful. The overweight patient should be encouraged to begin a weight reduction plan.

Medical Management

Ligation and Stripping

Surgery for varicose veins requires that the deep veins be patent and functional. The saphenous vein is ligated and divided. The vein is ligated high in the groin, where the saphenous vein meets the femoral vein. Also, the vein may be removed (stripped). After the vein is ligated, an incision is made 2 to 3 cm below the knee, and a metal or plastic wire is passed the full length of the vein to the point of ligation. The wire is then withdrawn, pulling (removing, stripping) the vein as it is removed. Pressure and elevation minimize bleeding during surgery.

Thermal Ablation

Thermal ablation is a nonsurgical approach using thermal energy. Radiofrequency ablation uses an electrical contact inside the vein. As the device is withdrawn, the vein is sealed. Laser ablation uses a laser fiber tip that seals the vein (decompressed). Topical gel may be used first to numb the skin along the course of the saphenous vein. To protect the surrounding tissue, several small punctures are made along the vein, and 100 to 200 mL of dilute lidocaine is delivered to the perivenous space using ultrasound guidance. The goal of this tumescent anesthesia (ie, anesthesia that causes localized swelling) is to provide analgesia, thermal protection (the cuff of fluid surrounds the veins and accompanying nerves), and extrinsic compression of the vein. The saphenous vein is entered percutaneously near the knee using ultrasound guidance. A catheter is introduced into the saphenous vein and advanced to the saphenofemoral junction. The device is then activated and withdrawn, sealing the vein. Small bandages and graduated compression stockings are applied after the procedure. The patient is asked not to remove the stockings for at least 48 hours and then to rewrap the legs and wear the compression stockings while ambulatory for at least 3 weeks. Patients are ambulatory prior to being discharged from the outpatient facility and have no activity restrictions, except that swimming is discouraged for 3 weeks. Nonsteroidal anti-inflammatory medications such as acetaminophen (Tylenol) or ibuprofen (Motrin) are used as needed for pain. The patient is informed that bruising may occur along the course of the saphenous vein, may experience leg cramps for a few days, and may find it difficult to straighten the knees for up to 1.5 weeks.

Sclerotherapy

Sclerotherapy involves injection of an irritating chemical into a vein to produce localized phlebitis and fibrosis, thereby obliterating the lumen of the vein. This treatment may be performed alone for small varicosities or may follow vein ablation, ligation, or stripping. Sclerosing is palliative rather than curative. Sclerotherapy is typically performed in an examination or procedure room and does not require sedation. After the sclerosing agent is injected, anti-embolism stockings are applied to the leg and are worn for approximately 5 days after the procedure. Graduated compression stockings are then worn for an additional 5 weeks. After sclerotherapy, walking activities are encouraged as prescribed to maintain blood flow in the leg and to dilute the sclerosing agent.

Nursing Management

Ligation and stripping can be performed in an outpatient setting, or the patient can be admitted to the hospital on the day of surgery and discharged the next day if a bilateral procedure is to be performed and the patient is at high risk for postoperative complications. If the procedure is performed in an outpatient setting, nursing measures are the same as if the patient were hospitalized. Bed rest is discouraged and the patient is encouraged to become ambulatory as soon as sedation has worn off. The patient is instructed to walk every hour for 5 to 10 minutes while awake for the first 24 hours if he or she can tolerate the discomfort, and then to increase walking and activity as tolerated. Graduated compression stockings are worn continuously for about 1 week after vein stripping. The nurse assists the patient to perform exercises and move the legs. The foot of the bed should be elevated. Standing and sitting are discouraged.

Promoting Comfort and Understanding

Analgesic agents are prescribed to help the patient move the affected extremities more comfortably. Dressings are inspected for bleeding, particularly at the groin, where the risk of bleeding is greatest. The nurse is alert for reported sensations of “pins and needles.” Hypersensitivity to touch in the involved extremity may indicate a temporary or permanent nerve injury resulting from surgery, because the saphenous vein and nerve are close to each other in the leg.

Usually, the patient may shower after the first 24 hours. The patient is instructed to dry the incisions well with a clean towel using a patting technique, rather than rubbing. Alternatively, the patient may be instructed to dry the area using a blow-dryer. Application of skin lotion is avoided until the incisions are completely healed to avoid infection. The patient is instructed to apply sunscreen or zinc oxide to the incisional area prior to sun exposure; otherwise, hyperpigmentation of the incision, scarring, or both may occur.

If the patient underwent sclerotherapy, a burning sensation in the injected leg may be experienced for 1 or 2 days. The nurse may encourage the use of a mild analgesic medication as prescribed and walking to provide relief.

Promoting Home and Community-Based Care

Long-term venous compression is essential after discharge, and the patient needs to obtain adequate supplies of graduated compression stockings or elastic bandages. Exercise of the

legs is necessary; the development of an individualized plan requires consultation with the patient and the health care team.

LYMPHATIC DISORDERS

The lymphatic system consists of a set of vessels that spread throughout most of the body. These vessels start as lymph capillaries that drain unabsorbed plasma from the interstitial spaces (spaces between the cells). The lymphatic capillaries unite to form the lymph vessels, which pass through the lymph nodes and then empty into the large thoracic duct that joins the jugular vein on the left side of the neck.

The fluid drained from the interstitial space by the lymphatic system is called lymph. The flow of lymph depends on the intrinsic contractions of the lymph vessels, the contraction of muscles, respiratory movements, and gravity. The lymphatic system of the abdominal cavity maintains a steady flow of digested fatty food (chyle) from the intestinal mucosa to the thoracic duct. In other parts of the body, the lymphatic system's function is regional; the lymphatic vessels of the head, for example, empty into clusters of lymph nodes located in the neck, and those of the extremities empty into nodes of the axillae and the groin.

Lymphangitis and Lymphadenitis

Lymphangitis is an acute inflammation of the lymphatic channels. It arises most commonly from a focus of infection in an extremity. Usually, the infectious organism is a hemolytic streptococcus. The characteristic red streaks that extend up the arm or the leg from an infected wound outline the course of the lymphatic vessels as they drain.

The lymph nodes located along the course of the lymphatic channels also become enlarged, red, and tender (acute lymphadenitis). They can also become necrotic and form an abscess (suppurative lymphadenitis). The nodes involved most often are those in the groin, axilla, or cervical region.

Because these infections are nearly always caused by organisms that are sensitive to antibiotics, it is unusual to see abscess formation. Recurrent episodes of lymphangitis are often associated with progressive lymphedema. After acute attacks, a graduated compression stocking should be worn on the affected extremity for several months to prevent long-term edema.

Lymphedema and Elephantiasis

Lymphedema may be primary (congenital malformations) or secondary (acquired obstructions). Tissue swelling occurs in the extremities because of an increased quantity of lymph that results from obstruction of lymphatic vessels. It is especially marked when the extremity is in a dependent position. Initially, the edema is soft and pitting. As the condition progresses, the edema becomes firm, nonpitting, and unresponsive to treatment. The most common type is con-

genital lymphedema (lymphedema praecox), which is caused by hypoplasia of the lymphatic system of the lower extremity. This disorder is usually seen in women and first appears between 15 and 25 years of age.

The obstruction may be in the lymph nodes and the lymphatic vessels. Sometimes, it is seen in the arm after an axillary node dissection (eg, for breast cancer) and in the leg in association with varicose veins or chronic thrombophlebitis. In the latter case, the lymphatic obstruction usually is caused by chronic lymphangitis. Lymphatic obstruction caused by a parasite (filaria) is most frequently seen in the tropics. When chronic swelling is present, there may be frequent bouts of acute infection characterized by high fever and chills and increased residual edema after the inflammation has resolved. These lead to chronic fibrosis, thickening of the subcutaneous tissues, and hypertrophy of the skin. This condition, in which chronic swelling of the extremity recedes only slightly with elevation, is referred to as elephantiasis.

Medical Management

The goal of therapy is to reduce and control the edema and prevent infection. Active and passive exercises assist in moving lymphatic fluid into the bloodstream. External compression devices milk the fluid proximally from the foot to the hip or from the hand to the axilla. When the patient is ambulatory, custom-fitted, graduated compression stockings or sleeves are worn; those with the highest compression strength (exceeding 40 mm Hg) are required. When the leg is affected, continuous bed rest with the leg elevated may aid in mobilizing the fluids. Manual lymphatic drainage performed by specially trained therapists is a technique designed to direct or shift the congested lymph through functioning lymphatics that have preserved drainage. Manual lymphatic drainage is incorporated in a sequential treatment approach used in combination with compression bandages, exercises, skin care, pressure gradient sleeves, and pneumatic pumps, depending on the severity and stage of the lymphedema (Ely, Osheroff, Chambliss, et al., 2006).

Pharmacologic Therapy

As initial therapy, the diuretic furosemide (Lasix) may be prescribed to prevent fluid overload due to mobilization of extracellular fluid. Diuretics have also been used along with elevation of the leg and the use of graduated compression stockings or sleeves. However, the use of diuretics alone has little benefit because their main action is to limit capillary filtration by decreasing the circulating blood volume. If lymphangitis or cellulitis is present, antibiotic therapy is initiated. The patient is taught to inspect the skin for evidence of infection.

Surgical Management

Surgery is performed if the edema is severe and uncontrolled by medical therapy, if mobility is severely compromised, or if infection persists. One surgical approach involves the excision of the affected subcutaneous tissue and fascia, with skin grafting to cover the defect. Another procedure involves the surgical relocation of superficial lymphatic vessels into the deep lymphatic system by means of a buried dermal flap to provide a conduit for lymphatic drainage.

Nursing Management

After surgery, the management of skin grafts and flaps is the same as when these therapies are used for other conditions. Antibiotics may be prescribed for 5 to 7 days. Constant elevation of the affected extremity and observation for complications are essential. Complications may include flap necrosis, hematoma or abscess under the flap, and cellulitis. The nurse instructs the patient or caregiver to inspect the dressing daily. Unusual drainage or any inflammation around the wound margin suggests infection and should be reported to the surgeon. The patient is informed that there may be a loss of sensation in the skin graft area. The patient is also instructed to avoid the application of heating pads or exposure to sun to prevent burns or trauma to the area.

CELLULITIS

Cellulitis is the most common infectious cause of limb swelling. Cellulitis can occur as a single isolated event or a series of recurrent events. It is sometimes misdiagnosed as recurrent thrombophlebitis or chronic venous insufficiency.

Pathophysiology

Cellulitis occurs when an entry point through normal skin barriers allows bacteria to enter and release their toxins in the subcutaneous tissues.

Clinical Manifestations

The acute onset of swelling, localized redness, and pain is frequently associated with systemic signs of fever, chills, and sweating. The redness may not be uniform and often skips areas. Regional lymph nodes may also be tender and enlarged.

Medical Management

Mild cases of cellulitis can be treated on an outpatient basis with oral antibiotic therapy. If the cellulitis is severe, the patient is treated with IV antibiotics. The key to preventing recurrent episodes of cellulitis lies in adequate antibiotic therapy for the initial event and in identifying the site of bacterial entry. Cracks and fissures that occur in the skin between the toes must be examined as potential sites of bacterial entry. Other locations include drug use injection sites, contusions, abrasions, ulceration, ingrown toenails, and hangnails.

Nursing Management

The patient is instructed to elevate the affected area above heart level and apply warm, moist packs to the site every 2 to 4 hours. Patients with sensory and circulatory deficits, such as those caused by diabetes and paralysis, should use caution when applying warm packs because burns may occur; it is advisable to use a thermometer or have a caregiver ensure that the temperature is not more than lukewarm. Education should focus on preventing a recurrent episode. The patient with peripheral vascular disease or diabetes mellitus should receive education or reinforcement about skin and foot care.

CRITICAL THINKING EXERCISES

1 A 75-year-old man has been diagnosed with stenosis of his external iliac artery and is scheduled for an angiogram with a possible balloon angioplasty and stent placement. What factors would you consider when planning his postprocedure care, continuing care, and home care? If the patient is taking warfarin (Coumadin) for atrial fibrillation and has renal insufficiency (creatinine of 1.8 mg/dL) as a complication of diabetes, how would you address these factors in the plan of care?

2 An 84-year-old woman with diabetes mellitus, hypertension, and heart failure presents to the outpatient clinic with complaints of long-standing edema of her left leg “ever since her hip surgery 20 years ago.” Further questioning reveals a previous diagnosis of left femoral DVT. On physical examination, the left lower extremity is edematous (the left calf is 2 cm larger than the right calf), with hemosiderin stains on the lower one-third calf. What additional information regarding the patient’s history would be helpful in determining a nursing diagnosis? What additional information is needed as part of the physical examination to aid in determining the diagnosis and implementing an intervention?

EBP 3 A man has been diagnosed with a recurrent DVT of the femoral vein. He has been instructed to wear graduated compression stockings. He tells you that he does not think that they help prevent DVTs. What is the strength of the evidence from the research literature that suggests that graduated compression stockings prevent DVTs in patients with recurrent DVTs? Is the length of the stocking (eg, calf length, midhigh length) associated with decreased rates of recurrence of DVTs?

4 A 50-year-old man presents to the community clinic. He recently moved to the area and needs a physical examination prior to beginning a job as a truck driver. The patient is found to have a history of diabetes mellitus (“diet controlled”) and has a 30-year history of smoking two packs of cigarettes per day (60-year pack-year history). Physical examination reveals bilateral varicose veins and 1+ pitting ankle edema. What additional information is needed as part of the history and physical examination? What risk factor modifications would you want to address with this patient?

Assessment and Management of Patients With Hypertension

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

- 1 Define normal blood pressure and categories of abnormal pressures.
- 2 Identify risk factors for hypertension.
- 3 Explain the differences between normal blood pressure and hypertension and discuss the significance of hypertension.
- 4 Describe treatment approaches for hypertension, including lifestyle and medication therapy.
- 5 Use the nursing process as a framework for care of the patient with hypertension.
- 6 Describe hypertensive crises and their treatment.

GLOSSARY

- dyslipidemia:** abnormal blood lipid levels, including high total, low-density lipoprotein, and triglyceride levels as well as low high-density lipoprotein levels
- glomerular filtration rate (GFR):** flow rate of filtered fluid through the kidney, an indicator of renal function
- hypertensive emergency:** a situation in which blood pressure is severely elevated and there is evidence of actual or probable target organ damage
- hypertensive urgency:** a situation in which blood pressure is severely elevated but there is no evidence of target organ damage
- isolated systolic hypertension:** a condition mostly commonly seen in the elderly in which the systolic pressure is greater than 140 mm Hg and the diastolic pressure is within normal limits (less than 90 mm Hg)
- monotherapy:** medication therapy with a single medication
- primary hypertension:** also called essential hypertension; denotes high blood pressure from an unidentified cause
- rebound hypertension:** blood pressure that is controlled with medication and that becomes uncontrolled (abnormally high) with the abrupt discontinuation of medication
- secondary hypertension:** high blood pressure from an identified cause, such as renal disease
- Seventh Joint National Committee on the Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC 7):** committee established to study and make recommendations about hypertension in the United States; findings and recommendations of JNC 7 are contained in an extensive report published in 2003

Hypertension is defined by the **Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC 7)** as a systolic blood pressure greater than 140 mm Hg and a diastolic pressure greater than 90 mm Hg based on the average of two or more accurate blood pressure measurements taken during two or more contacts with a health care provider (Chobanian, Bakris, Black, et al., 2003). Table 32-1 shows the classification of blood pressure established by JNC 7. The categories of blood pressure, from normal to stage 2 hypertension, emphasize the direct relationship between the risk of morbidity and mortality from increasing levels of blood pressure and the specific levels of both the systolic and diastolic blood pressures. The higher either the systolic or diastolic pressure, the greater the health risk (Lewington, Clarke, Qizilbash, et al., 2002).

JNC 7 defines a blood pressure of less than 120/80 mm Hg diastolic as normal, 120 to 129/80 to 89 mm Hg as prehypertension, and 140/90 mm Hg or higher as hypertension (see Table 32-1) (Chobanian, et al., 2003). The term *stage* is used to define two levels of hypertension so that it is similar to the terms used to describe cancer progression; thus, the public and health care professionals will understand that consistently higher elevations in blood pressure from prehypertension to stage 1 or 2 are associated with greater health risks. JNC 7 introduced the category of *prehypertension* to emphasize that people whose blood pressure begins to rise above 120/80 mm Hg are more likely to become hypertensive, and that even small increases in pressure are associated with increased risk of stroke, heart attack, heart failure, and cardiovascular death (Hsia, Margolis, Eaton, et al., 2007). To prevent or delay progression to hypertension and reduce risk, JNC 7 urged health care providers to encourage people with blood pressures in the prehypertension category to begin lifestyle modifications such as nutritional changes and exercise. JNC 7 recommended that people with stage 1 hypertension be treated with medications and be seen by their health care provider every month until their blood pressure goal is reached and subsequently about every 3 to 6 months. People with stage 2 hypertension or with other complicating conditions need to be seen more frequently.

Hypertension

About 31% of the adults in the United States have hypertension, and the prevalence increases significantly as people get older or have other cardiovascular risk factors. The preva-

Table 32-1 CLASSIFICATION OF BLOOD PRESSURE FOR ADULTS AGE 18 AND OLDER*

BP Classification*	Systolic BP (mm Hg)		Diastolic BP (mm Hg)
Normal	<120	and	<80
Prehypertension	120–139	or	or 80–89
Stage 1 hypertension	140–159	or	90–99
Stage 2 hypertension	≥160	or	≥100

*Based on the average of two or more properly measured, seated readings taken on each of two or more office visits.

From the Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure. (2003). *Hypertension*, 42(6), 1206–1252.

lence also varies by ethnicity, with African Americans having the highest prevalence at approximately 37% (Wong, Lopez, L'Italien, et al., 2007). In the total U.S. population of persons with hypertension, 90% to 95% have **primary hypertension**, high blood pressure from an unidentified cause (Oparil, Zaman & Calhoun, 2003). The remaining 5% to 10% of this group have **secondary hypertension**, high blood pressure related to identified causes. These causes include narrowing of the renal arteries, renal parenchymal disease, hyperaldosteronism (mineralocorticoid hypertension), certain medications, pregnancy, and coarctation of the aorta (Chiong, Aronow, Khan, et al., 2008).

Hypertension is sometimes called the “silent killer” because people who have it are often symptom free. In a national survey conducted from 2003 to 2004, 24% of people who had pressures exceeding 140/90 mm Hg were unaware of their elevated blood pressure (Ong, Cheung, Man, et al., 2007). Once identified, elevated blood pressure should be monitored at regular intervals because hypertension is a lifelong condition.

Hypertension often accompanies other risk factors for atherosclerotic heart disease, such as **dyslipidemia** (abnormal blood fat levels), obesity, diabetes mellitus, metabolic syndrome, and a sedentary lifestyle. The prevalence is also higher in persons who have other cardiovascular conditions including heart failure, coronary artery disease, and a history of having had a stroke (Ong, et al., 2007). Cigarette smoking does not cause high blood pressure; however, if a person with hypertension smokes, his or her risk of dying from heart disease or related disorders increases significantly (Baliunas, Patra, Rehm, et al., 2007).

High blood pressure can be viewed in three ways: as a sign, a risk factor for atherosclerotic cardiovascular disease, or a disease. As a sign, nurses and other health care professionals use blood pressure to monitor a patient’s clinical status. Elevated pressure may indicate an excessive dose of vasoconstrictive medication or other problems. As a risk factor, hypertension contributes to the rate at which atherosclerotic plaque accumulates within arterial walls. As a disease, hypertension is a major contributor to death from cardiac, cerebrovascular, renal, and peripheral vascular disease.

Prolonged blood pressure elevation eventually damages blood vessels throughout the body, particularly in target organs such as the heart, kidneys, brain, and eyes. The usual consequences of prolonged, uncontrolled hypertension are myocardial infarction, heart failure, renal failure, strokes, and impaired vision. Hypertrophy (enlargement) of the left ventricle of the heart may occur as it works to pump blood against the elevated pressure. An echocardiogram is the recommended method of determining whether hypertrophy has occurred.

Pathophysiology

Blood pressure is the product of cardiac output multiplied by peripheral resistance. Cardiac output is the product of the heart rate multiplied by the stroke volume. In normal circulation, pressure is transferred from the heart muscle to the blood each time the heart contracts, and then pressure is exerted by the blood as it flows through the blood vessels. Hypertension can result from an increase in cardiac output,

Physiology ■■■ Pathophysiology

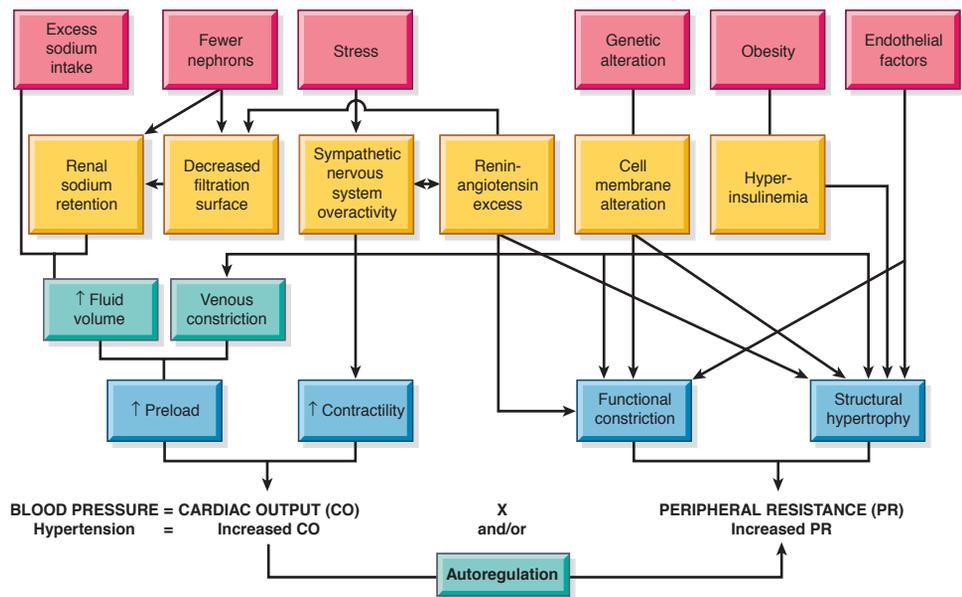

Figure 32-1 Factors involved in control of blood pressure. (Adapted from Kaplan, N. M., Lieberman, E. & Neal, W. (2006). *Kaplan's clinical hypertension* (9th ed.). Philadelphia: Lippincott Williams & Wilkins.)

an increase in peripheral resistance (constriction of the blood vessels), or both. Although no precise cause can be identified for most cases of hypertension, it is understood that hypertension is a multifactorial condition. Because hypertension is a sign, it is most likely to have many causes, just as fever has many causes. For hypertension to occur there must be a change in one or more factors affecting peripheral resistance or cardiac output (Fig. 32-1). In addition, there must also be a problem with the body's control systems that monitor or regulate pressure. Single gene mutations associated with the mechanisms used by the kidneys to reabsorb sodium ions have been identified for a few rare types of hypertension, but most types of hypertension are thought to be polygenic (ie, mutations in more than one gene) (Williams, 2007).

Many factors have been implicated as causes of hypertension:

- Increased sympathetic nervous system activity related to dysfunction of the autonomic nervous system
- Increased renal reabsorption of sodium, chloride, and water related to a genetic variation in the pathways by which the kidneys handle sodium
- Increased activity of the renin–angiotensin–aldosterone system, resulting in expansion of extracellular fluid volume and increased systemic vascular resistance
- Decreased vasodilation of the arterioles related to dysfunction of the vascular endothelium
- Resistance to insulin action, which may be a common factor linking hypertension, type 2 diabetes mellitus, hypertriglyceridemia, obesity, and glucose intolerance

Gerontologic Considerations

Structural and functional changes in the heart and blood vessels contribute to increases in blood pressure that occur with aging. These changes include accumulation of atherosclerotic plaque, fragmentation of arterial elastins, increased

collagen deposits, and impaired vasodilation. The result of these changes is decreased elasticity of the major blood vessels. Consequently, the aorta and large arteries are less able to accommodate the volume of blood pumped out by the heart (stroke volume), and the energy that would have stretched the vessels instead elevates the systolic blood pressure, resulting in an elevated systolic pressure without a change in diastolic pressure. This condition, known as **isolated systolic hypertension**, is more common in older adults and is associated with significant cardiovascular and cerebrovascular morbidity and mortality.

Clinical Manifestations

Physical examination may reveal no abnormalities other than elevated blood pressure. Occasionally, retinal changes such as hemorrhages, exudates (fluid accumulation), arteriolar narrowing, and cotton-wool spots (small infarctions) occur. In severe hypertension, papilledema (swelling of the optic disk) may be seen. People with hypertension may be asymptomatic and remain so for many years. However, when specific signs and symptoms appear, they usually indicate vascular damage, with specific manifestations related to the organs served by the involved vessels. Coronary artery disease with angina and myocardial infarction are common consequences of hypertension. Left ventricular hypertrophy occurs in response to the increased workload placed on the ventricle as it contracts against higher systemic pressure. When heart damage is extensive, heart failure follows. Pathologic changes in the kidneys (indicated by increased blood urea nitrogen [BUN] and serum creatinine levels) may manifest as nocturia. Cerebrovascular involvement may lead to a stroke or transient ischemic attack (TIA), manifested by alterations in vision or speech, dizziness, weakness, a sudden fall, or transient or permanent paralysis on one side (hemiplegia). Cerebral infarctions account for most of the strokes and TIAs in patients with hypertension.

Assessment and Diagnostic Findings

A thorough health history and physical examination are necessary. The retinas are examined and laboratory studies are performed to assess possible target organ damage. Routine laboratory tests include urinalysis, blood chemistry (ie, analysis of sodium, potassium, creatinine, fasting glucose, and total and high-density lipoprotein [HDL] cholesterol levels), and a 12-lead electrocardiogram (ECG). Left ventricular hypertrophy can be assessed by echocardiography. Renal damage may be suggested by elevations in BUN and creatinine levels or by microalbuminuria or macroalbuminuria. Additional studies, such as creatinine clearance, renin level, urine tests, and 24-hour urine protein, may be performed.

A risk factor assessment, as advocated by JNC 7, is needed to classify and guide the treatment of hypertensive people at risk for cardiovascular damage. Risk factors and cardiovascular problems related to hypertension are presented in Chart 32-1.

Medical Management

The goal of hypertension treatment is to prevent complications and death by achieving and maintaining the arterial blood pressure at 140/90 mm Hg or lower. JNC 7 specifies a

lower goal pressure of 130/80 mm Hg for people with diabetes mellitus or chronic kidney disease, which is defined as either a reduced **glomerular filtration rate (GFR)** resulting in a serum creatinine of greater than 1.3 mg/dL in women or greater than 1.5 mg/dL in men, or albuminuria of greater than 300 mg/d (Chobanian, et al., 2003). The optimal management plan is one that is inexpensive, simple, and causes the least possible disruption in the patient's life.

The management options for hypertension are summarized in the treatment algorithm issued by JNC 7 (Fig. 32-2); these include lifestyle modifications and pharmacologic therapy. Table 32-2 summarizes recommended lifestyle modifications. The clinician uses the algorithm with the risk factor assessment data and the patient's blood pressure category to choose the initial and subsequent treatment plans for the patient. Research findings demonstrate that weight loss, reduced alcohol and sodium intake, and regular physical activity are effective lifestyle adaptations to reduce blood pressure (Appel, Champagne, Harsha, et al., 2003; Appel, Sacks, Carey, et al., 2005; Cook, Cutler, Obarzanek, et al., 2007; Stranges, Wu, Dorn, et al., 2004). Studies also show that diets high in fruits, vegetables, and low-fat dairy products can prevent the development of hypertension and can lower elevated blood pressure (Appel, et al., 2005). Table 32-3 shows the Dietary Approaches to Stop Hypertension (DASH) diet, which has been shown to lower blood pressure in people who follow it (Appel, et al., 2003).

Pharmacologic Therapy

The medications used for treating hypertension decrease peripheral resistance, blood volume, or the strength and rate of myocardial contraction. For patients with uncomplicated hypertension and no specific indications for another medication, the recommended initial medications include diuretics, beta-blockers, or both. Patients are first given low doses of medication. If blood pressure does not fall to less than 140/90 mm Hg, the dose is increased gradually, and additional medications are included as necessary to achieve control. Table 32-4 describes the various pharmacologic agents that are recommended for the treatment of hypertension. When the blood pressure is less than 140/90 mm Hg for at least 1 year, gradual reduction of the types and doses of medication is indicated. To promote compliance, clinicians try to prescribe the simplest treatment schedule possible, ideally one pill once each day (Schroeder, Fahey & Ebrahim, 2004).

Gerontologic Considerations

Hypertension, particularly elevated systolic blood pressure, increases the risk of death, stroke, and heart failure in people older than 50 years and treatment reduces this risk (Chobanian, et al., 2003). Like younger patients, older patients should begin treatment with lifestyle modifications. If medications are needed to achieve the blood pressure goal of less than 140/90 mm Hg, the starting dose should be half that used in younger patients.

Compared to people between the ages of 50 and 80, there has been much less research on hypertension treatment and appropriate goals in persons over the age of 80. Results from a randomized, controlled trial in participants

CHART 32-1 **Risk Factors for Cardiovascular Problems in Hypertensive Patients**

Major Risk Factors (in Addition to Hypertension)

- Smoking
- Dyslipidemia (elevated LDL [or total] cholesterol and/or low HDL cholesterol)*
- Diabetes mellitus*
- Impaired renal function (GFR <60 mL/min and/or microalbuminuria)
- Obesity (BMI ≥30 kg/m²)*
- Physical inactivity
- Age (older than 55 years for men, 65 years for women)
- Family history of cardiovascular disease (in female relative younger than 65 years or male relative younger than 55 years)

Target Organ Damage or Clinical Cardiovascular Disease

- Heart disease (left ventricular hypertrophy, angina or previous myocardial infarction, previous coronary revascularization, heart failure)
- Stroke (cerebrovascular accident, brain attack) or TIA
- Chronic kidney disease
- Peripheral arterial disease
- Retinopathy

*These risk factors plus hypertension, elevated triglyceride levels, and abdominal obesity are components of the metabolic syndrome.

BMI, body mass index; GFR, glomerular filtration rate; HDL, high-density lipoprotein; LDL, low-density lipoprotein; TIA, transient ischemic attack.

Adapted from Table 6 of the Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure. (2003). *Hypertension*, 42(6), 1206–1252.

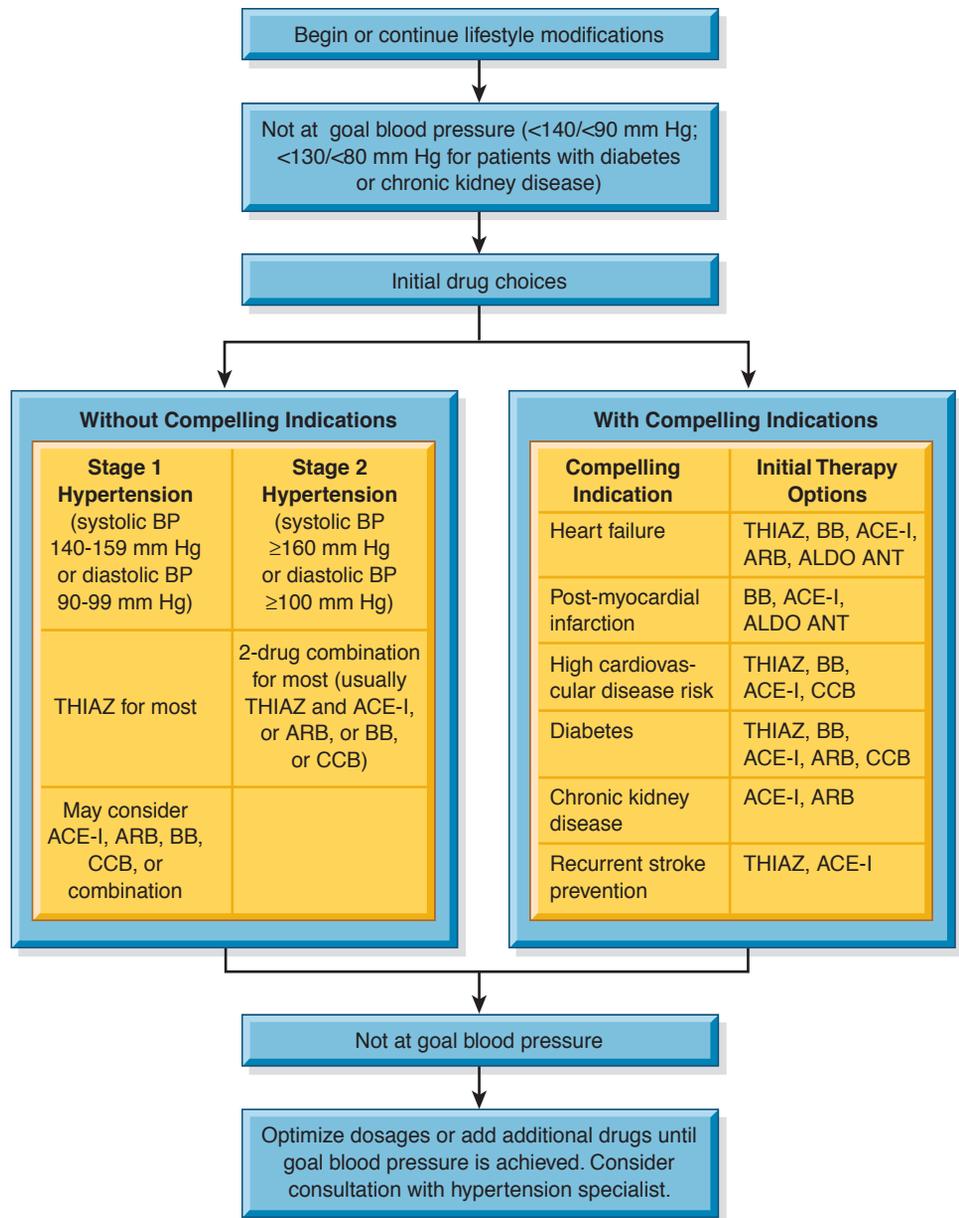

Figure 32-2 Algorithm of hypertension treatment. Treatment begins with lifestyle modifications and continues with various medication regimens. ACE-I, angiotensin-converting enzyme inhibitor; ALDO ANT, aldosterone antagonist; ARB, angiotensin receptor blocker; BB, beta-blocker; BP, blood pressure; CCB, calcium channel blocker; THIAZ, thiazide diuretic From the Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure. Reference card available from the National, Heart, Lung, and Blood Institute, available at www.nhlbi.nih.gov/guidelines/hypertension/phycard.pdf

Table 32-2 LIFESTYLE MODIFICATIONS TO PREVENT AND MANAGE HYPERTENSION*

Modification	Recommendation	Goal of SBP [†] Reduction (Range) [‡]
Weight reduction	Maintain normal body weight (body mass index 18.5–24.9 kg/m ²).	5–20 mm Hg/10 kg
Adopt DASH (Dietary Approaches to Stop Hypertension) eating plan	Consume a diet rich in fruits, vegetables, and low-fat dairy products with a reduced content of saturated and total fat.	8–14 mm Hg
Dietary sodium reduction	Reduce dietary sodium intake to no more than 100 mmol/day (2.4 g sodium or 6 g sodium chloride).	2–8 mm Hg
Physical activity	Engage in regular aerobic physical activity such as brisk walking (at least 30 min/day, most days of the week).	4–9 mm Hg
Moderation of alcohol consumption	Limit consumption to no more than 2 drinks (eg, 24 oz beer, 10 oz wine, or 3 oz 80-proof whiskey) per day in most men and to no more than 1 drink per day in women and lighter-weight people.	2–4 mm Hg

*For overall cardiovascular risk reduction, stop smoking.

[†]SBP, systolic blood pressure.

[‡]The effects of implementing these modifications are dose- and time-dependent and could be greater for some individuals.

From the Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure. (2003). *Hypertension*, 42(6), 1206–1252.

Table 32-3 THE DASH (DIETARY APPROACHES TO STOP HYPERTENSION) DIET

Food Group	Number of Servings/Day
Grains and grain products	7 or 8
Vegetables	4 or 5
Fruits	4 or 5
Low-fat or fat-free dairy foods	2 or 3
Meat, fish, and poultry	2 or fewer
Nuts, seeds, and dry beans	4 or 5 weekly

The diet is based on 2,000 calories per day.

Source: www.nhlbi.nih.gov/health/public/heart/hbp/dash/index.htm

over 80 years of age demonstrated a significant reduction in strokes, all-cause mortality, cardiovascular mortality, and heart failure in the participants treated with diuretics and angiotensin-converting enzyme (ACE) inhibitors versus a placebo. Because previous research findings suggest that excessive blood pressure may lead to adverse events in persons over the age of 80, the study authors recommended and used a target blood pressure of 150/80 mm Hg (Beckett, Peters, Fletcher, et al., 2008; Gueyffier, Bulpitt, Boissel, et al., 1999).

NURSING PROCESS

THE PATIENT WITH HYPERTENSION

Assessment

When hypertension is initially detected, nursing assessment involves carefully monitoring the blood pressure at frequent intervals and then at routinely scheduled intervals. The American Heart Association has defined the standards for blood pressure measurement, including conditions required before measurements are made, equipment specifications, and techniques for measuring blood pressure to obtain accurate and reliable readings (Chart 32-2) (Pickering, Hall, Appel, et al., 2005). When the patient begins an antihypertensive treatment regimen, blood pressure assessments are needed to determine the effectiveness of medication therapy and to detect any changes in blood pressure that may indicate the need for a modification in the treatment plan.

A complete history is obtained to assess for signs and symptoms that indicate target organ damage (ie, whether specific tissues are damaged by the elevated blood pressure). Such manifestations may include anginal pain; shortness of breath; alterations in speech, vision, or balance; nosebleeds; headaches; dizziness; or nocturia.

During the physical examination, the nurse must also pay specific attention to the rate, rhythm, and character of the apical and peripheral pulses to detect effects of hypertension on the heart and blood vessels. A thorough assessment can yield valuable information about the extent to which the hypertension has affected the body and about any other personal, social, or financial factors related to the condition. For example, some patients' ability to adhere to an antihypertensive medication regimen may be influenced by their financial resources to buy the medication and health insurance.

Diagnosis

Nursing Diagnoses

Based on the assessment data, nursing diagnoses for the patient may include the following:

- Deficient knowledge regarding the relation between the treatment regimen and control of the disease process
- Noncompliance with therapeutic regimen related to side effects of prescribed therapy

Collaborative Problems/Potential Complications

Based on the assessment data, potential complications that may develop include the following:

- Left ventricular hypertrophy
- Myocardial infarction
- Heart failure
- TIAs
- Cerebrovascular accident (CVA, stroke, or brain attack)
- Renal insufficiency and failure
- Retinal hemorrhage

Planning and Goals

The major goals for the patient include understanding of the disease process and its treatment, participation in a self-care program, and absence of complications.

Nursing Interventions

The objective of nursing care for patients with hypertension focuses on lowering and controlling the blood pressure without adverse effects and without undue cost. To achieve these goals, the nurse must support and teach the patient to adhere to the treatment regimen by implementing necessary lifestyle changes, taking medications as prescribed, and scheduling regular follow-up appointments with the health care provider to monitor progress or identify and treat any complications of disease or therapy.

Increasing Knowledge

The patient needs to understand the disease process and how lifestyle changes and medications can control hypertension. The nurse needs to emphasize the concept of controlling hypertension rather than curing it. The nurse can encourage the patient to consult a dietitian to help develop a plan for improving nutrient intake or for weight loss. The program usually consists of restricting sodium and fat intake, increasing intake of fruits and vegetables, and implementing regular physical activity. Explaining that it takes 2 to 3 months for the taste buds to adapt to changes in salt intake may help the patient adjust to reduced salt intake. The patient should be advised to limit alcohol intake (see Table 32-2 for specific recommendations), and tobacco should be avoided because anyone with high blood pressure is already at increased risk for heart disease, and smoking amplifies this risk. Support groups for weight control, smoking cessation, and stress reduction may be beneficial for some patients; others can benefit from the support of family and friends. The nurse assists the patient to develop and adhere to an appropriate exercise regimen, because regular activity is a significant factor in weight reduction and a

Table 32-4  MEDICATION THERAPY FOR HYPERTENSION

Medications	Major Action	Advantages and Contraindications	Effects and Nursing Considerations
Diuretics and Related Drugs			
Thiazide Diuretics chlorthalidone chlorothiazide (Diuril) hydrochlorothiazide indapamide methyclothiazide metolazone (Zaroxolyn)	Decrease of blood volume, renal blood flow, and cardiac output Depletion of extracellular fluid Negative sodium balance (from natriuresis), mild hypokalemia Directly affect vascular smooth muscle	Relatively inexpensive Effective orally Effective during long-term administration Mild side effects Enhance other antihypertensive medications Counter sodium retention effects of other antihypertensive medications <i>Contraindications:</i> Gout, known sensitivity to sulfonamide-derived medications, severely impaired kidney function, and history of hyponatremia	Side effects include dry mouth, thirst, weakness, drowsiness, lethargy, muscle aches, muscular fatigue, tachycardia, GI disturbance. Postural hypotension may be potentiated by alcohol, barbiturates, opioids, or hot weather. Because thiazides cause loss of sodium, potassium, and magnesium, monitor for signs of electrolyte imbalance. Encourage intake of potassium-rich foods (eg, fruits). <i>Gerontologic Considerations:</i> Risk of postural hypotension is significant because of volume depletion; measure blood pressure in three positions; caution patient to rise slowly.
Loop Diuretics furosemide (Lasix) bumetanide (Bumex) torsemide (Demadex)	Volume depletion Blocks reabsorption of sodium, chloride, and water in kidney	Action rapid Potent Used when thiazides fail or patient needs rapid diuresis <i>Contraindications:</i> Same as for thiazides	Risk of volume and electrolyte depletion from the profound diuresis that can occur. Fluid and electrolyte replacement may be required. <i>Gerontologic Considerations:</i> Same as for thiazides.
Potassium-Sparing Diuretics amiloride (Midamor) triamterene (Dyrenium)	Blocks sodium reabsorption Acts on distal tubule independently of aldosterone	Causes potassium retention <i>Contraindications:</i> Renal disease, azotemia, severe hepatic disease, hyperkalemia	Drowsiness, lethargy, headache. Monitor for hyperkalemia if given with ACE inhibitor or angiotensin receptor blocker. Diarrhea and other GI symptoms—administer medication after meals.
Aldosterone Receptor Blockers eplerenone (Inspra) spironolactone (Aldactone)	Competitive inhibitors of aldosterone binding	Indicated for patients with a history of myocardial infarction or symptomatic ventricular dysfunction <i>Contraindications:</i> Hyperkalemia and impaired renal function Eplerenone is contraindicated in diabetes mellitus with microalbuminuria	Drowsiness, lethargy, headache. Monitor for hyperkalemia if given with ACE inhibitor or angiotensin receptor blocker. Diarrhea and other GI symptoms—administer medication after meals. Avoid use of potassium supplements or salt substitutes. Teach patients, families, and caregivers signs and symptoms of hyperkalemia. Spironolactone may cause gynecomastia.

Continued on following page

Table 32-4 MEDICATION THERAPY FOR HYPERTENSION (Continued)

Medications	Major Action	Advantages and Contraindications	Effects and Nursing Considerations
Central Alpha₂-Agonists and Other Centrally Acting Drugs			
reserpine (Harmony)	Impairs synthesis and reuptake of norepinephrine	Slows pulse, which counteracts tachycardia of hydralazine <i>Contraindications:</i> History of depression, psychosis, obesity, chronic sinusitis, peptic ulcer	May cause severe depression; report manifestations, as this may require that drug be discontinued. Nasal congestion. Use with caution if history of gallbladder, renal, or cardiac disease, or seizure disorder. <i>Gerontologic Considerations:</i> Depression and postural hypotension common in elderly.
methyldopa (Aldomet)	Dopa-decarboxylase inhibitor; displaces norepinephrine from storage sites	Drug of choice for pregnant women with hypertension Useful in patients with renal failure or prostate disease Does not decrease cardiac output or renal blood flow Does not induce oliguria <i>Contraindications:</i> Liver disease	Drowsiness, dizziness. Dry mouth; nasal congestion (troublesome at first but then tends to disappear). Use with caution with renal disease. <i>Gerontologic Considerations:</i> May produce mental and behavioral changes in the elderly.
clonidine (Catapres) clonidine patch (Catapres-TTs)	Exact mode of action not understood, but acts through the central nervous system, apparently through centrally mediated alpha-adrenergic stimulation in the brain, producing blood pressure reduction	Little or no orthostatic effect; moderately potent, and sometimes is effective when other medications fail to lower blood pressure <i>Contraindications:</i> Severe coronary artery disease, pregnancy	Dry mouth, drowsiness, sedation, and occasional headaches and fatigue. Anorexia, malaise, and vomiting with mild disturbance of liver function have been reported. Rebound or withdrawal hypertension is relatively common; monitor blood pressure when stopping medication. Common side effects include dry mouth, dizziness, sleepiness, fatigue, headache, constipation, and impotence.
guanfacine (Tenex)	Stimulates central alpha ₂ -adrenergic receptors	Reduces heart rate and causes vasodilation. Serious adverse reactions are uncommon; use with caution in persons with diminished liver function, recent myocardial infarction, or known cardiovascular disease	
Beta-Blockers			
atenolol (Tenormin) betaxolol (Kerlone) bisoprolol (Zebeta) propranolol (Inderal) propranolol long-acting (Inderal LA) metoprolol (Lopressor) metoprolol extended release (Toprol XL) nadolol (Corgard) timolol (Blocadren)	Block the sympathetic nervous system (beta-adrenergic receptors), especially the sympathetics to the heart, producing a slower heart rate and lowered blood pressure	Reduce pulse rate in patients with tachycardia and blood pressure elevation Indicated for patients who also have stable angina pectoris and silent ischemia <i>Contraindications:</i> Bronchial asthma, allergic rhinitis, right ventricular failure from pulmonary hypertension, heart failure, depression, diabetes mellitus, dyslipidemia, heart block, peripheral vascular disease, heart rate less than 60 bpm	Mental depression manifested by insomnia, lassitude, weakness, and fatigue. Avoid sudden discontinuation. Lightheadedness and occasional nausea, vomiting, and epigastric distress. Check heart rate before giving. <i>Gerontologic Considerations:</i> Risk of toxicity is increased for elderly patients with decreased renal and liver function. Take blood pressure in three positions and observe for hypotension.
Beta-Blockers with Intrinsic Sympathomimetic Activity			
acebutolol (Sectral) penbutolol (Levatol) pindolol (Visken)	Block both cardiac beta-1 and beta-2 receptors Also have antiarrhythmic activity by slowing atrioventricular conduction	<i>Advantages:</i> Similar to beta-blockers <i>Contraindications:</i> Similar to beta-blockers	Avoid sudden discontinuation. Withhold if bradycardia or heart block is present. Use with caution with COPD, diabetes mellitus. Similar to beta-blockers.

Continued

Table 32-4

MEDICATION THERAPY FOR HYPERTENSION (Continued)

Medications	Major Action	Advantages and Contraindications	Effects and Nursing Considerations
Alpha₁-Blockers doxazosin (Cardura) prazosin hydrochloride (Minipress) terazosin (Hytrin)	Peripheral vasodilator acting directly on the blood vessel; similar to hydralazine	Act directly on the blood vessels and are effective agents in patients with adverse reactions to hydralazine <i>Contraindications:</i> Angina pectoris and coronary artery disease; induces tachycardia if not preceded by administration of propranolol and a diuretic	Occasional vomiting and diarrhea, urinary frequency, and cardiovascular collapse, especially if given in addition to hydralazine without lowering the dose of the latter. Patients occasionally experience drowsiness, lack of energy, and weakness.
Combined Alpha- and Beta-Blockers carvedilol (Coreg) labetalol hydrochloride (Trandate)	Block alpha- and beta-adrenergic receptors; cause peripheral dilation and decrease peripheral vascular resistance	Fast acting No decrease in renal blood flow <i>Contraindications:</i> Asthma, cardiogenic shock, severe tachycardia, heart block	Orthostatic hypotension, tachycardia.
Vasodilators fenoldopam mesylate (Corlopan)	Stimulates dopamine and alpha ₂ -adrenergic receptors	Given intravenously for hypertensive emergencies; use with caution in patients with glaucoma, recent stroke (brain attack), asthma, hypokalemia, or diminished liver function	Headache, flushing, hypotension, sweating, tachycardia caused by vasodilation. Observe for local reactions at the injection site.
hydralazine (Apresoline)	Decreases peripheral resistance but concurrently elevates cardiac output Acts directly on smooth muscle of blood vessels	Not used as initial therapy; used in combination with other medications Used also in pregnancy-induced hypertension <i>Contraindications:</i> Angina or coronary disease, heart failure, hypersensitivity	Headache, tachycardia, flushing, and dyspnea may occur—can be prevented by pretreating with reserpine. Peripheral edema may require diuretics. May produce lupus erythematosus-like syndrome. Tachycardia, angina pectoris, ECG changes, edema.
minoxidil (Loniten)	Direct vasodilating action on arteriolar vessels, causing decreased peripheral vascular resistance; reduces systolic and diastolic pressures	Hypotensive effect more pronounced than with hydralazine No effect on vasomotor reflexes so does not cause postural hypotension <i>Contraindications:</i> Pheochromocytoma	Take blood pressure and apical pulse before administration. Monitor intake and output and daily weights. Causes hirsutism. Dizziness, headache, nausea, edema, tachycardia, palpitations.
sodium nitroprusside (Nitropress) nitroglycerin	Peripheral vasodilation by relaxation of smooth muscle	Fast acting Used only in hypertensive emergencies <i>Contraindications:</i> Sepsis, azotemia, high intracranial pressure	Can cause thiocyanate and cyanide intoxication.
Angiotensin-Converting Enzyme Inhibitors benazepril (Lotensin) captopril (Capoten) enalapril (Vasotec) enalaprilat (Vasotec IV) fosinopril (Monopril) lisinopril (Prinivil, Zestril) moexipril (Univase) perindopril (Aceon) quinapril (Accupril) ramipril (Altace) trandolapril (Mavik)	Inhibit conversion of angiotensin I to angiotensin II Lower total peripheral resistance	Fewer cardiovascular side effects Can be used with thiazide diuretic and digitalis Hypotension can be reversed by fluid replacement Angioedema is a rare but potentially life-threatening complication <i>Contraindications:</i> Renal impairment, pregnancy	<i>Gerontologic Considerations:</i> Require reduced dosages and the addition of loop diuretics when there is renal dysfunction.
Angiotensin II Receptor Blockers candesartan (Atacand) eprosartan (Teveten) irbesartan (Avapro) losartan (Cozaar) olmesartan (Benicar) telmisartan (Micardis) valsartan (Diovan)	Block the effects of angiotensin II at the receptor Reduce peripheral resistance	Minimal side effects <i>Contraindications:</i> Pregnancy, renovascular disease	Monitor for hyperkalemia.

Continued on following page

 Table 32-4 MEDICATION THERAPY FOR HYPERTENSION (Continued)			
Medications	Major Action	Advantages and Contraindications	Effects and Nursing Considerations
Calcium Channel Blockers			
Nondihydropyridines			
diltiazem extended release (Cardizem CD, Dilacor XR, Tiazac) diltiazem long-acting (Cardizem LA)	Inhibit calcium ion influx Reduce cardiac afterload	Inhibit coronary artery spasm not controlled by beta-blockers or nitrates <i>Contraindications:</i> Sick sinus syndrome; AV block; hypotension; heart failure	Do not discontinue suddenly. Observe for hypotension. Report irregular heartbeat, dizziness, edema. Instruct on regular dental care because of potential gingivitis.
verapamil immediate release (Calan, Isoptin) verapamil long-acting (Calan SR, Isoptin SR) verapamil (Covera HS, Verelan PM)	Inhibits calcium ion influx Slows velocity of conduction of cardiac impulse	Effective antiarrhythmic Rapid IV onset Blocks SA and AV node channels <i>Contraindications:</i> Sinus or AV node disease; severe heart failure; severe hypotension	Administer on empty stomach or before meal. Do not discontinue suddenly. Depression may subside when medication is discontinued. To relieve headaches, reduce noise, monitor electrolytes. Decrease dose for patients with liver or renal failure.
Dihydropyridines			
amlodipine (Norvasc) felodipine (Plendil) isradipine (Dynacirc CR) nicardipine (Cardene) nifedipine long-acting (Procardia XL, Adalat CC) nisoldipine (Sular)	Inhibit calcium ion influx across membranes Vasodilating effects on coronary arteries and peripheral arteriole Decrease cardiac work and energy consumption, increase delivery of oxygen to myocardium	Rapid action Effective by oral or sublingual route No tendency to slow SA nodal activity or prolong AV node conduction Isolated systolic hypertension <i>Contraindications:</i> None (except heart failure for nifedipine)	Administer on empty stomach. Use with caution in patients with diabetes. Small frequent meals if nausea. Muscle cramps, joint stiffness, sexual difficulties may disappear when dose decreased. Report irregular heartbeat, constipation, shortness of breath, edema. May cause dizziness.
Direct Renin Inhibitors			
aliskiren (Tekturna)	Blocks the conversion of angiotensinogen to angiotensin I by inhibiting the activity of the enzyme renin	Given once daily for mild to moderate high blood pressure with minimal side effects Headaches, dizziness, and diarrhea are most frequent side effects Angioedema is a rare but potentially life-threatening complication <i>Contraindicated in pregnancy;</i> has not been studied in persons with diminished renal function	Monitor for hyperkalemia and hypotension.

ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blocker; AV, atrioventricular; bpm, beats per minute; COPD, chronic obstructive pulmonary disease; ECG, electrocardiogram; GI, gastrointestinal; IV, intravenous; SA, sinoatrial.

blood pressure–reducing intervention in the absence of any loss in weight (Chobanian, et al., 2003).

Promoting Home and Community-Based Care

Blood pressure screenings with the sole purpose of case finding are not recommended by the National High Blood Pressure Education Program because approximately 75% of people with hypertension are already aware of their blood pressure levels (Ong, et al., 2007). If asked to participate in a blood pressure screening program, the nurse should ensure that proper blood pressure measurement technique is being used (see Chart 32-2), that the manometers used are calibrated (Pickering, et al., 2005), and that provision has been made to provide follow-up for any person identified as having an elevated blood pressure level. Adequate time should also be

allowed to teach each person screened what the blood pressure numbers mean. Each person should be given a written record of his or her blood pressure at the screening.

TEACHING PATIENTS SELF-CARE. The therapeutic regimen is the responsibility of the patient in collaboration with the health care provider. The nurse can help the patient achieve blood pressure control through education about managing blood pressure (see teaching discussion above), setting goal blood pressures, and providing assistance with social support. Involving family members in education programs enables them to support the patient's efforts to control hypertension. Both the American Heart Association and the National Heart, Lung, and Blood Institute provide printed and electronic patient education materials.

Chart 32-2 • Measuring Blood Pressure (BP)

Equipment

For the Patient at Home

- Automatic or semiautomatic device with digital display of readings.

For the Practitioner

- Mercury sphygmomanometer, recently calibrated aneroid manometer, or validated electronic device.
- Cuff.

Instructions for the Patient

- Avoid smoking cigarettes or drinking caffeine for 30 minutes before BP is measured.
- Sit quietly for 5 minutes before the measurement.
- Sit comfortably with the forearm supported at heart level on a firm surface, with both feet on the ground; avoid talking while the measurement is being taken.

Instructions for the Practitioner

- Select the size of the cuff based on the size of the patient. (The cuff size should have a bladder width of at least 40% of limb circumference and length at least 80% of limb circumference.) The average adult cuff is 12 to 14 cm wide and 30 cm long. Using a cuff that is too small will give a higher BP measurement, and using a cuff that is too large results in a lower BP measurement compared to one taken with a properly sized cuff.

- Routinely calibrate the sphygmomanometer.
- Wrap the cuff firmly around the arm. Center the cuff bladder directly over the brachial artery.
- Position the patient's arm at the level of the heart.
- Palpate the systolic pressure before auscultating. This technique helps to detect the presence of an auscultatory gap more readily.
- Ask the patient to sit quietly while the BP is measured because the BP can increase when the patient is engaged in conversation.
- Initially, record BP results of both arms and take subsequent measurements from the arm with the higher BP. Normally, the BP should vary by no more than 5 mm Hg between arms.
- Record the site where the BP was measured and the position of the patient (eg, right arm).
- Inform the patient of his or her BP value and what it means. Emphasize the need for periodic reassessment, and encourage patients who measure BP at home to keep a written record of readings.

Interpretation

Assessment is based on the average of at least two readings. (If two readings differ by more than 5 mm Hg, additional readings are taken and an average reading is calculated from the results.)

Providing written information about the expected effects and side effects of medications is important. When side effects occur, patients need to understand the importance of reporting them and to whom they should be reported. Patients need to be informed that **rebound hypertension** can occur if antihypertensive medications are suddenly stopped. Thus, patients should be advised to have an adequate supply of medication. If they are traveling by airplane, they should pack the medication in their carry-on luggage. Both female and male patients should be informed that some medications, such as beta-blockers, may cause sexual dysfunction and that other medications are available if a problem with sexual function or satisfaction occurs. The nurse can encourage and teach patients to measure their blood pressure at home. This practice involves patients in their own care and emphasizes that failing to take medications may result in an identifiable rise in blood pressure. Patients need to know that blood pressure varies continuously and that the range within which their pressure varies should be monitored.

GERONTOLOGIC CONSIDERATIONS. Compliance with the therapeutic program may be more difficult for elderly people. The medication regimen can be difficult to remember, and the expense can be a problem. **Monotherapy** (treatment with a single agent), if appropriate, may simplify the medication regimen and make it less expensive. Special care must be taken to ensure that the elderly patient understands the regimen and can see and read instructions, open the medication container, and get the prescription refilled. The elderly person's family or caregivers should be included in the teaching program so that they understand the patient's

needs, can encourage adherence to the treatment plan, and know when and whom to call if problems arise or information is needed.

CONTINUING CARE. Regular follow-up care is imperative so that the disease process can continue to be optimally assessed and treated, as shown in Table 32-5. A history and physical examination should be completed at each clinic visit. The history should include all data pertaining to any potential problem, specifically medication-related problems such as postural (orthostatic) hypotension (experienced as dizziness or lightheadedness on standing).

NURSING ALERT

The patient and caregivers should be cautioned that antihypertensive medications can cause hypotension. Low blood pressure or postural hypotension should be reported immediately. The elderly have impaired cardiovascular reflexes and thus are more sensitive to the extracellular volume depletion caused by diuretics and to the sympathetic inhibition caused by adrenergic antagonists. The nurse teaches patients to change positions slowly when moving from a lying or sitting position to a standing position. The nurse also counsels elderly patients to use supportive devices such as handrails and walkers as necessary to prevent falls that could result from dizziness.

Deviation from the therapeutic program is a significant problem for people with hypertension and other chronic

Table 32-5 RECOMMENDATIONS FOR FOLLOW-UP BASED ON INITIAL BLOOD PRESSURE MEASUREMENTS FOR ADULTS WITHOUT ACUTE END ORGAN DAMAGE

Initial BP (mm Hg)*	Follow-Up Recommended†
Normal	Recheck in 2 years
Prehypertension	Recheck in 1 year‡
Stage 1 hypertension	Confirm within 2 months‡
Stage 2 hypertension	Evaluate or refer to source of care within 1 month For those with higher pressures (eg, >180/100 mm Hg), evaluate and treat immediately or within 1 week, depending on clinical situation and complications

*If systolic and diastolic values fall into different categories, follow recommendations for shorter follow-up (eg, 160/86 mm Hg should be evaluated or referred to source of care within 1 month).

†Modify the scheduling of follow-up according to reliable information about past blood pressure measurements, other cardiovascular risk factors, or target organ disease.

‡Provide advice about lifestyle modifications.

From the Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure. (2003). *Hypertension*, 42(6), 1206–1252.

conditions requiring lifetime management. An estimated 50% of patients discontinue their medications within 1 year of beginning to take them. Blood pressure control is achieved by only 37% (Chobanian, et al., 2003; Ong, et al., 2007). Compliance increases, however, when patients actively participate in self-care, including self-monitoring of blood pressure and diet, possibly because patients receive immediate feedback and have a greater sense of control.

Patients with hypertension must make considerable effort to adhere to recommended lifestyle modifications and to take regularly prescribed medications. The effort needed to follow the therapeutic plan may seem unreasonable to some, particularly when they have no symptoms without medications but do have side effects with medications. The recommended lifestyle changes are listed in Table 32-2. Continued education and encouragement are usually needed to enable patients to formulate an acceptable plan that helps them live with their hypertension and adhere to the treatment plan. Compromises may have to be made about some aspects of therapy to achieve higher-priority goals.

The nurse can assist with behavior change by supporting patients in making small changes with each visit that move them toward their goals. Another important factor is following up at each visit to see how the patient has progressed with the plans made at the prior visit. If the patient has had difficulty with a particular aspect of the plan, the patient and nurse can work together to develop an alternative or modification to the plan that the patient believes will be more successful.

Monitoring and Managing Potential Complications

Symptoms suggesting that hypertension is progressing to the extent that target organ damage is occurring must be detected early so that appropriate treatment can be initiated. When the patient returns for follow-up care, all body systems must be assessed to detect any evidence of vascular damage. An eye examination with an ophthalmoscope is particularly important because retinal blood vessel damage indicates similar damage elsewhere in the vascular system. The patient is questioned about blurred vision, spots in front of the eyes, and diminished visual acuity. The heart, nervous system, and kidneys are also carefully assessed. Any significant findings are promptly reported to determine whether additional diagnostic studies are required. Based on the findings, medications may be changed to improve blood pressure control.

Evaluation

Expected Patient Outcomes

- Maintains adequate tissue perfusion:
 - Maintains blood pressure at less than 140/90 mm Hg (or less than 130/80 mm Hg for people with diabetes mellitus or chronic kidney disease) with lifestyle modifications, medications, or both
 - Demonstrates no symptoms of angina, palpitations, or vision changes
 - Has stable BUN and serum creatinine levels
 - Has palpable peripheral pulses
- Complies with the self-care program:
 - Adheres to the dietary regimen as prescribed: reduces calorie, sodium, and fat intake; increases fruit and vegetable intake
 - Exercises regularly
 - Takes medications as prescribed and reports any side effects
 - Measures blood pressure routinely
 - Abstains from tobacco and excessive alcohol intake
 - Keeps follow-up appointments
- Has no complications:
 - Reports no changes in vision
 - Exhibits no retinal damage on vision testing
 - Maintains pulse rate and rhythm and respiratory rate within normal ranges
 - Reports no dyspnea or edema
 - Maintains urine output consistent with intake
 - Has renal function test results within normal range
 - Demonstrates no motor, speech, or sensory deficits
 - Reports no headaches, dizziness, weakness, changes in gait, or falls

Hypertensive Crises

JNC 7 describes two classes of hypertensive crisis that require immediate intervention: hypertensive emergency and hypertensive urgency (Chobanian, et al., 2003). Hypertensive emergencies and urgencies may occur in patients whose hypertension has been poorly controlled, whose hypertension

has been undiagnosed, or in those who have abruptly discontinued their medications. Once the hypertensive crisis has been managed, a complete evaluation is performed to review the patient's ongoing treatment plan and strategies to minimize the occurrence of subsequent hypertensive crises. The current recommendations for management of both hypertensive emergencies and urgencies are based on expert opinions because there are not clinical trial data comparing treatment options or identifying the impact of treatment on morbidity and mortality (Flanigan & Vitberg, 2006).

A **hypertensive emergency** is a situation in which blood pressure is extremely elevated (more than 180/120 mm Hg) and must be lowered immediately (not necessarily to less than 140/90 mm Hg) to halt or prevent damage to the target organs (Chobanian, et al., 2003; Haas & Marik, 2006). Assessment will reveal actual or developing clinical dysfunction of the target organ. Conditions associated with a hypertensive emergency include hypertension of pregnancy, acute myocardial infarction, dissecting aortic aneurysm, and intracranial hemorrhage. Hypertensive emergencies are acute, life-threatening blood pressure elevations that require prompt treatment in an intensive care setting because of the serious target organ damage that may occur. The therapeutic goals are reduction of the mean blood pressure by up to 25% within the first hour of treatment, a further reduction to a goal pressure of about 160/100 mm Hg over a period of up to 6 hours, and then a more gradual reduction in pressure over a period of days. The exceptions to these goals are the treatment of ischemic stroke (in which there is no evidence of benefit from immediate pressure reduction) and treatment of aortic dissection (in which the goal is to lower systolic pressure to less than 100 mm Hg if the patient can tolerate the reduction) (Chobanian, et al., 2003).

The medications of choice in hypertensive emergencies are those that have an immediate effect. Intravenous vasodilators, including sodium nitroprusside (Nitropress), nicardipine hydrochloride (Cardene), fenoldopam mesylate (Corlopam), enalaprilat, and nitroglycerin have immediate actions that are short lived (minutes to 4 hours), and they are therefore used for initial treatment. For more information about these medications, see Table 32-4. Experts also recommend assessing the individual's fluid volume status. If there is volume depletion secondary to natriuresis caused by the elevated blood pressure, then volume replacement with normal saline can prevent large sudden drops in blood pressure when antihypertensive medications are administered (Haas & Marik, 2006).

A **hypertensive urgency** describes a situation in which blood pressure is very elevated but there is no evidence of impending or progressive target organ damage (Chobanian, et al., 2003). Elevated blood pressures associated with severe headaches, nosebleeds, or anxiety are classified as urgencies. In these situations oral agents can be administered with the goal of normalizing blood pressure within 24 to 48 hours (Haas & Marik, 2006). Oral doses of fast-acting agents such as beta-adrenergic blocking agents (eg, labetalol [Trandate]), ACE inhibitors (eg, captopril [Capoten]), or alpha₂-agonists (eg, clonidine [Catapres]) are recommended for the treatment of hypertensive urgencies (see Table 32-4).

Extremely close hemodynamic monitoring of the patient's blood pressure and cardiovascular status is required during treatment of hypertensive emergencies and urgencies (see Chapter 26). The exact frequency of monitoring is a matter of clinical judgment and varies with the patient's condition. Taking vital signs every 5 minutes is appropriate if the blood pressure is changing rapidly; taking vital signs at 15- or 30-minute intervals in a more stable situation may be sufficient. A precipitous drop in blood pressure can occur that would require immediate action to restore blood pressure to an acceptable level.

CRITICAL THINKING EXERCISES

EBP 1 You are working as the admitting nurse in a hospital hypertension clinic. One of the patients today is an 88-year-old woman who has come in with her daughter. When you take her blood pressure you note that it is 210/158 mm Hg. As you talk with both the mother and daughter you find that the mother has not been taking her medications. She tells you that she thinks that at her age, high blood pressure is not that much of a problem. Her daughter is a nurse and is concerned about her mother. What is the evidence base that indicates that untreated hypertension can cause disability and death in people over the age of 80? What other information do you plan to gather from this patient and her daughter? What plan of action might you initiate?

EBP 2 Your nursing class is participating at a workplace health fair by taking blood pressures. The blood pressure of one young man, aged 32, is 128/88 mm Hg. What classification would be given to his blood pressure according to the JNC 7 recommendations? What further assessment would you do? What lifestyle factors would you discuss with him? Discuss the evidence that supports specific strategies aimed at preventing hypertension and how you would approach a discussion of possible changes he might want to make.

chapter 33

Assessment and Management of Patients With Hematologic Disorders

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

- 1 Describe the process of hematopoiesis.
- 2 Describe the processes involved in maintaining hemostasis.
- 3 Differentiate between the hypoproliferative and the hemolytic anemias and compare and contrast the physiologic mechanisms, clinical manifestations, medical management, and nursing interventions for each.
- 4 Use the nursing process as a framework for care of patients with anemia.
- 5 Compare the leukemias in terms of their incidence, physiologic alterations, clinical manifestations, management, and prognosis.
- 6 Use the nursing process as a framework for care of patients with acute leukemia.
- 7 Use the nursing process as a framework for care of patients with lymphoma or multiple myeloma.
- 8 Use the nursing process as a framework for care of patients with bleeding or thrombotic disorders.
- 9 Identify therapies for blood disorders, including the nursing implications for the administration of blood components.

GLOSSARY

absolute neutrophil count: a calculation of the number of circulating neutrophils, derived from the total white blood cells (WBCs) and the percentage of neutrophils counted in a microscope's visual field

anemia: decreased red blood cell (RBC) count

anergy: diminished reactivity to antigens (transient or complete)

angiogenesis: formation of new blood vessels

angular cheilosis: cracking sore at corner of mouth

aplasia: lack of cellular development (eg, of cells within the bone marrow)

band cell: slightly immature neutrophil

blast cell: primitive WBC

cytokines: hormones produced by leukocytes that are vital to regulation of hematopoiesis, apoptosis, and immune responses

D-dimer: test to measure fibrin breakdown; considered more specific than fibrin degradation products in the diagnosis of disseminated intravascular coagulation

differentiation: development of functions and characteristics that are different from those of the parent stem cell

erythrocyte: see red blood cell

erythrocyte sedimentation rate: laboratory test that measures the rate of settling of RBCs; elevation is indicative of inflammation; also called the "sed rate"

erythroid cells: any cell that is or will become a mature RBC

erythropoiesis: process of formation of RBCs

erythropoietin: hormone produced primarily by the kidney; necessary for erythropoiesis

fibrin: filamentous protein; basis of thrombus and blood clot

fibrinogen: protein converted into fibrin to form thrombus and clot

fibrinolysis: process of breakdown of fibrin clot

granulocyte: granulated WBC (neutrophil, eosinophil, basophil); sometimes used synonymously with neutrophil

haptoglobin: blood protein synthesized by liver; binds free hemoglobin released from erythrocytes, which is then removed by the reticuloendothelial system

GLOSSARY (Continued)

hematocrit: percentage of total blood volume consisting of RBCs

hematopoiesis: complex process of the formation and maturation of blood cells

hemoglobin: iron-containing protein of RBCs; delivers oxygen to tissues

hemolysis: destruction of RBCs; can occur within or outside of the vasculature

hemosiderin: iron-containing pigment derived from breakdown of hemoglobin

hemostasis: intricate balance between clot formation and clot dissolution

histiocytes: cells present in all loose connective tissue, capable of phagocytosis

hypochromia: pallor within the RBC caused by decreased hemoglobin content

left shift, or shift to the left: increased release of immature forms of WBCs from the bone marrow in response to need

leukocyte: see white blood cell

leukemia: uncontrolled proliferation of WBCs, often immature

leukopenia: less-than-normal amount of WBCs in circulation

lymphocyte: form of WBC involved in immune functions

lymphoid: pertaining to lymphocytes

lysis: destruction of cells

macrophage: reticuloendothelial cells capable of phagocytosis

microcytosis: smaller-than-normal RBCs

monocyte: large WBC that becomes a macrophage when it leaves the circulation and moves into body tissues

myeloid: pertaining to nonlymphoid blood cells that differentiate into RBCs, platelets, macrophages, mast cells, and various WBCs

myelopoiesis: formation and maturation of cells derived from myeloid stem cell

neutropenia: lower-than-normal number of neutrophils

neutrophil: fully mature WBC capable of phagocytosis; primary defense against bacterial infection

normochromic: normal RBC color, indicating normal amount of hemoglobin

normocytic: normal size of RBC

nucleated RBC: immature form of RBC; portion of nucleus remains within the RBC

oxyhemoglobin: combined form of oxygen and hemoglobin; found in arterial blood

pancytopenia: abnormal decrease in WBCs, RBCs, and platelets

petechiae: tiny capillary hemorrhages

phagocytosis: process of cellular ingestion and digestion of foreign bodies

plasma: liquid portion of blood

plasminogen: protein converted to plasmin to dissolve thrombi and clots

platelet: thrombocyte; a cellular component of blood involved in blood coagulation

poikilocytosis: variation in shape of RBCs

polycythemia: excess RBCs

red blood cell (RBC): erythrocyte; a cellular component of blood involved in the transport of oxygen and carbon dioxide

reticulocytes: slightly immature RBCs, usually only 1% of total circulating RBCs

reticuloendothelial system: complex system of cells throughout body capable of phagocytosis

serum: portion of blood remaining after coagulation occurs

stem cell: primitive cell, capable of self-replication and differentiation into myeloid or lymphoid stem cell

thrombin: enzyme necessary to convert fibrinogen into fibrin clot

thrombocyte: see platelet

thrombocytopenia: lower-than-normal platelet count

thrombocytosis: higher-than-normal platelet count

white blood cell (WBC): leukocyte; one of several cellular components of blood involved in defense of the body; subtypes include neutrophils, eosinophils, basophils, monocytes, and lymphocytes

Unlike many other body systems, the hematologic system encompasses the entire human body. Patients with hematologic disorders often have significant abnormalities in blood tests but few or no symptoms. Therefore, the nurse must have a good understanding of the pathophysiology of the patient's condition and the ability to make a thorough assessment that relies heavily on the interpretation of laboratory tests. It is equally important for the nurse to anticipate potential patient needs and to target nursing interventions accordingly. Because it is so important to the understanding of most hematologic diseases, a basic appreciation of blood cells and bone marrow function is necessary.

HEMATOLOGIC ASSESSMENT

Anatomic and Physiologic Overview

The hematologic system consists of the blood and the sites where blood is produced, including the bone marrow and the **reticuloendothelial system (RES)**. Blood is a specialized organ that differs from other organs in that it exists in a fluid state. Blood is composed of plasma and various types of cells. **Plasma** is the fluid portion of blood; it contains various proteins, such as albumin, globulin, **fibrinogen**, and other factors necessary for clotting, as well as electrolytes, waste products, and nutrients. About 55% of blood volume is plasma.

Blood

The cellular component of blood consists of three primary cell types (Table 33-1): **erythrocytes (red blood cells [RBCs], red cells)**, **leukocytes (white blood cells [WBCs])**, and **thrombocytes (platelets)**. These cellular components

of blood normally make up 40% to 45% of the blood volume. Because most blood cells have a short lifespan, the need for the body to replenish its supply of cells is continuous; this process is termed **hematopoiesis**. The primary site for hematopoiesis is the bone marrow. During embryonic development and in other conditions, the liver and spleen may also be involved.

Under normal conditions, the adult bone marrow produces about 175 billion erythrocytes, 70 billion **neutrophils** (a mature type of WBC), and 175 billion platelets each day. When the body needs more blood cells, as in infection (when neutrophils are needed to fight the invading pathogen) or in bleeding (when more RBCs are required), the marrow increases its production of the cells required. Thus, under normal conditions, the marrow responds to increased demand and releases adequate numbers of cells into the circulation.

Blood makes up approximately 7% to 10% of the normal body weight and amounts to 5 to 6 L of volume. Circulating through the vascular system and serving as a link between body organs, blood carries oxygen absorbed from the lungs and nutrients absorbed from the gastrointestinal (GI) tract to the body cells for cellular metabolism. Blood also carries hormones, antibodies, and other substances to their sites of action or use. In addition, blood carries waste products produced by cellular metabolism to the lungs, skin, liver, and kidneys, where they are transformed and eliminated from the body.

The danger that trauma can lead to excess blood loss always exists. To prevent this, an intricate clotting mechanism is activated when necessary to seal any leak in the blood vessels. Excessive clotting is equally dangerous, because it can obstruct blood flow to vital tissues. To prevent this, the body has a fibrinolytic mechanism that eventually dissolves clots (thrombi) formed within blood vessels. The balance between these two systems, clot (thrombus) formation and clot dissolution or **fibrinolysis**, is called **hemostasis**.

Bone Marrow

The bone marrow is the site of hematopoiesis, or blood cell formation (Fig. 33-1). In adults, blood cell formation is usually limited to the pelvis, ribs, vertebrae, and sternum. Marrow is one of the largest organs of the body, making up 4% to 5% of total body weight. It consists of islands of cellular components (red marrow) separated by fat (yellow marrow). As people age, the proportion of active marrow is gradually replaced by fat; however, in healthy adults, the fat can again be replaced by active marrow when more blood cell production is required. In adults with disease that causes marrow destruction, fibrosis, or scarring, the liver and spleen can also resume production of blood cells by a process known as extramedullary hematopoiesis.

The marrow is highly vascular. Within it are primitive cells called **stem cells**. The stem cells have the ability to self-replicate, thereby ensuring a continuous supply of stem cells throughout the life cycle. When stimulated to do so, stem cells can begin a process of **differentiation** into either **myeloid** or **lymphoid** stem cells. These stem cells are committed to produce specific types of blood cells. Lymphoid stem cells produce either T or B **lymphocytes**. Myeloid stem cells differentiate into three broad cell types: erythrocytes,

Table 33-1 BLOOD CELLS

Cell Type	Major Function
WBC (Leukocyte)	Fights infection
Neutrophil	Essential in preventing or limiting bacterial infection via phagocytosis
Monocyte	Enters tissue as macrophage; highly phagocytic, especially against fungus; immune surveillance
Eosinophil	Involved in allergic reactions (neutralizes histamine); digests foreign proteins
Basophil	Contains histamine; integral part of hypersensitivity reactions
Lymphocyte	Integral component of immune system
T lymphocyte	Responsible for cell-mediated immunity; recognizes material as "foreign" (surveillance system)
B lymphocyte	Responsible for humoral immunity; many mature into plasma cells to form antibodies
Plasma cell	Secretes immunoglobulin (Ig, antibody); most mature form of B lymphocyte
RBC (Erythrocyte)	Carries hemoglobin to provide oxygen to tissues; average lifespan is 120 days
Platelet (Thrombocyte)	Fragment of megakaryocyte; provides basis for coagulation to occur; maintains hemostasis; average lifespan is 10 days

RBC, red blood cell; WBC, white blood cell.

Physiology ■ ■ ■ Pathophysiology

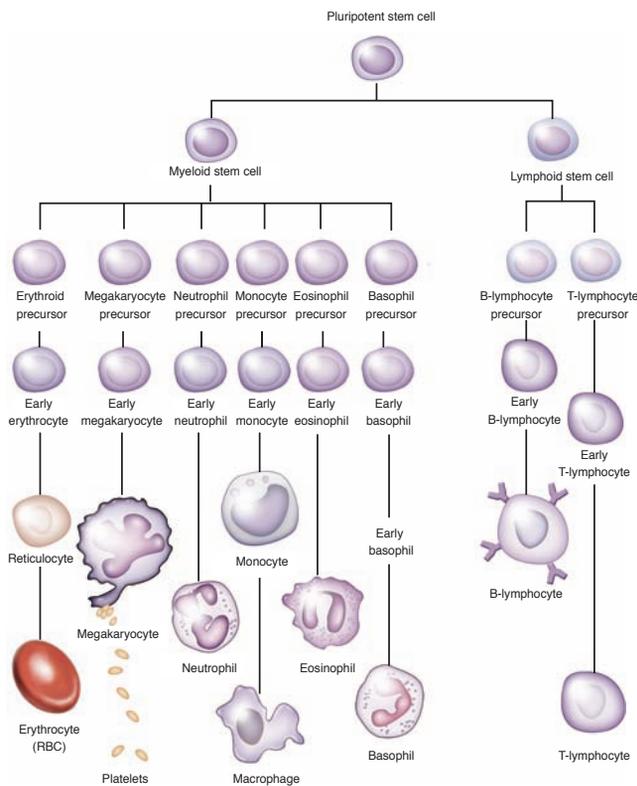

Figure 33-1 Hematopoiesis. Uncommitted (pluripotent) stem cells can differentiate into myeloid or lymphoid stem cells. These stem cells then undergo a complex process of differentiation and maturation into normal cells that are released into the circulation. The myeloid stem cell is responsible not only for all nonlymphoid white blood cells but also for the production of red blood cells (RBCs) and platelets. Each step of the differentiation process depends in part on the presence of specific growth factors for each cell type. When the stem cells are dysfunctional, they may respond inadequately to the need for more cells, or they may respond excessively, sometimes uncontrollably, as in leukemia.

leukocytes, and platelets. Thus, with the exception of lymphocytes, all blood cells are derived from myeloid stem cells. A defect in a myeloid stem cell can cause problems with erythrocyte, leukocyte, and platelet production.

Blood Cells

Erythrocytes (Red Blood Cells)

The normal erythrocyte is a biconcave disk that resembles a soft ball compressed between two fingers (Fig. 33-2). It has a diameter of about 8 μm and is so flexible that it can pass easily through capillaries that may be as small as 2.8 μm in diameter. The membrane of the red cell is very thin so that gases, such as oxygen and carbon dioxide, can easily diffuse across it; the disk shape provides a large surface area that facilitates the absorption and release of oxygen molecules.

Mature erythrocytes consist primarily of **hemoglobin**, which contains iron and makes up 95% of the cell mass. Mature erythrocytes have no nuclei, and they have many

fewer metabolic enzymes than do most other cells. The presence of a large amount of hemoglobin enables the red cell to perform its principal function, the transport of oxygen between the lungs and tissues. Occasionally the marrow releases slightly immature forms of erythrocytes, called **reticulocytes**, into the circulation. This occurs as a normal response to an increased demand for erythrocytes (as in bleeding) or in some disease states.

The oxygen-carrying hemoglobin molecule is made up of four subunits, each containing a heme portion attached to a globin chain. Iron is present in the heme component of the molecule. An important property of heme is its ability to bind to oxygen loosely and reversibly. Oxygen readily binds to hemoglobin in the lungs and is carried as **oxyhemoglobin** in arterial blood. Oxyhemoglobin is a brighter red than hemoglobin that does not contain oxygen (reduced hemoglobin); thus, arterial blood is a brighter red than venous blood. The oxygen readily dissociates (detaches) from hemoglobin in the tissues, where the oxygen is needed for cellular metabolism. In venous blood, hemoglobin combines with hydrogen ions produced by cellular metabolism and thus buffers excessive acid. Whole blood normally contains about 15 g of hemoglobin per 100 mL of blood.

Erythropoiesis

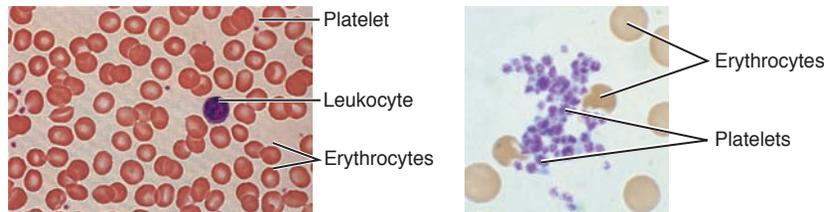

Erythroblasts arise from the primitive myeloid stem cells in bone marrow. The erythroblast is an immature nucleated cell that gradually loses its nucleus. At this stage, the cell is known as a reticulocyte. Further maturation into an erythrocyte entails the loss of the dark-staining material within the cell and slight shrinkage. The mature erythrocyte is then released into the circulation. Under conditions of rapid **erythropoiesis** (ie, erythrocyte production), reticulocytes and other immature cells (eg, **nucleated RBCs**) may be released prematurely into the circulation. This is often seen when the liver or spleen takes over as the site of erythropoiesis and more nucleated red cells appear within the circulation.

Differentiation of the primitive myeloid stem cell into an erythroblast is stimulated by **erythropoietin**, a hormone produced primarily by the kidney. If the kidney detects low levels of oxygen, as occurs when fewer red cells are available to bind oxygen (ie, **anemia**), or with people living at high altitudes with lower atmospheric oxygen concentrations, erythropoietin levels increase. The increased erythropoietin then stimulates the marrow to increase production of erythrocytes. The entire process of erythropoiesis typically takes 5 days.

For normal erythrocyte production, the bone marrow also requires iron, vitamin B₁₂, folic acid, pyridoxine (vitamin B₆), protein, and other factors. A deficiency of these factors during erythropoiesis can result in decreased red cell production and anemia.

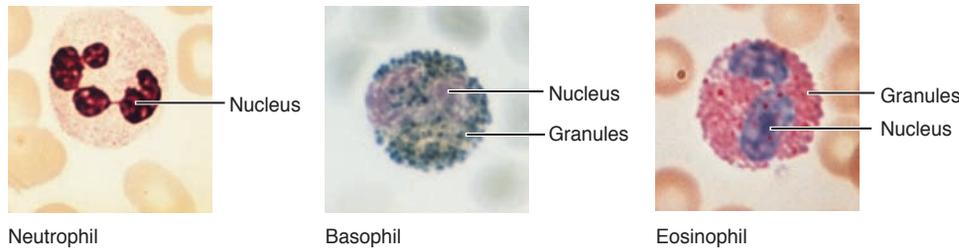

Iron Stores and Metabolism. The average daily diet in the United States contains 10 to 15 mg of elemental iron, but only 0.5 to 1 mg of ingested iron is normally absorbed from the small intestine. The rate of iron absorption is regulated by the amount of iron already stored in the body and by the rate of erythrocyte production. Additional amounts of iron, up to 2 mg daily, must be absorbed by women of childbearing age

to replace that lost during menstruation. Total body iron content in the average adult is approximately 3 g, most of which is present in hemoglobin or in one of its breakdown products. Iron is stored as ferritin and when required, the iron is released into the plasma, binds to transferrin, and is transported into the membranes of the normoblasts (erythrocyte precursor cells) within the marrow, where it is incorporated into hemoglobin. Iron is lost in the feces, either in bile, blood, or mucosal cells from the intestine.

The concentration of iron in blood is normally about 75 to 175 $\mu\text{g}/\text{dL}$ (13 to 31 $\mu\text{mol}/\text{L}$) for men and 65 to 165 $\mu\text{g}/\text{dL}$ (11 to 29 $\mu\text{mol}/\text{L}$) for women. With iron deficiency, bone marrow iron stores are rapidly depleted; hemoglobin synthesis is depressed, and the erythrocytes produced by the marrow are small and low in hemoglobin. Iron deficiency in the adult generally indicates blood loss (eg, from bleeding in the GI tract or heavy menstrual flow). Lack of dietary iron is rarely the sole cause of iron deficiency anemia in adults. The source of iron deficiency should be investigated promptly, because iron deficiency in an adult may be a sign of bleeding in the GI tract or colon cancer.

Vitamin B₁₂ and Folic Acid Metabolism. Vitamin B₁₂ and folic acid are required for the synthesis of deoxyribonucleic acid (DNA) in RBCs. Both vitamin B₁₂ and folic acid are derived from the diet. Folic acid is absorbed in the proximal small intestine, but only small amounts are stored within the body. If the diet is deficient in folic acid, stores within

the body quickly become depleted. Because vitamin B₁₂ is found only in foods of animal origin, strict vegetarians may ingest little vitamin B₁₂. Vitamin B₁₂ combines with intrinsic factor produced in the stomach. The vitamin B₁₂–intrinsic factor complex is absorbed in the distal ileum. People who have had a partial or total gastrectomy may have limited amounts of intrinsic factor, and therefore the absorption of vitamin B₁₂ may be diminished. The effects of either decreased absorption or decreased intake of vitamin B₁₂ are not apparent for 2 to 4 years.

Vitamin B₁₂ and folic acid deficiencies are characterized by the production of abnormally large erythrocytes called megaloblasts. Because these cells are abnormal, many are sequestered (trapped) while still in the bone marrow, and their rate of release is decreased. Some of these cells actually die in the marrow before they can be released into the circulation. This results in megaloblastic anemia.

Red Blood Cell Destruction

The average lifespan of a normal circulating erythrocyte is 120 days. Aged erythrocytes lose their elasticity and become trapped in small blood vessels and the spleen. They are removed from the blood by the reticuloendothelial cells, particularly in the liver and the spleen. As the erythrocytes are destroyed, most of their hemoglobin is recycled. Some hemoglobin also breaks down to form bilirubin and is secreted in the bile. Most of the iron is recycled to form new hemoglobin molecules within the bone marrow; small amounts

are lost daily in the feces and urine and monthly in menstrual flow.

Leukocytes (White Blood Cells)

Leukocytes are divided into two general categories: granulocytes and lymphocytes. In normal blood, the total leukocyte count is 4000 to 11,000 cells/mm³. Of these, approximately 60% to 80% are granulocytes and 20% to 40% are lymphocytes. Both of these types of leukocytes primarily protect the body against infection and tissue injury.

Granulocytes

Granulocytes are defined by the presence of granules in the cytoplasm of the cell. Granulocytes are divided into three main subgroups, which are characterized by the staining properties of these granules (see Fig. 33-2). Eosinophils have bright-red granules in their cytoplasm, whereas the granules in basophils stain deep blue. The third and most numerous cell in this class is the neutrophil, with granules that stain a pink to violet hue. Neutrophils are also called polymorphonuclear neutrophils (PMNs, or polys) or segmented neutrophils (segs).

The nucleus of the mature neutrophil has multiple lobes (usually two to five) that are connected by thin filaments of nuclear material, or a “segmented” nucleus; it is usually twice the size of an erythrocyte. The somewhat less mature granulocyte has a single-lobed, elongated nucleus and is called a **band cell**. Ordinarily, band cells account for only a small percentage of circulating granulocytes, although their percentage can increase greatly under conditions in which neutrophil production increases, such as infection. An increased number of band cells is sometimes called a **left shift** or **shift to the left**. (Traditionally, the diagram of neutrophil maturation showed the myeloid stem cell on the left with progressive maturation stages toward the right, ending with a fully mature neutrophil on the far right side. A shift to the left indicates that more immature cells are present in the blood than normal.)

Fully mature neutrophils result from the gradual differentiation of myeloid stem cells, specifically myeloid **blast cells**. The process, called **myelopoiesis**, is highly complex and depends on many factors. These factors, including specific **cytokines** such as growth factors, are normally present within the marrow itself. As the blast cell matures, the cytoplasm of the cell changes in color (from blue to violet) and granules begin to form with the cytoplasm. The shape of the nucleus also changes. The entire process of maturation and differentiation takes about 10 days (see Fig. 33-1). Once the neutrophil is released into the circulation from the marrow, it stays there for only about 6 hours before it migrates into the body tissues to perform its function of **phagocytosis** (ingestion and digestion of bacteria and particles). Neutrophils die here within 1 to 2 days. The number of circulating granulocytes found in the healthy person is relatively constant, but in infection large numbers of these cells are rapidly released into the circulation.

Agranulocytes

Monocytes. **Monocytes** (also called mononuclear leukocytes) are leukocytes with a single-lobed nucleus and a granule-free cytoplasm—hence the term *agranulocyte* (see Fig. 33-2). In normal adult blood, monocytes account for

approximately 5% of the total leukocytes. Monocytes are the largest of the leukocytes. Produced by the bone marrow, they remain in the circulation for a short time before entering the tissues and transforming into **macrophages**. Macrophages are particularly active in the spleen, liver, peritoneum, and alveoli; they remove debris from these areas and phagocytize bacteria within the tissues.

Lymphocytes. Mature lymphocytes are small cells with scanty cytoplasm (see Fig. 33-2). Immature lymphocytes are produced in the marrow from the lymphoid stem cells. A second major source of production is the thymus. Cells derived from the thymus are known as T lymphocytes (or T cells); those derived from the marrow can also be T cells but are more commonly B lymphocytes (or B cells). Lymphocytes complete their differentiation and maturation primarily in the lymph nodes and in the lymphoid tissue of the intestine and spleen after exposure to a specific antigen. Mature lymphocytes are the principal cells of the immune system, producing antibodies and identifying other cells and organisms as “foreign.”

Function of Leukocytes

Leukocytes protect the body from invasion by bacteria and other foreign entities. The major function of neutrophils is phagocytosis. Neutrophils arrive at a given site within 1 hour after the onset of an inflammatory reaction and initiate phagocytosis, but they are short-lived. An influx of monocytes follows; these cells continue their phagocytic activities for long periods as macrophages. This process constitutes a second line of defense for the body against inflammation and infection. Although neutrophils can often work adequately against bacteria without the help of macrophages, macrophages are particularly effective against fungi and viruses. Macrophages also digest senescent (aging or aged) blood cells, primarily within the spleen.

The primary function of lymphocytes is to attack foreign material. One group of lymphocytes (T lymphocytes) kills foreign cells directly or releases lymphokines, substances that enhance the activity of phagocytic cells. T lymphocytes are responsible for delayed allergic reactions, rejection of foreign tissue (eg, transplanted organs), and destruction of tumor cells. This process is known as *cellular immunity*. The other group of lymphocytes (B lymphocytes) is capable of differentiating into plasma cells. Plasma cells, in turn, produce antibodies called immunoglobulins (Ig), which are protein molecules that destroy foreign material by several mechanisms. This process is known as *humoral immunity*.

Eosinophils and basophils function in hypersensitivity reactions. Eosinophils are important in the phagocytosis of parasites. The increase in eosinophil levels in allergic states indicates that these cells are involved in the hypersensitivity reaction; they neutralize histamine. Basophils produce and store histamine as well as other substances involved in hypersensitivity reactions. The release of these substances provokes allergic reactions.

Platelets (Thrombocytes)

Platelets, or thrombocytes, are not technically cells; rather, they are granular fragments of giant cells in the bone marrow called megakaryocytes (see Fig. 33-2). Platelet production in

the marrow is regulated in part by the hormone thrombopoietin, which stimulates the production and differentiation of megakaryocytes from the myeloid stem cell.

Platelets play an essential role in the control of bleeding. They circulate freely in the blood in an inactive state, where they nurture the endothelium of the blood vessels, maintaining the integrity of the vessel. When vascular injury occurs, platelets collect at the site and are activated. They adhere to the site of injury and to each other, forming a platelet plug that temporarily stops bleeding. Substances released from platelet granules activate coagulation factors in the blood plasma and initiate the formation of a stable clot composed of **fibrin**, a filamentous protein. Platelets have a normal lifespan of 7 to 10 days.

Plasma and Plasma Proteins

After cellular elements are removed from blood, the remaining liquid portion is called plasma. More than 90% of plasma is water. The remainder consists primarily of plasma proteins, clotting factors (particularly fibrinogen), and small amounts of other substances such as nutrients, enzymes, waste products, and gases. If plasma is allowed to clot, the remaining fluid is called **serum**. Serum has essentially the same composition as plasma, except that fibrinogen and several clotting factors have been removed during the clotting process.

Plasma proteins consist primarily of albumin and the globulins. The globulins can be separated into three main fractions (alpha, beta, and gamma), each of which consists of distinct proteins that have different functions. Important proteins in the alpha and beta fractions are the transport globulins and the clotting factors that are made in the liver. The transport globulins carry various substances in bound form in the circulation. For example, thyroid-binding globulin carries thyroxin, and transferrin carries iron. The clotting factors, including fibrinogen, remain in an inactive form in the blood plasma until activated by the clotting cascade. The gamma-globulin fraction refers to the immunoglobulins, or antibodies. These proteins are produced by well-differentiated B lymphocytes and plasma cells. The actual fractionation of the globulins can be seen on a specific laboratory test (serum protein electrophoresis).

Albumin is particularly important for the maintenance of fluid balance within the vascular system. Capillary walls are impermeable to albumin, so its presence in the plasma creates an osmotic force that keeps fluid within the vascular space. Albumin, which is produced by the liver, has the capacity to bind to several substances that are transported in plasma (eg, certain medications, bilirubin, some hormones). People with impaired hepatic function may have low concentrations of albumin, with a resultant decrease in osmotic pressure and the development of edema.

Reticuloendothelial System

The RES is composed of special tissue macrophages. When released from the marrow, monocytes spend a short time in the circulation (about 24 hours) and then enter the body tissues. Within the tissues, the monocytes continue to differentiate into macrophages, which can survive for months or years. Macrophages have a variety of important functions. They defend the body against foreign invaders (ie,

bacteria and other pathogens) via phagocytosis. They remove old or damaged cells from the circulation. They stimulate the inflammatory process and present antigens to the immune system (see Chapter 50). Macrophages give rise to tissue **histiocytes**, including Kupffer cells of the liver, peritoneal macrophages, alveolar macrophages, and other components of the RES. Thus, the RES is a component of many other organs within the body, particularly the spleen, lymph nodes, lungs, and liver.

The spleen is the site of activity for most macrophages. Most of the spleen (75%) is made of red pulp; here the blood enters the venous sinuses through capillaries that are surrounded by macrophages. Within the red pulp are tiny aggregates of white pulp, consisting of B and T lymphocytes. The spleen sequesters newly released reticulocytes from the marrow, removing nuclear fragments and other materials (eg, denatured hemoglobin, iron) before the now fully mature erythrocyte returns to the circulation. Although a minority of erythrocytes (less than 5%) pool in the spleen, a significant proportion of platelets (20% to 40%) pool here. If the spleen is enlarged, a greater proportion of red cells and platelets can be sequestered. The spleen is a major source of hematopoiesis in fetal life. It can resume hematopoiesis later in adulthood if necessary, particularly when marrow function is compromised (eg, in bone marrow fibrosis). The spleen has important immunologic functions as well. It forms substances called opsonins that promote the phagocytosis of neutrophils; it also forms the antibody immunoglobulin M (IgM) after exposure to an antigen.

Hemostasis

Hemostasis is the process of preventing blood loss from intact vessels and of stopping bleeding from a severed vessel, which requires adequate numbers of functional platelets. Platelets nurture the endothelium and thereby maintain the structural integrity of the vessel wall. Two processes are involved in arresting bleeding: primary and secondary hemostasis (Fig. 33-3).

In primary hemostasis, the severed blood vessel constricts. Circulating platelets aggregate at the site and adhere to the vessel and to one another. An unstable hemostatic plug is formed. For the coagulation process to be correctly activated, circulating inactive coagulation factors must be converted to active forms. This process occurs on the surface of the aggregated platelets at the site of vessel injury. The end result is the formation of fibrin, which reinforces the platelet plug and anchors it to the injury site. This process is termed secondary hemostasis. The process of blood coagulation is highly complex. It can be activated by the intrinsic or the extrinsic pathway. Both pathways are needed for maintenance of normal hemostasis.

Many factors are involved in the reaction cascade that forms fibrin. When tissue is injured, the extrinsic pathway is activated by the release of thromboplastin from the tissue. As the result of a series of reactions, prothrombin is converted to **thrombin**, which in turn catalyzes the conversion of fibrinogen to fibrin. Clotting by the intrinsic pathway is activated when the collagen that lines blood vessels is exposed. Clotting factors are activated sequentially until, as

Physiology ■ ■ ■ Pathophysiology

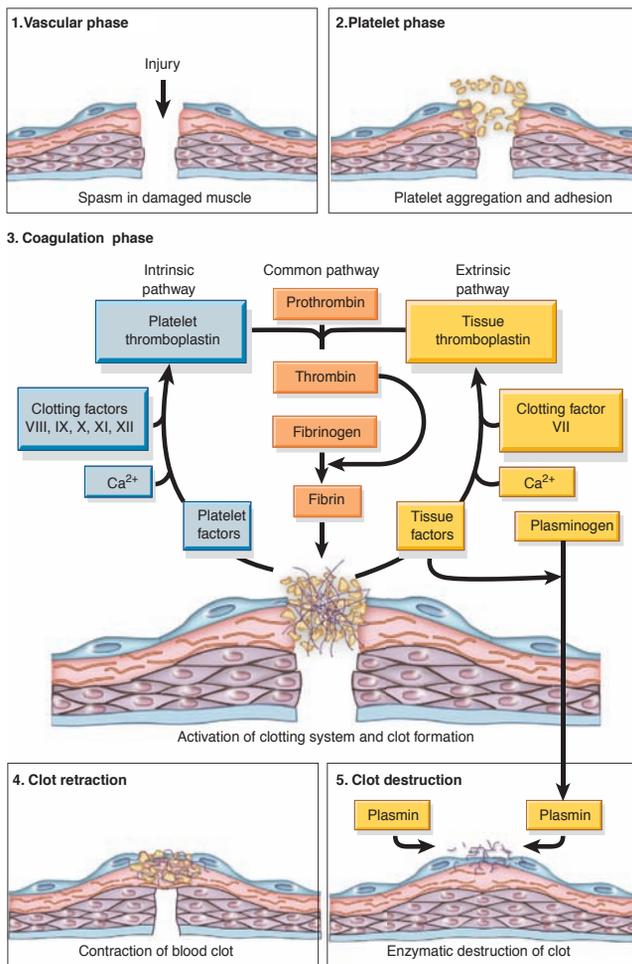

Figure 33-3 Hemostasis. When the endothelial surface of a blood vessel is injured, several processes occur. In primary hemostasis, platelets within the circulation are attracted to the exposed layer of collagen at the site of injury. They adhere to the site of injury, releasing factors that stimulate other platelets to aggregate at the site, forming an unstable platelet plug. In secondary hemostasis, based on the type of stimulus, one of two clotting pathways is initiated—the intrinsic or extrinsic pathway—and the clotting factors within that pathway are activated. The end result from either pathway is the conversion of prothrombin to thrombin. Thrombin is necessary for fibrinogen to be converted into fibrin, the stabilizing protein that anchors the fragile platelet plug to the site of injury to prevent further bleeding and permit the injuring vessel or site to heal. Modified from www.irvingcrowley.com/cls/clotting.gif.

with the extrinsic pathway, fibrin is ultimately formed. Although the intrinsic pathway is slower, this sequence is probably most often responsible for clotting *in vivo*.

As the injured vessel is repaired and again covered with endothelial cells, the fibrin clot is no longer needed. The fibrin is digested via two systems: the plasma fibrinolytic system and the cellular fibrinolytic system. The substance **plasminogen** is required to lyse (break down) the fibrin. Plasminogen, which is present in all body fluids, circulates with fibrinogen and is therefore incorporated into the fib-

rin clot as it forms. When the clot is no longer needed (eg, after an injured blood vessel has healed), the plasminogen is activated to form plasmin. Plasmin digests the fibrinogen and fibrin. The breakdown particles of the clot, called fibrin degradation products, are released into the circulation. Through this system, clots are dissolved as tissue is repaired, and the vascular system returns to its normal baseline state.

Gerontologic Considerations

In elderly patients, the bone marrow's ability to respond to the body's need for blood cells (erythrocytes, leukocytes, and platelets) may be decreased. This decreased ability is a result of many factors, including diminished production of the growth factors necessary for hematopoiesis by stromal cells within the marrow or a diminished response to the growth factors (in the case of erythropoietin). In addition, in elderly patients, the bone marrow may be more susceptible to the myelosuppressive effects of medications. As a result of these factors, when an elderly person needs more blood cells, the bone marrow may not be able to increase production of these cells adequately. **Leukopenia** (a decreased number of circulating leukocytes) or anemia can result.

Assessment and Diagnostic Evaluation

Most hematologic diseases reflect a defect in the hematopoietic, hemostatic, or reticuloendothelial system. The defect can be quantitative (eg, increased or decreased production of cells), qualitative (eg, the cells that are produced are defective in their normal functional capacity), or both. Initially, many hematologic conditions cause few symptoms. Therefore, extensive laboratory tests are often required to diagnose a hematologic disorder. For most hematologic conditions, continued monitoring via specific blood tests is required because it is very important to assess for changes in test results over time. In general, it is important to assess trends in test results because these trends help the clinician decide whether the patient is responding appropriately to interventions.

Hematologic Studies

The most common tests used are the complete blood count (CBC) and the peripheral blood smear (see Appendix A). The CBC identifies the total number of blood cells (leukocytes, erythrocytes, and platelets) as well as the hemoglobin, **hematocrit** (percentage of blood volume consisting of erythrocytes), and RBC indices. Because cellular morphology (shape and appearance of the cells) is particularly important in accurately diagnosing most hematologic disorders, the blood cells involved must be examined. This process is referred to as the manual examination of the peripheral smear, which may be part of the CBC. In this test, a drop of blood is spread on a glass slide, stained, and examined under a microscope. The shape and size of the erythrocytes and platelets, as well as the actual appearance of the leukocytes, provide useful information in identifying

hematologic conditions. Blood for the CBC is typically obtained by venipuncture.

Bone Marrow Aspiration and Biopsy

The bone marrow aspiration and biopsy are crucial when additional information is needed to assess how a person's blood cells are being formed and to assess the quantity and quality of each type of cell produced within the marrow. These tests are also used to document infection or tumor within the marrow.

Normal bone marrow is in a semifluid state and can be aspirated through a special large needle. In adults, bone marrow is usually aspirated from the iliac crest and occasionally from the sternum. The aspirate provides only a sample of cells. Aspirate alone may be adequate for evaluating certain conditions, such as anemia. However, when more information is required, a biopsy is also performed. Biopsy samples are taken from the posterior iliac crest; occasionally, an anterior approach is required. A marrow biopsy shows the architecture of the bone marrow as well as its degree of cellularity.

Most patients need no more preparation than a careful explanation of the procedure, but for some very anxious patients, an antianxiety agent may be useful. It is always important for the physician or nurse to describe and explain to the patient the procedure and the sensations that will be experienced. The risks, benefits, and alternatives are also discussed. A signed informed consent is needed before the procedure is performed.

Before aspiration, the skin is cleansed using aseptic technique. Then a small area is anesthetized with a local anesthetic agent through the skin and subcutaneous tissue to the periosteum of the bone. It is not possible to anesthetize the bone itself. The bone marrow needle is introduced with a stylet in place. When the needle is felt to go through the outer cortex of bone and enter the marrow cavity, the stylet is removed, a syringe is attached, and a small volume (5 mL) of blood and marrow is aspirated. Patients typically feel a pressure sensation as the needle is advanced into position. The actual aspiration always causes sharp but brief pain, resulting from the suction exerted as the marrow is aspirated into the syringe; the patient should be warned about this. Taking deep breaths or using relaxation techniques often helps ease the discomfort.

If a bone marrow biopsy is necessary, it is best performed after the aspiration and in a slightly different location, because the marrow structure may be altered after aspiration. A special biopsy needle is used. Because these needles are large, the skin may be punctured first with a surgical blade to make a 3- or 4-mm incision. The biopsy needle is advanced well into the marrow cavity. When the needle is properly positioned, a portion of marrow is cored out. The patient feels a pressure sensation but should not feel actual pain. The nurse should instruct the patient to inform the physician if pain occurs so that an additional anesthetic agent can be administered.

Hazards of either bone marrow aspiration or biopsy include bleeding and infection. The risk of bleeding is somewhat increased if the patient's platelet count is low or if the patient has been taking a medication (eg, aspirin) that alters platelet function. After the marrow sample is obtained,

pressure is applied to the site for several minutes. The site is then covered with a sterile dressing. Most patients have no discomfort after a bone marrow aspiration, but the site of a biopsy may ache for 1 or 2 days. Warm tub baths and a mild analgesic agent (eg, acetaminophen [Tylenol]) may be useful. Aspirin-containing analgesic agents should be avoided because they can aggravate or potentiate bleeding.

ANEMIA

Anemia is a condition in which the hemoglobin concentration is lower than normal; it reflects the presence of fewer than the normal number of erythrocytes within the circulation. As a result, the amount of oxygen delivered to body tissues is also diminished. Anemia is not a specific disease state but a sign of an underlying disorder. It is by far the most common hematologic condition.

Classification of Anemias

Anemia may be classified in several ways (Table 33-2). A physiologic approach classifies anemia according to whether the deficiency in erythrocytes is caused by a defect in their production (hypoproliferative anemia), by their destruction (hemolytic anemia), or by their loss (bleeding).

In hypoproliferative anemias, the marrow cannot produce adequate numbers of erythrocytes. Decreased erythrocyte production is reflected by an inappropriately normal or low reticulocyte count. Inadequate production of erythrocytes may result from marrow damage due to medications (eg, chloramphenicol) or chemicals (eg, benzene) or from a lack of factors (eg, iron, vitamin B₁₂, folic acid, erythropoietin) necessary for erythrocyte formation.

In hemolytic anemias, premature destruction of erythrocytes results in the liberation of hemoglobin from the erythrocytes into the plasma; the released hemoglobin is converted in large part to bilirubin and therefore, the bilirubin concentration rises. The increased erythrocyte destruction leads to tissue hypoxia, which in turn stimulates erythropoietin production. This increased production is reflected in an increased reticulocyte count as the bone marrow responds to the loss of erythrocytes. Hemolysis can result from an abnormality within the erythrocyte itself (eg, sickle cell anemia, glucose-6-phosphate dehydrogenase [G-6-PD] deficiency) or within the plasma (eg, immune hemolytic anemias), or from direct injury to the erythrocyte within the circulation (eg, hemolysis caused by mechanical heart valve). Chart 33-1 identifies causes of hemolytic anemia.

It is usually possible to determine whether the presence of anemia in a given patient is caused by destruction or by inadequate production of erythrocytes on the basis of the following factors:

- The marrow's ability to respond to decreased erythrocytes (as evidenced by an increased reticulocyte count in the circulating blood)
- The degree to which young erythrocytes proliferate in the bone marrow and the manner in which they mature (as observed on bone marrow biopsy)
- The presence or absence of end products of erythrocyte destruction within the circulation (eg, increased bilirubin level, decreased **haptoglobin** level)

Table 33-2 CLASSIFICATION OF ANEMIAS

Type of Anemia	Laboratory Findings
Hypoproliferative (Resulting From Defective RBC Production)	
Iron deficiency	Decreased reticulocytes, iron, ferritin, iron saturation, MCV; increased TIBC
Vitamin B ₁₂ deficiency (megaloblastic)	Decreased vitamin B ₁₂ level; increased MCV
Folate deficiency (megaloblastic)	Decreased folate level; increased MCV
Decreased erythropoietin production (eg, from renal dysfunction)	Decreased erythropoietin level; normal MCV and MCH; increased creatinine level (likely)
Cancer/inflammation	Normal MCV, MCH; normal or decreased erythropoietin level; increased % of iron saturation, ferritin level; decreased iron, TIBC
Bleeding (Resulting From RBC Loss)	
Bleeding from gastrointestinal tract, epistaxis (nosebleed), trauma, bleeding from genitourinary tract (eg, menorrhagia)	Increased reticulocyte level; normal Hgb and Hct if measured soon after bleeding starts, but levels decrease thereafter; normal MCV initially but later decreases; decreased ferritin and iron levels (later)
Hemolytic (Resulting From RBC Destruction)	
Altered erythropoiesis (sickle cell anemia, thalassemia, other hemoglobinopathies)	Decreased MCV; fragmented RBCs; increased reticulocyte level
Hypersplenism (hemolysis)	Increased MCV
Drug-induced anemia	Increased spherocyte level
Autoimmune anemia	Increased spherocyte level
Mechanical heart valve–related anemia	Fragmented red cells

Hct, hematocrit; Hgb, hemoglobin concentration; MCH, mean corpuscular hemoglobin; MCV, mean corpuscular volume; RBCs, red blood cells; TIBC, total iron-binding capacity.

Clinical Manifestations

Aside from the severity of the anemia itself, several factors influence the development of anemia-associated symptoms: the rapidity with which the anemia has developed, the duration of the anemia (ie, its chronicity), the metabolic requirements of the patient, other concurrent disorders or disabilities (eg, cardiac or pulmonary disease), and complications or concomitant features of the condition that produced the anemia.

In general, the more rapidly an anemia develops, the more severe its symptoms. An otherwise healthy person can often tolerate as much as a 50% gradual reduction in hemoglobin without pronounced symptoms or significant incapacity, whereas the rapid loss of as little as 30% may precipitate profound vascular collapse in the same person. A person who has become gradually anemic, with hemoglobin levels between 9 and 11 g/dL, usually has few or no symptoms other than slight tachycardia on exertion and fatigue.

People who customarily are very active or who have significant demands on their lives (eg, a single, working mother of small children) are more likely to have symptoms, and those symptoms are more likely to be pronounced than in more sedentary people. Patients with hypothyroidism with decreased oxygen needs may be completely asymptomatic, without tachycardia or increased cardiac output, at a hemoglobin level of 10 g/dL. Similarly, patients with coexistent cardiac, vascular, or pulmonary disease may develop more pronounced symptoms of anemia (eg, dyspnea, chest pain, muscle pain or cramping) at a higher hemoglobin level than those without these concurrent health problems.

Finally, some anemias are complicated by various other abnormalities that do not result from the anemia but are inherently associated with these particular diseases. These abnormalities may give rise to symptoms that completely overshadow those of the anemia, as in the painful crises of sickle cell anemia.

Chart 33-1 • Causes of Hemolytic Anemias

Inherited Hemolytic Anemia

- Abnormal hemoglobin
 - Sickle cell anemia*
 - Thalassemia*
- Red blood cell membrane abnormality
 - Hereditary spherocytosis*
 - Hereditary elliptocytosis
 - Acanthocytosis
 - Stomatocytosis
- Enzyme deficiencies
 - Glucose-6-phosphate dehydrogenase (G-6-PD) deficiency*

Acquired Hemolytic Anemia

- Antibody related
 - Iso-antibody/transfusion reaction*
 - Autoimmune hemolytic anemia (AIHA)*
 - Cold agglutinin disease
- Not antibody related
 - Red blood cell membrane defects
 - Paroxysmal nocturnal hemoglobinuria (PNH)
 - Liver disease
 - Uremia
 - Trauma
 - Mechanical heart valve
 - Microangiopathic hemolytic anemia
 - Infection
 - Bacterial
 - Parasitic
 - Disseminated intravascular coagulation (DIC)*
 - Toxins
 - Hypersplenism*

*Discussed in text.

Assessment and Diagnostic Findings

A variety of hematologic studies are performed to determine the type and cause of the anemia. In an initial evaluation, the hemoglobin, hematocrit, reticulocyte count, and RBC indices, particularly the mean corpuscular volume (MCV) and red cell distribution width (RDW), are particularly useful. Iron studies (serum iron level, total iron-binding capacity [TIBC], percent saturation, and ferritin), as well as serum vitamin B₁₂ and folate levels, are also frequently obtained. Other tests include haptoglobin and erythropoietin levels. The remaining CBC values are useful in determining whether the anemia is an isolated problem or part of another hematologic condition, such as leukemia or myelodysplastic syndrome (MDS). Bone marrow aspiration may be performed. In addition, other diagnostic studies may be performed to determine the presence of underlying chronic illness, such as malignancy, or the source of any blood loss, such as polyps or ulcers within the GI tract.

Complications

General complications of severe anemia include heart failure, paresthesias, and delirium. Patients with underlying heart disease are far more likely to have angina or symptoms of heart failure than those without heart disease. Complications associated with specific types of anemia are included in the description of each type.

Medical Management

Management of anemia is directed toward correcting or controlling the cause of the anemia; if the anemia is severe, the erythrocytes that are lost or destroyed may be replaced with a transfusion of packed red blood cells (PRBCs). The management of the various types of anemia is covered in the discussions that follow.

Gerontologic Considerations

Anemia is the most common hematologic condition affecting elderly patients. A systematic review has found that anemia affects 40% of elderly patients admitted to hospitals and 47% of elderly patients in long-term care facilities (Gaskell, Derry, Moore, et al., 2008). In the population at large, anemia occurs in 26% of men and 20% of women older than 85 years of age (Steensma & Tefferi, 2007). The impact of anemia on function is significant. A review among the elderly has noted that increased fragility, decreased mobility and exercise performance, increased risk of falling, diminished cognitive function, increased risk of developing dementia and major depression, and lower skeletal muscle and bone density are associated with anemia (Steensma & Tefferi, 2007).

NURSING PROCESS

THE PATIENT WITH ANEMIA

Assessment

The health history and physical examination provide important data about the type of anemia involved, the extent and type of symptoms it produces, and the impact of those symptoms on the patient's life. Weak-

ness, fatigue, and general malaise are common, as are pallor of the skin and mucous membranes (conjunctivae, oral mucosa).

Jaundice may be present in patients with megaloblastic anemia or hemolytic anemia. The tongue may be smooth and red (in iron deficiency anemia) or beefy red and sore (in megaloblastic anemia); the corners of the mouth may be ulcerated (**angular cheilosis**) in both types of anemia. People with iron deficiency anemia may crave ice, starch, or dirt; this craving is known as pica. The nails may be brittle, ridged, and concave.

The health history should include a medication history, because some medications can depress bone marrow activity, induce hemolysis, or interfere with folate metabolism. An accurate history of alcohol intake, including the amount and duration, should be obtained. Family history is important, because certain anemias are inherited. It is necessary to ask about athletic endeavors, because extreme exercise can decrease erythropoiesis and erythrocyte survival.

A nutritional assessment is important, because it may indicate deficiencies in essential nutrients such as iron, vitamin B₁₂, and folic acid. Children of indigent families may be at higher risk for anemia because of nutritional deficiencies. Strict vegetarians are also at risk for megaloblastic types of anemia if they do not supplement their diet with vitamin B₁₂. The elderly also may have a diminished intake of vitamin B₁₂ or folate.

Cardiac status should be carefully assessed. When the hemoglobin level is low, the heart attempts to compensate by pumping faster and harder in an effort to deliver more blood to hypoxic tissue. This increased cardiac workload can result in such symptoms as tachycardia, palpitations, dyspnea, dizziness, orthopnea, and exertional dyspnea. Heart failure may eventually develop, as evidenced by an enlarged heart (cardiomegaly) and liver (hepatomegaly) and by peripheral edema.

Assessment of the GI system may disclose complaints of nausea, vomiting (with specific questions about the appearance of any emesis [eg, looks like "coffee grounds"]), melena or dark stools, diarrhea, anorexia, and glossitis (inflammation of the tongue). Stools should be tested for occult blood. Women should be questioned about their menstrual periods (eg, excessive menstrual flow, other vaginal bleeding) and the use of iron supplements during pregnancy.

Neurologic examination is also important because pernicious anemia affects the central and peripheral nervous systems. Assessment should include the presence and extent of peripheral numbness and paresthesias, ataxia, poor coordination, and confusion. Delirium can sometimes result from other types of anemia, particularly in the elderly. Finally, it is important to monitor relevant laboratory test results and to note any changes over time.

Diagnosis

Nursing Diagnoses

Based on the assessment data, major nursing diagnoses for the patient with anemia may include:

- Fatigue related to decreased hemoglobin and diminished oxygen-carrying capacity of the blood

- Altered nutrition, less than body requirements, related to inadequate intake of essential nutrients
- Altered tissue perfusion related to inadequate hemoglobin and hematocrit
- Noncompliance with prescribed therapy

Collaborative Problems/Potential Complications

Based on the assessment data, potential complications that may develop include:

- Heart failure
- Angina
- Paresthesias
- Confusion

Planning and Goals

The major goals for the patient may include decreased fatigue, attainment or maintenance of adequate nutrition, maintenance of adequate tissue perfusion, compliance with prescribed therapy, and absence of complications.

Nursing Interventions

Managing Fatigue

The most common symptom and complication of anemia is fatigue. Fatigue is often the symptom that has the greatest negative impact on a patient's level of functioning and consequent quality of life. Therefore, it should not be minimized. Patients often describe the fatigue from anemia as oppressive. Fatigue can be significant, yet the anemia may not be severe enough to warrant transfusion. Fatigue can interfere with a person's ability to work and to participate in activities with family and friends. Patients often lose interest in hobbies and activities, including sexual activity. The distress from fatigue is often related to a person's responsibilities and life demands as well as the amount of assistance and support received from others.

Nursing interventions can focus on assisting the patient to prioritize activities and to establish a balance between activity and rest that is acceptable to the patient. Patients with chronic anemia need to maintain some physical activity and exercise to prevent the deconditioning that results from inactivity.

Maintaining Adequate Nutrition

Inadequate intake of essential nutrients, such as iron, vitamin B₁₂, folic acid, and protein, can cause some anemias. The symptoms associated with anemia (eg, fatigue, anorexia) can in turn interfere with maintaining adequate nutrition. A healthy diet should be encouraged. The nurse should inform the patient that alcohol interferes with the utilization of essential nutrients and should advise the patient to avoid or limit his or her intake of alcoholic beverages. Dietary teaching sessions should be individualized, involve family members, and include cultural aspects related to food preferences and food preparation. Dietary supplements (eg, vitamins, iron, folate, protein) may be prescribed.

Equally important, the patient and family must understand the role of nutritional supplements in the proper context, because many forms of anemia are not the result of a nutritional deficiency. In such cases, even an excessive in-

take of nutritional supplements will not improve the anemia. A potential problem in patients with chronic transfusion requirements occurs with the indiscriminate use of iron supplements. Unless an aggressive program of chelation therapy is implemented, these people are at risk for iron overload from their transfusions. The addition of an iron supplement only exacerbates the situation.

Maintaining Adequate Perfusion

Patients with acute blood loss or severe hemolysis may have decreased tissue perfusion from decreased blood volume or reduced circulating erythrocytes (decreased hematocrit). Lost volume is replaced with transfusions or intravenous (IV) fluids, based on symptoms and laboratory test results. Supplemental oxygen may be necessary, but it is rarely needed on a long-term basis unless there is underlying severe cardiac or pulmonary disease. The nurse monitors the patient's vital signs and pulse oximeter readings closely; other medications, such as antihypertensive agents, may need to be adjusted or withheld.

Promoting Compliance With Prescribed Therapy

For patients with anemia, medications or nutritional supplements are often prescribed to treat the condition. These patients need to understand the purpose of the medication, how to take the medication and over what time period, and how to manage any side effects of therapy. To enhance compliance, the nurse assists the patient to develop ways to incorporate the therapeutic plan into everyday activities, rather than merely giving the patient a list of instructions. For example, many patients have difficulty taking iron supplements because of related GI effects. Rather than seeking assistance from a health care provider in managing the problem, some patients simply stop taking the iron.

Abruptly stopping some medications can have serious consequences, as in the case of high-dose corticosteroids to manage hemolytic anemias. Some medications, such as growth factors, are extremely expensive. Patients receiving these medications may need assistance to obtain needed insurance coverage or to explore alternative ways to obtain these medications.

Monitoring and Managing Potential Complications

A significant complication of anemia is heart failure from chronic diminished blood volume and the heart's compensatory effort to increase cardiac output. Patients with anemia should be assessed for signs and symptoms of heart failure (see Chapter 30).

In megaloblastic forms of anemia, the significant potential complications are neurologic. A neurologic assessment should be performed for patients with known or suspected megaloblastic anemia. Patients may initially complain of paresthesias in their lower extremities. These paresthesias are usually manifested as numbness and tingling on the bottom of the foot, and they gradually progress. As the anemia progresses, other signs become apparent. Position and vibration sense may be diminished; difficulty maintaining balance is not uncommon, and some patients have gait disturbances as well. Initially mild confusion may develop; it may become severe.

Evaluation

Expected Patient Outcomes

1. Reports less fatigue
 - a. Follows a progressive plan of rest, activity, and exercise
 - b. Prioritizes activities
 - c. Paces activities according to energy level
2. Attains and maintains adequate nutrition
 - a. Eats a healthy diet
 - b. Develops a meal plan that promotes optimal nutrition
 - c. Maintains adequate amounts of iron, vitamins, and protein from diet or supplements
 - d. Adheres to nutritional supplement therapy when prescribed
 - e. Verbalizes understanding of rationale for using recommended nutritional supplements
 - f. Verbalizes understanding of rationale for avoiding nonrecommended nutritional supplements
3. Maintains adequate perfusion
 - a. Has vital signs within baseline for patient
 - b. Has pulse oximetry (arterial oxygenation) value within normal limits
4. Absence of complications
 - a. Avoids or limits activities that cause dyspnea, palpitations, dizziness, or tachycardia
 - b. Uses rest and comfort measures to alleviate dyspnea
 - c. Has vital signs within baseline for patient
 - d. Has no signs of increasing fluid retention (eg, peripheral edema, decreased urine output, neck vein distention)
 - e. Remains oriented to time, place, and situation
 - f. Ambulates safely, using assistive devices as necessary
 - g. Remains free of injury
 - h. Verbalizes understanding of importance of serial CBC measurements
 - i. Maintains safe home environment; obtains assistance as necessary

Hypoproliferative Anemias

IRON DEFICIENCY ANEMIA

Iron deficiency anemia typically results when the intake of dietary iron is inadequate for hemoglobin synthesis. The body can store about one fourth to one third of its iron, and it is not until those stores are depleted that iron deficiency anemia actually begins to develop. Iron deficiency anemia is the most common type of anemia in all age groups, and it is the most common anemia in the world. It is particularly prevalent in developing countries, where inadequate iron stores can result from inadequate intake of iron (seen with vegetarian diets) or from blood loss (eg, from intestinal hookworm). Iron deficiency is also common among adults in the United States and the most common cause is blood loss. In fact, the cause of iron deficiency anemia should be considered to be bleeding until proven otherwise.

The most common cause of iron deficiency anemia in men and postmenopausal women is bleeding from ulcers, gastritis, inflammatory bowel disease, or GI tumors. The most common causes of iron deficiency anemia in premenopausal women are menorrhagia (ie, excessive menstrual bleeding) and pregnancy with inadequate iron supplementation. Patients with chronic alcoholism often have chronic blood loss from the GI tract, which causes iron loss and eventual anemia. Other causes include iron malabsorption, as is seen after gastrectomy or with celiac disease.

Clinical Manifestations

Patients with iron deficiency primarily have symptoms of anemia. If the deficiency is severe or prolonged, they may also have a smooth, sore tongue; brittle and ridged nails; and angular cheilosis. These signs subside after iron replacement therapy. The health history may be significant for multiple pregnancies, GI bleeding, and pica.

Assessment and Diagnostic Findings

The definitive method of establishing the diagnosis of iron deficiency anemia is bone marrow aspiration. The aspirate is stained to detect iron, which is at a low level or even absent. However, few patients with suspected iron deficiency anemia undergo bone marrow aspiration. In many patients, the diagnosis can be established with other tests, particularly in patients with a history of conditions that predispose them to this type of anemia.

There is a strong correlation between laboratory values that measure iron stores and hemoglobin levels. After iron stores are depleted (as reflected by low serum ferritin levels), the hemoglobin level falls. The diminished iron stores cause small erythrocytes to be produced by the marrow. Therefore, as the anemia progresses, the MCV, which measures the size of the erythrocytes, also decreases. Hematocrit and RBC levels are also low in relation to the hemoglobin level. Other laboratory tests that measure iron stores are useful but are not as consistent indicators as a low ferritin level, which reflects low iron stores. Typically, patients with iron deficiency anemia have a low serum iron level and an elevated TIBC, which measures the transport protein supplying the marrow with iron as needed (also referred to as transferrin). However, other disease states, such as infection and inflammatory conditions, can also cause a low serum iron level and TIBC, as well as an elevated ferritin level. Currently, the most reliable and clinically useful laboratory findings in evaluating iron deficiency anemia are the ferritin and hemoglobin values.

Medical Management

Except in the case of pregnancy, the cause of iron deficiency should be investigated. Anemia may be a sign of a curable GI cancer or of uterine fibroid tumors. Stool specimens should be tested for occult blood. People 50 years of age or older should have periodic colonoscopy, endoscopy, or x-ray examination of the GI tract to detect ulcerations, gastritis, polyps, or cancer (U.S. Preventive Services Task Force, 2008). Several oral iron preparations—ferrous sulfate, ferrous gluconate, and ferrous fumarate—are available for treating iron deficiency anemia. The hemoglobin level may increase in only a few weeks, and the anemia can be

corrected in a few months. Iron store replenishment takes much longer, so it is important that the patient continue taking the iron for as long as 6 to 12 months.

In some cases, oral iron is poorly absorbed or poorly tolerated, or iron supplementation is needed in large amounts. In these situations, IV or, infrequently, intramuscular (IM) administration of iron may be needed. Before parenteral administration of a full dose, a small test dose should be administered parenterally to avoid the risk of anaphylaxis. Emergency medications (eg, epinephrine) should be close at hand. If no signs of allergic reaction have occurred after 30 minutes, the remaining dose of iron may be administered. Newer formulations of iron are associated with a lower incidence of anaphylaxis and test doses may not be necessary. Several doses are required to replenish the patient's iron stores.

Nursing Management

Preventive education is important, because iron deficiency anemia is common in menstruating and pregnant women. Food sources high in iron include organ meats (eg, beef or calf's liver, chicken liver), other meats, beans (eg, black, pinto, and garbanzo), leafy green vegetables, raisins, and molasses. Taking iron-rich foods with a source of vitamin C (eg, orange juice) enhances the absorption of iron.

The nurse helps the patient select a healthy diet. Nutritional counseling can be provided for those whose usual diet is inadequate. Patients with a history of eating fad diets or strict vegetarian diets are counseled that such diets often contain inadequate amounts of absorbable iron. The nurse encourages the patient to continue iron therapy as long as it is prescribed, although the patient may no longer feel fatigued.

Because iron is best absorbed on an empty stomach, the patient is instructed to take the supplement an hour before meals. Iron supplements are usually given in the oral form, typically as ferrous sulfate. Most patients can use the less expensive, more standard forms of ferrous sulfate. Tablets with enteric coating may be poorly absorbed and should be avoided. Many patients have difficulty tolerating iron supplements because of GI side effects (primarily constipation, but also cramping, nausea, and vomiting). Some iron formulations are designed to limit GI side effects by the addition of a stool softener or use of sustained-release formulations to limit nausea or gastritis. Specific patient teaching aids (Chart 33-2) can assist patients with the use of iron supplements.

If taking iron on an empty stomach causes gastric distress, the patient may need to take it with meals. However, doing so diminishes iron absorption by as much as 50%, thus prolonging the time required to replenish iron stores. Antacids or dairy products should not be taken with iron, because they greatly diminish its absorption. Polysaccharide iron complex forms are also available; they have less GI toxicity but are more expensive.

Liquid forms of iron that cause less GI distress are available. However, they can stain the teeth; the patient should be instructed to take this medication through a straw, to rinse the mouth with water, and to practice good oral hygiene after taking this medication. Finally, the patient should be in-

CHART
33-2

PATIENT EDUCATION *Taking Oral Iron Supplements*

- Take iron on an empty stomach (1 hour before or 2 hours after a meal). Iron absorption is reduced with food, especially dairy products.
- To prevent gastrointestinal distress, the following schedule may work better if more than one tablet a day is prescribed: Start with only one tablet per day for a few days, then increase to two tablets per day, then three tablets per day. This method permits the body to adjust gradually to the iron.
- Increase the intake of vitamin C (citrus fruits and juices, strawberries, tomatoes, broccoli), to enhance iron absorption.
- Eat foods high in fiber to minimize problems with constipation.
- Remember that stools will become dark in color.
- To prevent staining the teeth with a liquid preparation, use a straw or place a spoon at the back of the mouth to take the supplement. Rinse the mouth thoroughly afterward.

formed that iron salts may color the stool dark green or black. However, iron replacement therapy does not cause a false-positive result on stool analyses for occult blood.

IV supplementation may be used when the patient's iron stores are completely depleted, the patient cannot tolerate oral forms of iron supplementation (see Medical Management), or both. The volume of iron required when IM administration is used may be excessive, causing some local pain and possibly staining the skin. These side effects are minimized by using the Z-track technique for administering iron dextran deep into the gluteus maximus muscle (buttock). The nurse avoids vigorously rubbing the injection site after the injection. Because of the problems with IM administration, the IV route is preferred when oral administration is not possible.

ANEMIAS IN RENAL DISEASE

The degree of anemia in patients with end-stage renal disease varies greatly, but in general patients do not become significantly anemic until the serum creatinine level exceeds 3 mg/100 mL. The symptoms of anemia are often the most disturbing of the patient's symptoms. If untreated, the hematocrit usually falls to between 20% and 30%, although in rare cases it may fall to less than 15%. The erythrocytes are normal in appearance.

This anemia is caused by both a mild shortening of erythrocyte lifespan and a deficiency of erythropoietin (necessary for erythropoiesis). As renal function decreases, erythropoietin, which is produced by the kidney, also decreases. Because erythropoietin is also produced outside the kidney, some erythropoiesis continues, even in patients whose kidneys have been removed. However, the number of RBCs produced is small, and the degree of erythropoiesis is inadequate.

Patients undergoing long-term hemodialysis lose blood into the dialyzer and therefore may become iron deficient. Folic acid deficiency develops because this vitamin passes

into the dialysate. Therefore, patients who receive hemodialysis and who have anemia should be evaluated for iron and folate deficiency and treated appropriately.

The availability of recombinant erythropoietin (epoetin alfa [Epogen, Procrit], darbepoetin alfa [Aranesp]) has dramatically altered the management of anemia in end-stage renal disease by decreasing the need for RBC transfusion, with its associated risks. Erythropoietin, in combination with oral iron supplements, can raise and maintain hematocrit levels significantly. Recent data suggest that targeting too high a hemoglobin level (above 13 g/dL) may lead to increased risk of heart failure, heart attack, or stroke (Saingh, Szczech, Tang, et al., 2006). The National Kidney Foundation has modified its anemia management guidelines to allow titration of the erythropoietin dose to maintain the hemoglobin level between 11 and 12 g/dL, not to exceed 13 g/dL (Fishbane & Nissenson, 2007). Therefore, the hemoglobin should be checked frequently and the dose of erythropoietin titrated to maintain an appropriate hemoglobin level.

ANEMIA OF CHRONIC DISEASE

The term *anemia of chronic disease* is a misnomer in that only the chronic diseases of inflammation, infection, and malignancy cause this type of anemia. Many chronic inflammatory diseases are associated with a **normochromic, normocytic** anemia (ie, the erythrocytes are normal in color and size). These disorders include rheumatoid arthritis; severe, chronic infections; and many cancers. It is therefore imperative that the “chronic disease” be diagnosed when this form of anemia is identified so that it can be appropriately managed.

The anemia is usually mild to moderate and nonprogressive. It develops gradually over 6 to 8 weeks and then stabilizes at a hematocrit seldom less than 25%. The hemoglobin level rarely falls below 9 g/dL, and the bone marrow has normal cellularity with increased stores of iron as the iron is diverted from the serum. Erythropoietin levels are low, perhaps because of decreased production, and iron use is blocked by **erythroid cells** (cells that are or will become mature erythrocytes). A moderate shortening of erythrocyte survival also occurs.

Most of these patients have few symptoms and do not require treatment for the anemia. With successful treatment of the underlying disorder, the bone marrow iron is used to make erythrocytes and the hemoglobin level rises. These patients do not benefit from additional iron supplementation.

APLASTIC ANEMIA

Aplastic anemia is a rare disease caused by a decrease in or damage to marrow stem cells, damage to the microenvironment within the marrow, and replacement of the marrow with fat. The precise etiology is unknown, but it is hypothesized that the body’s T cells mediate an inappropriate attack against the bone marrow (Young, Calado & Scheinberg, 2006), resulting in bone marrow **aplasia** (ie, markedly reduced hematopoiesis). Therefore, in addition to severe anemia, significant **neutropenia** and thrombocytopenia (ie, a deficiency of platelets) also occur.

Pathophysiology

Aplastic anemia can be congenital or acquired, but most cases are idiopathic (ie, without apparent cause). Infections and pregnancy can trigger it, or it may be caused by certain medications, chemicals, or radiation damage. Agents that may produce marrow aplasia include benzene and benzene derivatives (eg, airplane glue, paint remover, dry-cleaning solutions). Certain toxic materials, such as inorganic arsenic, glycol ethers, plutonium, and radon, have also been implicated as potential causes.

Clinical Manifestations

The manifestations of aplastic anemia are often insidious. Complications resulting from bone marrow failure may occur before the diagnosis is established. Typical complications are infection and the symptoms of anemia (eg, fatigue, pallor, dyspnea). Purpura (bruising) may develop later and should trigger a CBC and hematologic evaluation if these were not performed initially. If the patient has had repeated throat infections, cervical lymphadenopathy may be seen. Other lymphadenopathies and splenomegaly sometimes occur. Retinal hemorrhages are common.

Assessment and Diagnostic Findings

In many situations, aplastic anemia occurs when a medication or chemical is ingested in toxic amounts. However, in a few people, it develops after a medication has been taken at the recommended dosage. This may be considered an idiosyncratic reaction in those who are highly susceptible, possibly caused by a genetic defect in the medication biotransformation or elimination process. A bone marrow aspirate shows an extremely hypoplastic or even aplastic (very few to no cells) marrow replaced with fat.

Medical Management

It is presumed that the lymphocytes of patients with aplastic anemia destroy the stem cells and consequently impair the production of erythrocytes, leukocytes, and platelets. Despite its severity, aplastic anemia can be treated in most people. Those who are younger than 60 years, who are otherwise healthy, and who have a compatible donor can be cured of the disease by a bone marrow transplant (BMT) or peripheral blood stem cell transplant (PBSCT). In others, the disease can be managed with immunosuppressive therapy, commonly using a combination of antithymocyte globulin (ATG) and cyclosporine or androgens. ATG, a purified gamma-globulin solution, is obtained from horses or rabbits immunized with human T lymphocytes. Side effects during the infusion are common and may include fever and chills. The sudden onset of a rash or bronchospasm may herald anaphylaxis and requires prompt management (see Chapters 53 and 71). Serum sickness, as evidenced by fever, rash, arthralgias, and pruritus, may develop in some patients; it may take weeks to resolve. A study of almost 1000 patients showed that those over the age of 16, those treated with immunosuppressive therapy other than ATG and cyclosporine, and those whose interval between diagnosis and treatment exceeded 23 days had a poor overall prognosis (Locasciulli, Oneto, Bacigalupo, et al., 2007).

Immunosuppressants prevent the patient’s lymphocytes from destroying the stem cells. If relapse occurs (ie, the patient

becomes pancytopenic again), reinstatement of the same immunologic agents may induce another remission. Corticosteroids are not very useful as immunosuppressive agents, because patients with aplastic anemia are particularly susceptible to the development of bone complications from corticosteroids (eg, aseptic necrosis of the head of the femur).

Supportive therapy plays a major role in the management of aplastic anemia. Any offending agent is discontinued. The patient is supported with transfusions of PRBCs and platelets as necessary. Death usually is caused by hemorrhage or infection.

Nursing Management

Patients with aplastic anemia are vulnerable to problems related to erythrocyte, leukocyte, and platelet deficiencies. They should be assessed carefully for signs of infection and bleeding. Specific interventions are delineated in the sections on neutropenia and thrombocytopenia. Nurses must also monitor for side effects of therapy, particularly for hypersensitivity reaction while administering ATG. If patients require long-term cyclosporine therapy, they should be monitored for long-term effects, including renal or liver dysfunction, hypertension, pruritus, visual impairment, tremor, and skin cancer. They should also be informed that the metabolism of ATG is altered by many other medications; thus, each new prescription needs careful assessment for drug–drug interactions. Patients also need to understand the importance of not abruptly stopping their immunosuppressive therapy.

MEGALOBlastic ANEMIAS

In the anemias caused by deficiencies of vitamin B₁₂ or folic acid, identical bone marrow and peripheral blood changes occur because both vitamins are essential for normal DNA synthesis. In either anemia, the erythrocytes that are produced are abnormally large and are called megaloblastic red cells. Other cells derived from the myeloid stem cell (non-lymphoid leukocytes, platelets) are also abnormal. A bone marrow analysis reveals hyperplasia (abnormal increase in the number of cells), and the precursor erythroid and myeloid cells are large and bizarre in appearance. However, many of these abnormal erythroid and myeloid cells are destroyed within the marrow, so the mature cells that do leave the marrow are actually fewer in number. Thus, **pancytopenia** (a decrease in all myeloid-derived cells) can develop. In advanced stages of disease, the hemoglobin value may be as low as 4 to 5 g/dL, the leukocyte count 2000 to 3000/mm³, and the platelet count less than 50,000/mm³. Those cells that are released into the circulation are often abnormally shaped. The neutrophils are hypersegmented. The platelets may be abnormally large. The erythrocytes are abnormally shaped, and the shapes may vary widely (**poikilocytosis**). Because the erythrocytes are very large, the MCV is very high, usually exceeding 110 μm³.

Pathophysiology

Folic Acid Deficiency

Folic acid is stored as compounds referred to as folates. The folate stores in the body are much smaller than those of vitamin B₁₂, and they are quickly depleted when the dietary

intake of folate is deficient (within 4 months). Folate is found in green vegetables and liver. Folate deficiency occurs in people who rarely eat uncooked vegetables. Alcohol increases folic acid requirements, and at the same time patients with alcoholism usually have a diet that is deficient in the vitamin. Folic acid requirements are also increased in patients with chronic hemolytic anemias and in women who are pregnant, because the need for erythrocyte production is increased in these conditions. Some patients with malabsorptive diseases of the small bowel, such as sprue, may not absorb folic acid normally.

Vitamin B₁₂ Deficiency

A deficiency of vitamin B₁₂ can occur in several ways. Inadequate dietary intake is rare but can develop in strict vegetarians who consume no meat or dairy products. Faulty absorption from the GI tract is more common. This occurs in conditions such as Crohn's disease, or after ileal resection or gastrectomy. Another cause is the absence of intrinsic factor, as in pernicious anemia. Intrinsic factor is normally secreted by cells within the gastric mucosa; it binds with dietary vitamin B₁₂ and travels with it to the ileum, where the vitamin is absorbed. Without intrinsic factor, orally consumed vitamin B₁₂ cannot be absorbed, and erythrocyte production is eventually diminished. Even if adequate vitamin B₁₂ and intrinsic factor are present, a deficiency may occur if disease involving the ileum or pancreas impairs absorption. Pernicious anemia, which tends to run in families, is primarily a disorder of adults, particularly the elderly.

The body normally has large stores of vitamin B₁₂, so years may pass before the deficiency results in anemia. Because the body compensates so well, the anemia can be severe before the patient becomes symptomatic. Patients with pernicious anemia have a higher incidence of gastric cancer than the general population; these patients should have endoscopies at regular intervals (every 1 to 2 years) to screen for early gastric cancer.

Clinical Manifestations

Symptoms of folic acid and vitamin B₁₂ deficiencies are similar, and the two anemias may coexist. However, the neurologic manifestations of vitamin B₁₂ deficiency do not occur with folic acid deficiency, and they persist if vitamin B₁₂ is not replaced. Therefore, careful distinction between the two anemias must be made. Serum levels of both vitamins can be measured. In the case of folic acid deficiency, even small amounts of folate increase the serum folate level, sometimes to normal. Measuring the amount of folate within the red cell itself (red cell folate) is therefore a more sensitive test in determining true folate deficiency.

After the body stores of vitamin B₁₂ are depleted, the patient may begin to show signs and symptoms of the anemia. However, because the onset and progression of the anemia are so gradual, the body can compensate very well until the anemia is severe, so that the typical manifestations of anemia (weakness, listlessness, fatigue) may not be apparent initially. The hematologic effects of deficiency are accompanied by effects on other organ systems, particularly the GI tract and nervous system. Patients with pernicious anemia develop a smooth, sore, red tongue and mild diarrhea. They are extremely pale, particularly in the mucous membranes.

They may become confused; more often they have paresthesias in the extremities (particularly numbness and tingling in the feet and lower legs). They may have difficulty maintaining their balance because of damage to the spinal cord, and they also lose position sense (proprioception). These symptoms are progressive, although the course of illness may be marked by spontaneous partial remissions and exacerbations. Without treatment, patients can die after several years, usually from heart failure secondary to anemia.

Assessment and Diagnostic Findings

The classic method of determining the cause of vitamin B₁₂ deficiency is the Schilling test, in which the patient receives a small oral dose of radioactive vitamin B₁₂, followed in a few hours by a large, nonradioactive parenteral dose of vitamin B₁₂ (this aids in renal excretion of the radioactive dose). If the oral vitamin is absorbed, more than 8% is excreted in the urine within 24 hours; therefore, if no radioactivity is present in the urine (ie, the radioactive vitamin B₁₂ stays within the GI tract), the cause is GI malabsorption of the vitamin B₁₂. Conversely, if radioactivity is detected in the urine, the cause of the deficiency is not ileal disease or pernicious anemia. Later, the same procedure is repeated, but this time intrinsic factor is added to the oral radioactive vitamin B₁₂. If radioactivity is now detected in the urine (ie, the vitamin B₁₂ was absorbed from the GI tract in the presence of intrinsic factor), the diagnosis of pernicious anemia can be made. The Schilling test is useful only if the urine collections are complete; therefore, the nurse must promote the patient's understanding and compliance with this collection.

Other methods of establishing the diagnosis may be used. Although it is possible to measure methylmalonic acid levels in vitamin B₁₂ deficiency, these levels also increase in the setting of renal insufficiency. Furthermore, it is expensive to measure these levels, which also limits the utility of the test. A more useful, easier test is the intrinsic factor antibody test. A positive test indicates the presence of antibodies that bind the vitamin B₁₂–intrinsic factor complex and prevent it from binding to receptors in the ileum, thus preventing its absorption. Although this test is not specific for pernicious anemia alone, it can aid in the diagnosis.

Medical Management

Folate deficiency is treated by increasing the amount of folic acid in the diet and administering 1 mg of folic acid daily. Folic acid is administered intramuscularly only to people with malabsorption problems. Although many multivitamin preparations now contain folic acid, additional supplements may be necessary because the amount may be inadequate to fully replace deficient body stores. Patients with alcoholism should receive folic acid as long as they continue to consume alcohol.

Vitamin B₁₂ deficiency is treated by vitamin B₁₂ replacement. Vegetarians can prevent or treat deficiency with oral supplements with vitamins or fortified soy milk. When the deficiency is due to the more common defect in absorption or the absence of intrinsic factor, replacement is by monthly IM injections of vitamin B₁₂. A small amount of an oral dose of vitamin B₁₂ can be absorbed by passive diffusion, even in the absence of intrinsic factor,

but large doses (2 mg/day) are required if vitamin B₁₂ is to be replaced orally.

As vitamin B₁₂ is replaced, the reticulocyte count rises within 1 week, and in several weeks the blood counts are all normal. The tongue feels better and appears less red in several days. However, the neurologic manifestations require more time for recovery; if there is severe neuropathy, the patient may never recover fully. To prevent recurrence of pernicious anemia, vitamin B₁₂ therapy must be continued for life.

Nursing Management

Assessment of patients who have or are at risk for megaloblastic anemia includes inspection of the skin, mucous membranes, and tongue. Mild jaundice may be apparent and is best seen in the sclera without using fluorescent lights. Vitiligo (patchy loss of skin pigmentation) and premature graying of the hair are often seen in patients with pernicious anemia. Because of the neurologic complications associated with these anemias, a careful neurologic assessment is important, including tests of position and vibration sense.

The nurse needs to pay particular attention to ambulation and should assess the patient's gait and stability as well as the need for assistive devices (eg, canes, walkers) and for assistance in managing daily activities. Of particular concern is ensuring safety when position sense, coordination, and gait are affected. Physical and occupational therapy referrals may be needed. If sensation is altered, the patient needs to be instructed to avoid excessive heat and cold.

Because mouth and tongue soreness may limit nutritional intake, the nurse advises the patient to eat small amounts of bland, soft foods frequently. The nurse also may explain that other nutritional deficiencies, such as alcohol-induced anemia, can induce neurologic problems.

Promoting Home and Community-Based Care

The patient must be taught about the chronicity of the disorder and the need for monthly vitamin B₁₂ injections or daily oral vitamin B₁₂ even in the absence of symptoms. If parenteral replacement is used, many patients can be taught to self-administer their injections. The gastric atrophy associated with pernicious anemia increases the risk for gastric carcinoma, so the patient needs to understand that ongoing medical follow-up and screening are important.

MYELODYSPLASTIC SYNDROME

Myelodysplastic syndrome (MDS) is a group of disorders of the myeloid stem cell that causes dysplasia (abnormal development) in one or more types of cell lines. The most common feature of MDS—dysplasia of the erythrocytes—is manifested as a macrocytic anemia; however, the leukocytes (myeloid cells, particularly neutrophils) and platelets can also be affected. Although the bone marrow is actually hypercellular, many of the cells within it die before being released into the circulation. Therefore, the actual number of cells in the circulation is typically lower than normal. In addition to the quantitative defect (ie, fewer cells than normal), there is also a qualitative defect: the cells do not function normally. The neutrophils have diminished ability

to destroy bacteria by phagocytosis; platelets are less able to aggregate and are less adhesive than usual. The result of these qualitative defects is an increased risk of infection and bleeding, even when the actual number of circulating cells may not be excessively low.

Primary MDS tends to be a disease of people older than 60 years of age. Because the initial findings are so subtle, the disease may not be diagnosed until later in the illness trajectory, if at all. Thus, the actual incidence of MDS is not known.

Secondary MDS can occur at any age and result from prior toxic exposure to chemicals, including chemotherapeutic medications (particularly alkylating agents). Secondary MDS tends to have a poorer prognosis than does primary MDS. Thirty percent of MDS cases evolve into acute myeloid leukemia (AML); this type of leukemia tends to be resistant to standard therapy.

Clinical Manifestations

The manifestations of MDS can vary widely. Many patients are asymptomatic, with the illness being discovered incidentally when a CBC is performed for other purposes. Other patients have profound symptoms and complications from the illness. Fatigue is often present, at varying levels. Neutrophil dysfunction puts the person at risk for recurrent pneumonias and other infections. Because platelet function can also be altered, bleeding can occur. These problems may persist in a fairly steady state for months, even years. They may also progress over time; as the dysplasia evolves into a leukemic state, the complications increase in severity.

Assessment and Diagnostic Findings

The CBC typically reveals a macrocytic anemia; leukocyte and platelet counts may be diminished as well. Serum erythropoietin levels and the reticulocyte count may be inappropriately low. If the disease evolves into AML, more immature blast cells are noted on the CBC.

The official diagnosis of MDS is based on the results of a bone marrow aspiration and biopsy. Cytogenetic analysis of the bone marrow is important in determining the overall prognosis, risk of evolution into AML, and method of treatment.

Medical Management

Allogeneic BMT is the only cure for MDS. Traditionally, chemotherapy has been used, particularly in patients with more aggressive forms of the illness, but with disappointing results (Kantarjian, O'Brien, Huang, et al., 2007). Lenalidomide (Revlimid), azacitidine (Vidaza), and decitabine (Dacogen) have demonstrated promise in treating various subtypes of MDS (Demakos & Linebaugh, 2005; Giagounidis, Germing & Aul, 2007; Plimack, Kantarjian & Issa, 2007). Effective treatment can reduce dependence on transfusions and improve symptoms associated with the disease if patients are in remission (Thomas, 2007). Patients with hypocellular marrows may respond well to immunosuppressive therapy using ATG (Lim, Killick, Germing, et al., 2007).

For most patients with MDS, transfusions of RBCs may be required to control the anemia and its symptoms. These patients can develop iron overload from the repeated trans-

fusions; this risk can be diminished with prompt initiation of chelation therapy (see Nursing Management). In 20% of patients, the use of erythropoietin can be successful in reducing the need for transfusions and their complications. A recent meta-analysis has suggested that treatment with a specific synthetic form of erythropoietin, darbepoetin alfa (Aranesp), may increase hemoglobin levels (Ross, Allen, Probst, et al., 2007). Some patients may require ongoing platelet transfusions to prevent significant bleeding. Over time, these patients often have suboptimal increases in the platelet count after platelets are transfused. Infections need to be managed aggressively and promptly. The administration of granulocyte colony-stimulating factor (G-CSF) may be useful in some patients with infections and severe neutropenia.

Because MDS tends to occur in elderly people, other concurrent chronic conditions may limit treatment options. Secondary MDS and MDS that evolves into AML tend to be refractory to conventional therapy for leukemia.

Nursing Management

Caring for patients with MDS can be challenging because the illness is unpredictable. As with other hematologic conditions, some patients (especially those with no symptoms) have difficulty perceiving that they have a serious illness that can place them at risk of life-threatening complications. At the other extreme, many patients have tremendous difficulty coping with the uncertain trajectory of the illness and fear that the illness will evolve into AML. Thus, it is important for patients to understand their unique risk of the disease transforming to AML and to recognize that MDS is a chronic illness.

Patients with MDS need extensive instruction about infection risk, measures to avoid it, signs and symptoms of developing infection, and appropriate actions to take should such symptoms occur. Instruction should also be given regarding the risk of bleeding. Patients with MDS who are hospitalized may require neutropenic precautions.

Laboratory values need to be monitored closely to anticipate the need for transfusion and to determine response to treatment with growth factors. Patients with chronic transfusion requirements often benefit from the insertion of a vascular access device for this purpose. Patients receiving growth factors or chelation therapy need instruction about these medications, their side effects, and administration techniques, if self-administered.

Chelation therapy is a process that is used to remove excess iron acquired from chronic transfusions. Iron is bound to a substance, the chelating agent, and then excreted in the urine. Because chelation therapy removes only a small amount of iron with each treatment, patients with chronic transfusion requirements (and iron overload) need to continue chelation therapy as long as the iron overload exists, potentially for the rest of their lives. Renal and liver dysfunction are possible, so serum creatinine and liver function tests should be monitored and the medication held until the laboratory results return to baseline; the medication is typically resumed at a reduced dose. Patients should also have baseline and annual auditory and eye examinations, because hearing loss and visual changes can occur with chelation treatment.

Hemolytic Anemias

In hemolytic anemias, the erythrocytes have a shortened lifespan; thus, their number in the circulation is reduced. Fewer erythrocytes result in decreased available oxygen, causing hypoxia, which in turn stimulates an increase in erythropoietin release from the kidney. The erythropoietin stimulates the bone marrow to compensate by producing new erythrocytes and releasing some of them into the circulation somewhat prematurely as reticulocytes. If the red cell destruction persists, the hemoglobin is broken down excessively; about 80% of the heme is converted to bilirubin, conjugated in the liver, and excreted in the bile.

The mechanism of erythrocyte destruction varies, but all types of hemolytic anemia share certain laboratory features: The reticulocyte count is elevated, the fraction of indirect (unconjugated) bilirubin is increased, and the supply of haptoglobin (a binding protein for free hemoglobin) is depleted as more hemoglobin is released. As a result, the plasma haptoglobin level is low. If the marrow cannot compensate to replace the erythrocytes (indicated by a decreased reticulocyte count), the anemia will progress.

Hemolytic anemia has various forms. Inherited forms include sickle cell anemia, thalassemia and thalassemia major, G-6-PD deficiency, and hereditary spherocytosis. Acquired forms include autoimmune hemolytic anemia, non-immune-mediated paroxysmal nocturnal hemoglobinuria, microangiopathic hemolytic anemia, and heart valve hemolysis, as well as anemias associated with hypersplenism.

SICKLE CELL ANEMIA

Sickle cell anemia is a severe hemolytic anemia that results from inheritance of the sickle hemoglobin gene. This gene causes the hemoglobin molecule to be defective. The sickle hemoglobin (HbS) acquires a crystal-like formation when exposed to low oxygen tension. The oxygen level in venous blood can be low enough to cause this change; consequently, the erythrocyte containing HbS loses its round, pliable, biconcave disk shape and becomes deformed, rigid, and sickle shaped (Fig. 33-4). These long, rigid erythrocytes can adhere to the endothelium of small vessels; when they adhere to each other, blood flow to a region or an organ may be reduced. If ischemia or infarction results, the patient may have pain, swelling, and fever. The sickling process takes time; if the erythrocyte is again exposed to adequate amounts of oxygen (eg, when it travels through the pulmonary circulation) before the membrane becomes too rigid, it can revert to a normal shape. For this reason, the “sickling crises” are intermittent. Cold can aggravate the sickling process, because vasoconstriction slows the blood flow. Oxygen delivery can also be impaired by an increased blood viscosity, with or without occlusion due to adhesion of sickled cells; in this situation, the effects are seen in larger vessels, such as arterioles.

The *HbS* gene is inherited in people of African descent and to a lesser extent in people from the Middle East, the Mediterranean area, and aboriginal tribes in India. Sickle cell anemia is the most severe form of sickle cell disease. Less severe forms include sickle cell hemoglobin C (SC) disease, sickle cell hemoglobin D (SD) disease, and sickle

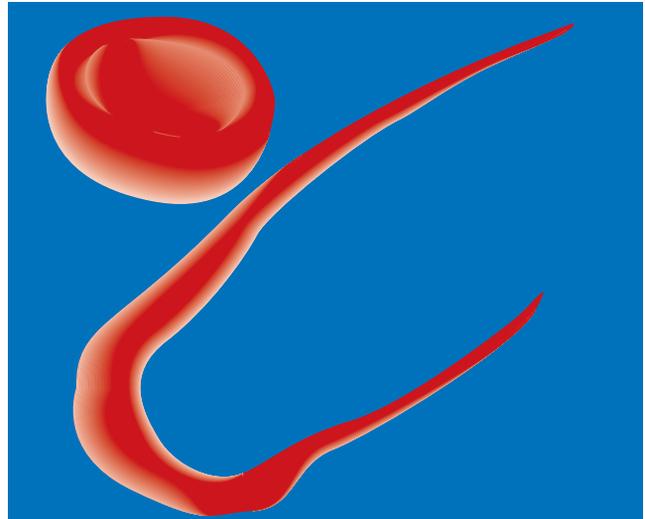

Figure 33-4 A normal red blood cell (upper left) and a sickled red blood cell.

cell beta-thalassemia. The clinical manifestations and management are the same as for sickle cell anemia. The term *sickle cell trait* refers to the carrier state for SC diseases; it is the most benign type of SC disease, in that less than 50% of the hemoglobin within an erythrocyte is HbS. However, if two people with sickle cell trait have children, the children may inherit two abnormal genes and will have sickle cell anemia. (Refer to Chapter 9 for additional discussion of genetic diseases.)

Clinical Manifestations

Symptoms of sickle cell anemia vary and are only somewhat based on the amount of HbS. Symptoms and complications result from chronic hemolysis or thrombosis. Sickled cells are rapidly hemolyzed and thus have a very short lifespan (10 to 12 days). Anemia is always present; usually hemoglobin values are 7 to 10 g/dL. Jaundice is characteristic and is usually obvious in the sclerae. The bone marrow expands in childhood in a compensatory effort to offset the anemia, sometimes leading to enlargement of the bones of the face and skull. The chronic anemia is associated with tachycardia, cardiac murmurs, and often an enlarged heart (cardiomegaly). Dysrhythmias and heart failure may occur in adults.

Virtually any organ may be affected by thrombosis, but the primary sites involve those areas with slower circulation, such as the spleen, lungs, and central nervous system. All the tissues and organs are vulnerable to microcirculatory interruptions by the sickling process and therefore are susceptible to hypoxic damage or ischemic necrosis. Patients with sickle cell anemia are unusually susceptible to infection, particularly pneumonia and osteomyelitis. Complications of sickle cell anemia include infection, stroke, renal failure, impotence, heart failure, and pulmonary hypertension (Table 33-3).

Sickle Cell Crisis

There are three types of sickle cell crisis in the adult population. The most common is the very painful *sickle crisis*, which results from tissue hypoxia and necrosis due to inadequate

Table 33-3 COMPLICATIONS IN SICKLE CELL ANEMIA*

Organ Involved	Mechanisms*	Diagnostic Findings	Signs and Symptoms
Spleen	Primary site of sickling → infarctions → ↓ phagocytic function of macrophages	Autosplenectomy; ↑ infection (esp. pneumonia, osteomyelitis)	Abdominal pain; fever, signs of infection
Lungs	Infection Infarction → ↑ pulmonary pressure → pulmonary hypertension	Pulmonary infiltrate ↑ sPLA ₂ [†]	Chest pain; dyspnea
Central nervous system	Infarction	Cerebral vascular accident (stroke)	Weakness (if severe); learning difficulties (if mild)
Kidney	Sickling → damage to renal medulla	Hematuria; inability to concentrate urine; renal failure	Dehydration
Heart	Anemia	Tachycardia; cardiomegaly → heart failure	Weakness, fatigue, dyspnea
Bone	↑ Erythroid production	Widening of medullary spaces and cortical thinning	Ache, arthralgias
Liver	Infarction of bone Hemolysis	Osteosclerosis → avascular necrosis Jaundice and gallstone formation; hepatomegaly	Bone pain, especially hips Abdominal pain
Skin and peripheral vasculature	↑ Viscosity/stasis → infarction → skin ulcers	Skin ulcers; ↓ wound healing	Pain
Eye	Infarction	Scarring, hemorrhage, retinal detachment	↓ Vision; blindness
Penis	Sickling → vascular thrombosis	Priapism → impotence	Pain, impotence

*Problems encountered in sickle cell anemia vary and are the result of a variety of mechanisms, as depicted in this table. Common physical findings and symptoms are also variable.

[†]sPLA₂: Secretory phospholipase A₂, a laboratory test that can predict impending acute chest syndrome (see text).

blood flow to a specific region of tissue or organ. *Aplastic crisis* results from infection with the human parvovirus. The hemoglobin level falls rapidly and the marrow cannot compensate, as evidenced by an absence of reticulocytes. *Sequestration crisis* results when other organs pool the sickled cells. Although the spleen is the most common organ responsible for sequestration in children, most children with sickle cell anemia have had a splenic infarction by 10 years of age, and the spleen is then no longer functional (autosplenectomy). In adults, the common organs involved in sequestration are the liver and, more seriously, the lungs.

Acute Chest Syndrome

Acute chest syndrome is manifested by fever, cough, tachycardia, and new infiltrates seen on the chest x-ray. These signs often mimic infection, which is often the cause. However, the infectious etiology appears to be atypical bacteria such as *Chlamydia pneumoniae* and *Mycoplasma pneumoniae* as well as viruses such as respiratory syncytial virus (RSV) and parvovirus (Melton & Haynes, 2006). Other causes include pulmonary fat embolism, pulmonary infarction, and pulmonary thromboembolism. Increased secretory phospholipase A₂ concentration has been identified as a predictor of impending acute chest syndrome; the increased amounts of free fatty acids can cause increased permeability of the pulmonary endothelium and leakage of the pulmonary capillaries (Styles, Abboud, Larkin, et al., 2007). Although this syndrome can progress to acute respiratory distress syndrome and death, prompt and aggressive intervention can result in a favorable outcome.

Pulmonary Hypertension

Pulmonary hypertension is a common sequela of sickle cell disease, and often the cause of death (Darbari, Kple-Faget, Kwagyan, et al., 2006). Diagnosing pulmonary hypertension is difficult because clinical symptoms rarely occur until damage is irreversible. Pulse oximetry measurements are typically normal, and breath sounds are clear to auscultation

until the disease has progressed to later stages. Although changes are not evident on chest x-ray, computed tomography (CT) of the chest often demonstrates microvascular pulmonary occlusion and diminished perfusion of the lung. The diagnosis of pulmonary hypertension is elusive, but screening patients with sickle cell disease with Doppler echocardiography is useful in identifying patients with elevated pulmonary artery pressures (Lee, Rosenzweig & Cairo, 2007; Hagar, Michlitsch, Gardner, et al., 2008).

Assessment and Diagnostic Findings

The patient with sickle cell trait usually has a normal hemoglobin level, a normal hematocrit, and a normal blood smear. In contrast, the patient with sickle cell anemia has a low hematocrit and sickled cells on the smear. The diagnosis is confirmed by hemoglobin electrophoresis.

Prognosis

Patients with sickle cell anemia are usually diagnosed in childhood, because they become anemic in infancy and begin to have sickle cell crises at 1 or 2 years of age. Some children die in the first years of life, typically of infection, but antibiotic use and parent teaching strategies have greatly improved the outcomes for these children. However, with current management strategies, the average life expectancy is still suboptimal, at 42 to 48 years. Young adults are often forced to live with multiple, often severe, complications from their disease. In some patients, the symptoms and complications diminish by 30 years of age; these patients live into the sixth decade or longer. Currently, there is no way to predict which patients will fall into this subgroup.

Medical Management

Treatment for sickle cell anemia is the focus of continued research. However, aside from the equally important aggressive management of symptoms and complications, there are currently few primary treatment modalities for sickle cell diseases.

Peripheral Blood Stem Cell Transplant

PBSCT may cure sickle cell anemia. However, this treatment modality is available to only a small subset of affected patients, because of either the lack of a compatible donor or because severe organ damage (eg, renal, liver, lung) that may be already present in the patient is a contraindication for PBSCT.

Pharmacologic Therapy

Hydroxyurea (Hydrea), a chemotherapy agent, has been shown to be effective in increasing fetal hemoglobin (ie, hemoglobin F) levels in patients with sickle cell anemia, thereby decreasing the formation of sickled cells. Patients who receive hydroxyurea appear to have fewer painful episodes of sickle cell crisis, a lower incidence of acute chest syndrome, and less need for transfusions. However, whether hydroxyurea can prevent or reverse actual organ damage remains unknown. Side effects of hydroxyurea include chronic suppression of leukocyte formation, teratogenesis, and potential for later development of a malignancy. Patient response to this agent varies significantly. The incidence and severity of side effects are also highly variable within a dose range. Some patients have toxicity with a very small dose (5 mg/kg/day), whereas others have little toxicity with a much higher dose (35 mg/kg/day).

Arginine has antisickling properties and enhances the availability of nitric oxide, the most potent vasodilator, resulting in decreased pulmonary artery pressure. Arginine may be useful in managing pulmonary hypertension and acute chest syndrome (Benza, 2008; Melton & Haynes, 2006).

Transfusion Therapy

RBC transfusions have been shown to be highly effective in several situations: in an acute exacerbation of anemia (eg, aplastic crisis), in the prevention of severe complications from anesthesia and surgery, in improving the response to infection (when it results in exacerbated anemia), and in severe cases of acute chest syndrome (Melton & Haynes, 2006). Transfusions are also effective in diminishing episodes of sickle cell crisis in pregnant women, but this does not improve fetal survival. Chronic transfusion therapy may be effective in preventing or managing complications from sickle cell disease, including stroke, chronic heart failure, and pulmonary hypertension (Mehta, Afenyi-Annan, Burns, et al., 2006).

The risk of complications from transfusion is important to consider. These risks include iron overload, which necessitates chelation therapy (see Myelodysplastic Syndrome, Nursing Management); poor venous access, which necessitates a vascular access device (and its attendant risk of infection or thrombosis); infections (hepatitis, human immunodeficiency virus [HIV]); and especially alloimmunization (an immune response to antigens from donor cells) from repeated transfusions. Another complication from transfusion is increased blood viscosity without reduction in the concentration of hemoglobin S. Exchange transfusion (in which the patient's own blood is removed and replaced via transfusion) may be performed to diminish the risk of increasing the viscosity excessively; the objective is to reduce the hematocrit

to less than 30%, with transfusions supplying more than 80% of the patient's blood volume. Finally, it is important to consider the significant financial cost of an aggressive transfusion and chelation program.

Patients with sickle cell anemia require daily folic acid replacements to maintain the supply required for increased erythropoiesis from hemolysis. Infections must be treated promptly with appropriate antibiotics; infection, particularly pneumococcal infection, remains a major cause of death. These patients should receive pneumococcal and annual influenza vaccinations (Mehta, et al., 2006).

Acute chest syndrome is managed by prompt initiation of antibiotic therapy. Incentive spirometry has been shown to decrease the incidence of pulmonary complications significantly. In severe cases, bronchoscopy may be required to identify the source of pulmonary disease. Hydration is important but must be carefully monitored. Corticosteroids may also be useful. Transfusions reverse the hypoxia and decrease the level of secretory phospholipase A₂. Pulmonary function should be monitored regularly to detect pulmonary hypertension early, when therapy (hydroxyurea, arginine, transfusions, or BMT) may have a positive impact.

Because repeated blood transfusions are necessary, patients may develop multiple autoantibodies, making cross-matching difficult. In this patient population, a hemolytic transfusion reaction (see later discussion) may mimic the signs and symptoms of a sickle cell crisis. The classic distinguishing factor is that with a hemolytic transfusion reaction, the patient becomes *more* anemic after being transfused. These patients need very close observation. Further transfusion is avoided if possible until the hemolytic process abates. If possible, the patient is supported with corticosteroids (prednisone), IV immunoglobulin (IVIG), and erythropoietin (Epojen).

Supportive Therapy

Supportive care is equally important. Pain management is a significant issue. The incidence of painful sickle cell crises is highly variable; many patients have pain on a daily basis. The severity of the pain may not be enough to cause the patient to seek assistance from health care providers but severe enough to interfere with the ability to work and function within the family unit. Acute pain episodes tend to be self-limited, lasting hours to days. If the patient cannot manage the pain at home, intervention is frequently sought in an urgent care facility or emergency department. Adequate hydration is important during a painful sickling episode. Oral hydration is acceptable if the patient can maintain adequate fluid intake; IV hydration with dextrose 5% in water (D₅W) or dextrose 5% in 0.25 normal saline solution (3 L/m²/24 hours) is usually required for sickle crisis. Supplemental oxygen may also be needed.

The use of medication to relieve pain is important (see Chapter 13 for a discussion of pain management). Aspirin is very useful in diminishing mild to moderate pain; it also diminishes inflammation and potential thrombosis (due to its ability to decrease platelet adhesion). Nonsteroidal anti-inflammatory drugs (NSAIDs) are useful for moderate pain or in combination with opioid analgesics. Although no tolerance develops with NSAIDs, a "ceiling effect" does develop whereby an increase in dosage does not increase

analgesia. NSAID use must be carefully monitored, because these medications can precipitate renal dysfunction. When opioid analgesic agents are used, morphine is the medication of choice for acute pain. Patient-controlled analgesia (PCA) is frequently used. A study of 19 patients hospitalized with 25 episodes of sickle crisis found that daily pain rating scores were comparable in those receiving morphine by PCA versus by continuous infusion (van Beers, van Tuijn, Nieuwkerk, et al., 2007). In addition, patients in the PCA group used less opioids, had fewer side effects (nausea and constipation), and had shorter hospital stays.

Chronic pain increases in incidence as the patient ages and is caused by continued complications (eg, avascular necrosis of the hip) from the sickling. With chronic pain management, the principal goal is to maximize functioning; pain may not be completely eliminated without sacrificing function. This concept may be difficult for patients to accept; they may need repeated explanations and support from nonjudgmental health care providers. Nonpharmacologic approaches to pain management are crucial in this setting. Examples include physical and occupational therapy, physiotherapy (including the use of heat, massage, and exercise), cognitive and behavioral intervention (including distraction, relaxation, and motivational therapy), and support groups.

Working with patients who have multiple episodes of severe pain can be challenging. It is important for health care providers to realize that patients with sickle cell disease must face a lifelong experience with severe and unpredictable pain. Such pain is disruptive to the patient's level of functioning, including social functioning, and may result in a feeling of helplessness. Patients with inadequate social support systems may have more difficulty coping with chronic pain.

NURSING PROCESS

THE PATIENT WITH SICKLE CELL CRISIS

Assessment

The patient is asked to identify factors that precipitated previous crises and measures he or she uses to prevent and manage crises. Pain levels should always be monitored using a pain intensity scale, such as a 0-to-10 scale. The quality of the pain (eg, sharp, dull, burning), the frequency of the pain (constant versus intermittent), and factors that aggravate or alleviate the pain are included in this assessment. If a sickle cell crisis is suspected, the nurse needs to determine whether the pain currently experienced is the same as or different from the pain typically encountered in crisis.

Because the sickling process can interrupt circulation in any tissue or organ, with resultant hypoxia and ischemia, a careful assessment of all body systems is necessary. Particular emphasis is placed on pain, swelling, and fever. All joint areas are carefully examined for pain and swelling. The abdomen is assessed for pain and tenderness because of the possibility of splenic infarction.

The cardiopulmonary systems must be assessed carefully, including auscultation of breath sounds, measurement of

oxygen saturation levels, and signs of cardiac failure, such as the presence and extent of dependent edema, an increased point of maximal impulse (PMI), and cardiomegaly (as seen on a chest x-ray). The patient is assessed for signs of dehydration by a history of fluid intake and careful examination of mucous membranes, skin turgor, urine output, and serum creatinine and blood urea nitrogen (BUN) values.

A careful neurologic examination is important to elicit symptoms of cerebral hypoxia. However, ischemic findings on magnetic resonance imaging (MRI) or Doppler studies may precede findings on the physical examination. MRI and Doppler studies are used for early diagnosis and may result in improved patient outcome because therapy can be initiated promptly.

Because patients with sickle cell anemia are susceptible to infections, they are assessed for the presence of any infectious process. Particular attention is given to examination of the chest, long bones, and femoral head, because pneumonia and osteomyelitis are especially common. Leg ulcers, which may be infected and slow to heal, are common.

The extent of anemia and the ability of the marrow to replenish erythrocytes are assessed by the hemoglobin level, hematocrit, and reticulocyte counts, and they are compared with the patient's baseline values. The patient's current and past history of medical management is also obtained, particularly chronic transfusion therapy, hydroxyurea use, and prior treatment for infection.

Diagnosis

Nursing Diagnoses

Based on the assessment data, major nursing diagnoses for the patient with sickle cell crisis may include:

- Acute pain related to tissue hypoxia due to agglutination of sickled cells within blood vessels
- Risk for infection
- Risk for powerlessness related to illness-induced helplessness
- Deficient knowledge regarding sickle crisis prevention

Collaborative Problems/Potential Complications

Based on the assessment data, potential complications may include:

- Hypoxia, ischemia, infection, and poor wound healing leading to skin breakdown and ulcers
- Dehydration
- Cerebrovascular accident (CVA, brain attack, stroke)
- Anemia
- Acute and chronic renal failure
- Heart failure, pulmonary hypertension, and acute chest syndrome
- Impotence
- Poor compliance
- Substance abuse related to poorly managed chronic pain

Planning and Goals

The major goals for the patient are relief of pain, decreased incidence of crisis, enhanced sense of self-esteem and power, and absence of complications.

Nursing Interventions

Managing Pain

Acute pain during a sickle cell crisis can be severe and unpredictable. The patient's subjective description and rating of pain on a pain scale must guide the use of analgesic agents. Any joint that is acutely swollen should be supported and elevated until the swelling diminishes. Relaxation techniques, breathing exercises, and distraction are helpful for some patients. After the acute painful episode has diminished, aggressive measures should be implemented to preserve function. Physical therapy, whirlpool baths, and transcutaneous electrical nerve stimulation (TENS) are examples of such modalities.

Preventing and Managing Infection

Nursing care focuses on monitoring patients for signs and symptoms of infection. Prescribed antibiotics should be initiated promptly, and patients should be assessed for signs of dehydration. If patients are to take prescribed oral antibiotics at home, they must understand the importance of completing the entire course of antibiotic therapy.

Promoting Coping Skills

This illness frequently leaves the patient feeling powerless and with decreased self-esteem because its acute exacerbations often result in chronic health problems. These feelings can be exacerbated by inadequate pain management, and enhancing pain management can be extremely useful in establishing a therapeutic relationship based on mutual trust. Nursing care that focuses on the patient's strengths rather than deficits can enhance effective coping skills. Providing the patient with opportunities to make decisions about daily care may increase the patient's feelings of control. The patient needs to understand the rationale for and importance of compliance with a therapeutic medication regimen.

Minimizing Deficient Knowledge

Patients with sickle cell anemia benefit from understanding what situations can precipitate a sickle cell crisis and the steps they can take to prevent or diminish such crises. Keeping warm and maintaining adequate hydration can be effective in diminishing the occurrence and severity of attacks.

If hydroxyurea is prescribed for a woman of childbearing age, she should be told that the drug can cause congenital harm to unborn children and advised about pregnancy prevention.

Monitoring and Managing Potential Complications

Management measures for many of the potential complications have been described in previous sections. Other measures follow.

LEG ULCERS. Leg ulcers require careful management and protection from trauma and contamination. Referral to a wound-ostomy-contingence nurse (WOCN) may facilitate healing and assist with prevention. If leg ulcers fail to heal, skin grafting may be necessary. Scrupulous aseptic technique is warranted to prevent nosocomial infections.

PRIAPISM LEADING TO IMPOTENCE. Male patients may develop sudden, painful episodes of priapism (persistent penile

erection). The patient is taught to empty his bladder at the onset of the attack, exercise, and take a warm bath. If an episode persists longer than 3 hours, medical attention, which consists of IV hydration, administration of analgesic agents, and possible penile intracavernosal aspiration, is recommended. Repeated episodes may lead to extensive vascular thrombosis, resulting in impotence.

CHRONIC PAIN AND SUBSTANCE ABUSE. Many patients have considerable difficulty coping with chronic pain and repeated episodes of sickle cell crisis and may find it difficult to adhere to a prescribed treatment plan. Some patients with sickle cell anemia develop problems with substance abuse. This results from inadequate management of acute pain during episodes of crisis, which then promotes mistrust of the health care system and (from the patient's perspective) the need to seek care from other sources. Prevention is the best way to manage this problem. Receiving care from a single provider over time is much more beneficial than receiving care from rotating physicians and staff in an emergency department. When crises occur, the staff in the emergency department should be in contact with the patient's primary health care provider so that optimal management can be achieved. An established pattern of substance abuse is very difficult to manage, but continuity of care and establishing written contracts with the patient can be useful.

Promoting Home and Community-Based Care

TEACHING PATIENTS SELF-CARE. Because patients with sickle cell anemia are typically diagnosed as children, parents participate in the initial education. As the child ages, educational interventions prepare the child to assume more responsibility for self-care. Most families can learn about vascular access device management and chelation therapy. Nurses in outpatient facilities or home care nurses may need to provide follow-up care for patients with vascular access devices.

CONTINUING CARE. The illness trajectory of sickle cell anemia is highly varied, with unpredictable episodes of complications and crises. Care is often provided on an emergency basis, especially for some patients with pain management problems (see previous section). All health care providers who provide services to patients with sickle cell disease and their families need to communicate regularly with each other. Patients need to learn which parameters are important for them to monitor and how to monitor them. Guidelines should also be given regarding when it is appropriate to seek urgent care.

Evaluation

Expected Patient Outcomes

Expected patient outcomes may include:

1. Control of pain
 - a. Uses analgesic agents to control acute pain
 - b. Uses relaxation techniques, breathing exercises, and distraction to help relieve pain
2. Is free of infection
 - a. Has normal temperature
 - b. Has leukocyte count within normal range ($4500/\text{mm}^3$ to $11,000/\text{mm}^3$)

- c. Identifies importance of continuing antibiotics at home (if applicable)
3. Expresses improved sense of control
 - a. Participates in goal setting and in planning and implementing daily activities
 - b. Participates in decisions about care
4. Increases knowledge about disease process
 - a. Identifies situations and factors that can precipitate sickle cell crisis
 - b. Describes lifestyle changes needed to prevent crisis
 - c. Describes the importance of warmth, adequate hydration, and prevention of infection in preventing crisis
5. Absence of complications

THALASSEMIA

The thalassemias are a group of hereditary anemias characterized by **hypochromia** (an abnormal decrease in the hemoglobin content of erythrocytes), extreme **microcytosis** (smaller-than-normal erythrocytes), destruction of blood elements (hemolysis), and variable degrees of anemia. The thalassemias occur worldwide, but the highest prevalence is found in people of Mediterranean, African, and Southeast Asian ancestry.

Thalassemias are associated with defective synthesis of hemoglobin; the production of one or more globulin chains within the hemoglobin molecule is reduced. When this occurs, the imbalance in the configuration of the hemoglobin causes it to precipitate in the erythroid precursors or the erythrocytes themselves. This increases the rigidity of the erythrocytes and thus the premature destruction of these cells.

Thalassemias are classified into two major groups according to which hemoglobin chain is diminished: alpha or beta. The alpha-thalassemias occur mainly in people from Asia and the Middle East, and the beta-thalassemias are most prevalent in people from Mediterranean regions but also occur in those from the Middle East or Asia. The alpha-thalassemias are milder than the beta forms and often occur without symptoms; the erythrocytes are extremely microcytic, but the anemia, if present, is mild.

The severity of beta-thalassemia varies depending on the extent to which the hemoglobin chains are affected. Patients with mild forms have microcytosis and mild anemia. If left untreated, severe beta-thalassemia (ie, thalassemia major or Cooley's anemia) can be fatal within the first few years of life. BMT offers a chance of cure, but when this is not possible, the disease is usually treated with transfusion of PRBCs. Patients may survive into their 50s. Patient teaching during the reproductive years should include preconception counseling about the risk of thalassemia major in offspring.

Thalassemia Major

Thalassemia major is characterized by severe anemia, marked hemolysis, and ineffective erythropoiesis. With early regular transfusion therapy, growth and development through childhood are facilitated. Organ dysfunction due to iron overload results from the excessive amounts of iron in multiple PRBC transfusions. Regular chelation therapy can

reduce the complications of iron overload and prolong the life of these patients. This disease is potentially curable by PBSCT if the procedure can be performed before liver damage occurs (ie, during childhood).

GLUCOSE-6-PHOSPHATE DEHYDROGENASE DEFICIENCY

The G-6-PD gene is the source of the abnormality in this disorder; this gene produces an enzyme within the erythrocyte that is essential for membrane stability. A few patients have inherited an enzyme that is so defective that they have a chronic hemolytic anemia; however, the most common type of defect results in hemolysis only when the erythrocytes are stressed by certain situations, such as fever or the use of certain medications. African Americans and people of Greek or Italian origin are those primarily affected by this disorder. The type of deficiency found in the Mediterranean population is more severe than that in the African American population, resulting in greater hemolysis and sometimes in life-threatening anemia. All types of G-6-PD deficiency are inherited as X-linked defects; therefore, many more men are at risk than women. In the United States, about 12% of African American males are affected. The deficiency is also common in those of Asian ancestry and in certain Jewish populations.

Oxidant drugs have hemolytic effects for people with G-6-PD deficiency. These medications include antimalarial agents (eg, chloroquine [Aralen]), sulfonamides (eg, trimethoprim/sulfamethoxazole [Bactrim, Septra]), nitrofurantoin (eg, Macrochantin), dapson, primaquine, phenazopyridine, chloramphenicol (Chloromycetin), and the street drug amyl nitrite ("poppers"). In affected people, a severe hemolytic episode can also result from ingestion of fava beans.

Clinical Manifestations

Patients are asymptomatic and have normal hemoglobin levels and reticulocyte counts most of the time. However, several days after exposure to an offending medication, they may develop pallor, jaundice, and hemoglobinuria (hemoglobin in the urine). The reticulocyte count increases, and symptoms of hemolysis develop. Special stains of the peripheral blood may then disclose Heinz bodies (degraded hemoglobin) within the erythrocytes. Hemolysis is often mild and self-limited. However, in the more severe Mediterranean type of G-6-PD deficiency, spontaneous recovery may not occur.

Assessment and Diagnostic Findings

The diagnosis is made by a screening test or by a quantitative assay of G-6-PD.

Medical Management

The treatment is to arrest the source and stop the offending medication. Transfusion is necessary only in the severe hemolytic state, which is more commonly seen in the Mediterranean variety of G-6-PD deficiency.

Nursing Management

Patients are educated about the disease and given a list of medications to avoid. If hemolysis develops, nursing interventions are the same as for hemolysis from other causes.

Patients should be instructed to wear MedicAlert bracelets that identify that they have G-6-PD deficiency. Genetic counseling may be indicated.

IMMUNE HEMOLYTIC ANEMIA

Hemolytic anemias can result from exposure of the erythrocyte to antibodies. Alloantibodies (ie, antibodies against the host, or “self”) result from the immunization of a person with foreign antigens (eg, the immunization of an Rh-negative person with Rh-positive blood). Alloantibodies tend to be large (IgM type) and cause immediate destruction of the sensitized erythrocytes, either within the blood vessel (intravascular hemolysis) or within the liver. An example of alloimmune hemolytic anemia in adults is anemia that results from a hemolytic transfusion reaction.

Autoantibodies may develop for many reasons. In many instances, the person’s immune system is dysfunctional, so that it falsely recognizes its own erythrocytes as foreign and produces antibodies against them. This mechanism is seen in people with chronic lymphocytic leukemia (CLL). Another mechanism is a deficiency in suppressor lymphocytes, which normally prevent antibody formation against a person’s own antigens. Autoantibodies tend to be of the IgG type. The erythrocytes are sequestered in the spleen and destroyed by the macrophages outside the blood vessel (extravascular hemolysis).

Autoimmune hemolytic anemias can be classified based on the body temperature involved when the antibodies react with the red blood cell antigen. Warm-body antibodies bind to erythrocytes most actively in warm conditions (37°C or 98.6°F); cold-body antibodies react in cold conditions (0°C or 32°F). Most autoimmune hemolytic anemias are the warm-body type. Autoimmune hemolytic anemia is associated with other disorders in most cases (eg, medication exposure, lymphoma, CLL, other malignancy, collagen vascular disease, autoimmune disease, infection). In idiopathic autoimmune hemolytic states, the reason why the immune system produces the antibodies is not known. This primary form affects patients of all ages and both genders equally, whereas the incidence of secondary forms is greater in people older than 45 years of age and in females.

Clinical Manifestations

Clinical manifestations can vary, and they usually reflect the degree of anemia. The hemolysis may be very mild, so that the patient’s marrow compensates adequately and the patient is asymptomatic. At the other extreme, the hemolysis can be so severe that the resultant anemia is life-threatening. Most patients complain of fatigue and dizziness. Splenomegaly is the most common physical finding, occurring in more than 80% of patients; hepatomegaly, lymphadenopathy, and jaundice are also common.

Assessment and Diagnostic Findings

Laboratory tests show a low hemoglobin level and hematocrit, most often with an accompanying increase in the reticulocyte count. Erythrocytes appear abnormal; spherocytes are common. The serum bilirubin level is elevated, and if the hemolysis is severe, the haptoglobin level is low or absent. The Coombs test (also referred to as the direct

antiglobulin test [DAT]), which detects antibodies on the surface of erythrocytes, shows a positive result.

Medical Management

Any possible offending medication should be immediately discontinued. The treatment consists of high doses of corticosteroids until hemolysis decreases. Corticosteroids decrease the macrophage’s ability to clear the antibody-coated erythrocytes. If the hemoglobin level returns toward normal, usually after several weeks, the corticosteroid dose can be lowered or, in some cases, tapered and discontinued. However, corticosteroids rarely produce a lasting remission. In severe cases, blood transfusions may be required. Because the antibody may react with all possible donor cells, careful blood typing is necessary, and the transfusion should be administered slowly and cautiously.

Splenectomy (ie, removal of the spleen) may be performed if corticosteroids do not produce a remission, because it removes the major site of erythrocyte destruction. If neither corticosteroid therapy nor splenectomy is successful, immunosuppressive agents may be administered. The two immunosuppressive agents most frequently used are cyclophosphamide (Cytoxan), which has a more rapid effect but more toxicity, and azathioprine (Imuran), which has a less rapid effect but less toxicity. The synthetic androgen danazol (Danocrine) can be useful in some patients, particularly in combination with corticosteroids. If corticosteroids or immunosuppressive agents are used, the taper must be gradual to prevent a rebound “hyperimmune” response and exacerbation of the hemolysis. Monoclonal antibodies (eg, rituximab [Rituxan]) can also be effective for some patients. Immunoglobulin administration is effective in about one third of patients, but the effect is transient and the medication is expensive. Transfusions may be necessary if the anemia is severe; it may be extremely difficult to cross-match samples of available units of PRBCs with that of the patient.

For patients with cold-antibody hemolytic anemia, no treatment may be required other than to advise the patient to keep warm; relocation to a warm climate may be advisable. However, in other situations, the hemolysis may warrant more aggressive interventions as described previously.

Nursing Management

Patients may have great difficulty understanding the pathologic mechanisms underlying the disease and may need repeated explanations in terms they can understand. Patients who have had a splenectomy should be vaccinated against pneumococcal infections (eg, with Pneumovax) and informed that they are permanently at greater risk for infection. Patients receiving long-term corticosteroid therapy, particularly those with concurrent diabetes or hypertension, need careful monitoring. They must understand the need for the medication and the importance of never abruptly discontinuing it. A written explanation and a tapering schedule should be provided, and adjustments based on hemoglobin levels should be emphasized. Similar teaching should be provided when immunosuppressive agents are used. Corticosteroid therapy is not without significant risk, and patients need to be monitored closely for complications. The short- and long-term complications of corticosteroid therapy are presented in Chapter 42.

 **NURSING ALERT**

It can be difficult to cross-match blood when antibodies are present. If imperfectly cross-matched RBCs must be transfused, the nurse should begin the infusion very slowly (10 to 15 mL over 20 to 30 minutes) and monitor the patient very closely for signs and symptoms of a hemolytic transfusion reaction.

HEREDITARY HEMOCHROMATOSIS

Hemochromatosis is a genetic condition in which excess iron is absorbed from the GI tract. Normally, the GI tract absorbs 1 to 2 mg of iron daily, but in those with hereditary hemochromatosis, this rate increases significantly. The excess iron is deposited in various organs, particularly the liver, myocardium, testes, thyroid, and pancreas. Eventually, the affected organs become dysfunctional. Although hereditary hemochromatosis is diagnosed in 0.5% of the population in the United States (ie, 1 million people), the actual prevalence is unknown because it is not always diagnosed. The genetic defect associated with hemochromatosis is most commonly seen as a specific mutation (C282Y homozygosity) of the *HFE* gene. Despite the high prevalence of the genetic mutation, the actual expression of the disease is much lower; the reason for this discrepancy is unclear (Adams & Barton, 2007). The actual prevalence of hemochromatosis is lower among Asian Americans, African Americans, Latinos, and Pacific Islanders (Whitlock, Garlitz, Harris, et al., 2006). Women are less often affected than men because women lose iron through menses.

Clinical Manifestations

Often there is no evidence of tissue damage until middle age, because the accumulation of iron in body organs occurs gradually. Symptoms of weakness, lethargy, arthralgia, weight loss, and loss of libido are common and occur earlier in the illness trajectory. The skin may appear hyperpigmented from melanin deposits (and occasionally **hemosiderin**, an iron-containing pigment) or appear bronze in color. Cardiac dysrhythmias and cardiomyopathy can occur, with resulting dyspnea and edema. Endocrine dysfunction is manifested as hypothyroidism, diabetes mellitus, and hypogonadism (testicular atrophy, diminished libido, and impotence). Cirrhosis is common in later stages of the disease, shortens life expectancy, and is a risk factor for hepatocellular carcinoma (Whitlock, et al., 2006).

Assessment and Diagnostic Findings

Diagnostic laboratory findings include an elevated serum iron level and high transferrin saturation (more than 60% in men, more than 50% in women). CBC values are typically normal. The definitive diagnostic test for hemochromatosis was formerly the liver biopsy, but testing for the associated genetic mutation is now more commonly used.

Medical Management

Therapy involves the removal of excess iron via therapeutic phlebotomy (removal of whole blood from a vein). Each unit of blood removed results in a decrease of 200 to 250 mg

of iron. The objective is to reduce the serum ferritin to less than 50 $\mu\text{g/L}$ and the transferrin saturation to 30% or less. To achieve this, frequent phlebotomy is required (1 to 2 units weekly). Phlebotomy is then necessary only every 1 to 4 months until the serum ferritin levels are maintained at 50 $\mu\text{g/L}$ (Brissot, 2007). After 1 to 3 years, the frequency of phlebotomy can often be further reduced to prevent reaccumulation of iron deposits. The goal is to maintain an iron saturation of less than 50% and a serum ferritin of less than 100 $\mu\text{g/L}$. Aggressive removal of excess iron can prevent end-organ dysfunction, particularly liver cirrhosis and its complications (ascites, hemorrhage, hepatocellular carcinoma) (Adams & Barton, 2007).

Nursing Management

Patients with hemochromatosis often limit their dietary intake of iron, although this is not effective. However, it is important for these patients to avoid any additional insults to the liver, such as alcohol abuse. Serial screening tests for hepatoma (eg, through monitoring alpha-fetoprotein) are important. Other body systems should be monitored for signs of organ dysfunction, particularly the endocrine and cardiac systems, so that appropriate management can be implemented quickly. Because patients with hemochromatosis require frequent phlebotomies, problems with venous access are common. Children of patients who are homozygous for the *HFE* gene mutation should be screened for the mutation as well. Patients who are heterozygous for the *HFE* gene do not develop the disease but need to be advised that they can transmit the gene to their children.

POLYCYTHEMIA

Polycythemia refers to an increased volume of erythrocytes. The term is used when the hematocrit is elevated (more than 55% in males, more than 50% in females). Dehydration (decreased volume of plasma) can cause an elevated hematocrit but not typically to the level to be considered polycythemia. Polycythemia is classified as either primary or secondary.

Polycythemia Vera

Polycythemia vera (“P vera”), or primary polycythemia, is a proliferative disorder of the myeloid stem cells. The bone marrow is hypercellular, and the erythrocyte, leukocyte, and platelet counts in the peripheral blood are elevated. However, erythrocyte elevation predominates; the hematocrit can exceed 60%. This phase can last for an extended period of 10 years or more. Over time, the spleen resumes its embryonic function of hematopoiesis and enlarges. Eventually, the bone marrow may become fibrotic, with a resultant inability to produce as many cells (“burnt out” or spent phase). The disease then evolves into myeloid metaplasia with myelofibrosis, MDS, or AML in a significant proportion of patients; this form of AML is usually refractory to standard treatment. The estimated incidence of polycythemia vera is 2 per 100,000 people (Johansson, 2006). The median age at onset is 65 years (Vannucchi, Antonioli,

Guglielmelli, et al., 2007). With treatment, median survival exceeds 10 years. Death typically results from thrombosis, hemorrhage, or evolution to AML.

Clinical Manifestations

Patients typically have a ruddy complexion and splenomegaly. Symptoms result from increased blood volumes and may include headache, dizziness, tinnitus, fatigue, paresthesias, and blurred vision, or from increased blood viscosity and may include angina, claudication, dyspnea, and thrombophlebitis, particularly if the patient has atherosclerotic blood vessels. For this reason, blood pressure is often elevated. Uric acid may be elevated, resulting in gout and renal stone formation. Another common and bothersome problem is generalized pruritus, which may be caused by histamine release due to an increased number of basophils. Erythromyalgia, a burning sensation in the fingers and toes, may be reported and is only partially relieved by cooling.

Assessment and Diagnostic Findings

Diagnosis is based on an elevated erythrocyte mass, a normal oxygen saturation level, and often an enlarged spleen. Other factors useful in establishing the diagnosis include elevated leukocyte and platelet counts. The erythropoietin level is not as low as would be expected with an elevated hematocrit; it is normal or only slightly low. Causes of secondary erythrocytosis should not be present (see later discussion).

The mutation of the enzyme JAK2 causes an erythrocyte hypersensitivity to the effects of erythropoietin. Although a mutation in JAK2 is found in the majority of people with polycythemia vera, it is not specific for the disease. Those with other hematologic disorders (essential thrombocythemia and myelofibrosis) also have this mutation (Vanucchi, et al., 2007).

Complications

Patients with polycythemia vera are at increased risk for thromboses that may result in CVAs (strokes, brain attacks) or myocardial infarctions (MIs); thrombotic complications are the most common cause of death. Bleeding is also a complication, possibly because the platelets are often very large and somewhat dysfunctional. The bleeding can be significant and can occur in the form of nosebleeds, ulcers, frank GI bleeding, hematuria, and intracranial hemorrhage.

Medical Management

The objective of management is to reduce the high blood cell mass. Phlebotomy is an important part of therapy. It involves removing enough blood (initially 500 mL once or twice weekly) to reduce blood viscosity and to deplete the patient's iron stores, thereby rendering the patient iron deficient and consequently unable to continue to manufacture erythrocytes excessively. Many patients are managed by routine phlebotomy on an intermittent basis, with the target of maintaining the hematocrit less than 45%.

Chemotherapeutic agents (eg, hydroxyurea) can be used to suppress marrow function, but this may increase the risk of leukemia. Patients receiving hydroxyurea appear to have a lower incidence of thrombotic complications than those treated by phlebotomy alone; this may result with a normal

platelet count. Anagrelide (Agrylin), which inhibits platelet aggregation, can also be useful in controlling the thrombocytosis associated with polycythemia vera. However, many patients have difficulty tolerating the medication; it can cause significant side effects, including headache, fluid retention, cardiac dysrhythmias, and heart failure. Furthermore, some studies suggest that anagrelide may be leukemogenic (ie, may cause leukemia), although this hypothesis is controversial (Fruchtman, Pettit, Gilbert, et al., 2005). Interferon alfa-2b (Intron-A) is the most effective treatment for managing the pruritus associated with polycythemia vera (McMullin, 2007) but may be difficult for patients to tolerate because of its frequent side effects (eg, flu-like syndrome, depression). Antihistamines, including histamine-2 blockers, are not particularly effective in controlling itching. Allopurinol (Zyloprim) is used to prevent gouty attacks in patients with elevated uric acid concentrations.

The use of aspirin to prevent thrombotic complications is controversial. High-dose aspirin may be associated with an increase in risk of bleeding and no decrease in risk of thrombosis. In contrast, low-dose aspirin decreases the risk of significant thrombotic complications (deep vein thrombosis [DVT], pulmonary embolism, MI, stroke) but does not increase the risk of significant bleeding; therefore, it is now recommended as an antithrombotic prophylaxis (Barbui & Finazzi, 2007). Aspirin is also useful in reducing the pain associated with erythromyalgia.

Nursing Management

The nurse's role is primarily that of educator. Risk factors for thrombotic complications, particularly smoking, obesity, and poorly controlled hypertension, should be assessed, and the patient should be instructed about the signs and symptoms of thrombosis. To reduce the likelihood of DVT, sedentary behavior, crossing the legs, and wearing tight or restrictive clothing (particularly stockings) should be discouraged. Patients with a history of significant bleeding are usually advised to avoid aspirin and aspirin-containing medications, because these medications alter platelet function. Minimizing alcohol intake should also be emphasized to further diminish the risk of bleeding. The patient needs to be instructed to avoid iron supplements, including those within multivitamin supplements, because the iron can further stimulate RBC production. For pruritus, the nurse may recommend bathing in tepid or cool water and avoiding vigorous toweling off after bathing. Cocoa butter- or oatmeal-based lotions and bath products or baking soda dissolved in bath water may also be effective.

Secondary Polycythemia

Secondary polycythemia is caused by excessive production of erythropoietin. This may occur in response to a reduced amount of oxygen, which acts as a hypoxic stimulus, as in heavy cigarette smoking, chronic obstructive pulmonary disease, or cyanotic heart disease, or in nonpathologic conditions such as living at a high altitude. It can also result from certain hemoglobinopathies (eg, hemoglobin Chesapeake), in which the hemoglobin has an abnormally high affinity for oxygen. Secondary polycythemia can also occur

from neoplasms (eg, renal cell carcinoma) that stimulate erythropoietin production.

Medical Management

When secondary polycythemia is mild, treatment may not be necessary; when treatment is necessary, it involves treating the primary conditions. If the cause cannot be corrected (eg, by treating the renal cell carcinoma or improving pulmonary function with smoking cessation), therapeutic phlebotomy may be necessary in symptomatic patients to reduce blood viscosity and volume as well as when the hematocrit is significantly elevated.

LEUKOPENIA

Leukopenia, a condition in which there are fewer leukocytes than normal, results from neutropenia (diminished neutrophils) or lymphopenia (diminished lymphocytes). Even if other types of leukocytes (eg, monocytes, basophils) are diminished, their numbers are too few to reduce the total leukocyte count significantly.

Neutropenia

Neutropenia (a neutrophil count of less than $2000/\text{mm}^3$) results from decreased production of neutrophils or increased destruction of these cells (Chart 33-3). Neutrophils are essential in preventing and limiting bacterial infection. A patient with neutropenia is at increased risk for infection from both exogenous and endogenous sources. (The GI tract and skin are common endogenous sources.) The risk of infection is based not only on the severity of the neutropenia but also on its duration. The actual number of neutrophils, known as the **absolute neutrophil count (ANC)**, is determined by a simple mathematical calculation using data obtained from the CBC and differential (see Chapter 16). The risk of in-

fection increases proportionately with the decrease in neutrophil count. The risk is significant when the ANC is less than $1000/\text{mm}^3$, is high when it is less than $500/\text{mm}^3$, and is almost certain when it is less than $100/\text{mm}^3$. The risk of developing infection also increases with the length of time during which neutropenia persists, even if it is somewhat mild. Conversely, even a severe neutropenia may not result in infection if the duration of the neutropenia is brief, as is often seen after chemotherapy (Chart 33-4).

Clinical Manifestations

There are no definite symptoms of neutropenia until the patient becomes infected. A routine CBC with differential, as obtained after chemotherapy treatment, can reveal neutropenia before the onset of infection.

NURSING ALERT

Patients with neutropenia often do not exhibit classic signs of infection. Fever is the most common indicator of infection, yet it is not always present, particularly if the patient is taking corticosteroids.

Medical Management

Treatment of the neutropenia varies depending on its cause. If the neutropenia is medication induced, the offending agent is stopped immediately, if possible. Treatment of an underlying neoplasm can temporarily make the neutropenia worse, but with bone marrow recovery, treatment may actually improve it. Corticosteroids may be used if the cause is an immunologic disorder. The use of growth factors such as G-CSF or granulocyte-macrophage colony-stimulating factor (GM-CSF) can be effective in increasing neutrophil production when the cause of the neutropenia is decreased production. Withholding or reducing the dose of chemotherapy or radiation therapy may be required when the neutropenia is caused by these treatments; however, in the case of potentially curative therapy, administration of growth factor is considered to be preferable, so that the maximum antitumor effect can be achieved by maintaining the chemotherapy regimen as originally planned.

If the neutropenia is accompanied by fever, the patient is considered to have an infection and usually is admitted to the hospital. Cultures of blood, urine, and sputum, as well as a chest x-ray, are obtained. To ensure adequate therapy against the infectious organisms, broad-spectrum antibiotics are initiated as soon as the cultures are obtained, although the antibiotics may be changed after culture and sensitivity results are available.

Nursing Management

Nurses in all settings have a crucial role in assessing the severity of neutropenia and in preventing and managing complications, which most often include infections. Patient teaching is equally important, particularly in the outpatient setting, so that the patient can implement appropriate self-care measures and know when and how to seek medical care (Chart 33-5). Patients at risk of neutropenia should have blood drawn for a CBC with differential; the frequency is based on the suspected severity and duration of the neutropenia. Nurses need to be

Chart 33-3 • Causes of Neutropenia

Decreased Production of Neutrophils

- Aplastic anemia, due to medications or toxins
- Metastatic cancer, lymphoma, leukemia
- Myelodysplastic syndromes
- Chemotherapy
- Radiation therapy

Ineffective Granulocytopoiesis

- Megaloblastic anemia

Increased Destruction of Neutrophils

- Hypersplenism
- Medication induced*
- Immunologic disorders (eg, systemic lupus erythematosus)
- Viral disease (eg, infectious hepatitis, mononucleosis)
- Bacterial infections

*Formation of antibody to medication, leading to a rapid decrease in neutrophils.

CHART
33-4

Risk Factors for Development of Infection and Bleeding in Patients With Hematologic Disorders

Risk of Infection

- *Severity of neutropenia:* Risk of infection is proportional to severity of neutropenia
- *Duration of neutropenia:* Increased duration leads to increased risk of infection
- *Nutritional status:* Decreased protein stores lead to decreased immune response and energy
- *Deconditioning:* Decreased mobility leads to decreased respiratory effort, leading to increased pooling of secretions
- *Lymphocytopenia; disorders of lymphoid system (chronic lymphocytic leukemia [CLL], lymphoma, myeloma):* Decreased cell-mediated and humoral immunity
- *Invasive procedures:* Break in skin integrity leads to increased opportunity for organisms to enter blood system
- *Hypogammaglobulinemia:* Decreased antibody formation
- *Poor hygiene:* Increased organisms on skin and mucous membranes including perineum
- *Poor dentition; mucositis:* Decreased endothelial integrity leads to increased opportunity for organisms to enter blood system
- *Antibiotic therapy:* Increased risk for superinfection, often fungal
- *Certain medications:* See text

Risk of Bleeding

- *Severity of thrombocytopenia:* Risk increases when platelet count decreases; usually not a significant risk until platelet count is lower than 20,000/mm³ or lower than 50,000/mm³ when invasive procedure performed
- *Duration of thrombocytopenia:* Risk increases when duration increases (eg, risk is less when duration is transient after chemotherapy than when duration is permanent with poor marrow production)
- *Sepsis:* Mechanism unknown; appears to cause increased platelet consumption
- *Increased intracranial pressure:* Increased blood pressure leads to rupture of blood vessels
- *Liver dysfunction:* Decreased synthesis of clotting factors
- *Renal dysfunction:* Decreased platelet function
- *Dysproteinemia:* Protein coats surface of platelet, leading to decreased platelet function; protein causes increased viscosity, which leads to increased stretching of capillaries and thus increased bleeding
- *Alcohol abuse:* Suppressive effect on marrow leads to decreased platelet production and decreased ability to function; decreased liver function results in decreased production of clotting factors
- *Splenomegaly:* Increased platelet destruction; spleen traps circulating platelets
- *Concurrent medications:* See text

able to calculate the ANC (see Chapter 16) to assess the severity of neutropenia and the risk of infection. Chart 33-6 identifies nursing interventions related to neutropenia. Chart 33-7 discusses the effects of diet among neutropenic outpatients.

Lymphopenia

Lymphopenia (a lymphocyte count less than 1500/mm³) can result from ionizing radiation, long-term use of corticosteroids, uremia, some neoplasms (eg, breast and lung

CHART
33-5

HOME CARE CHECKLIST The Patient at Risk For Infection

At the completion of the home care instruction, the patient or caregiver will be able to:	PATIENT	CAREGIVER
• Describe consequences of alterations in neutrophils, lymphocytes, immunoglobulins, or their sources.	✓	✓
• Verbalize the reason for being at risk for infection.	✓	✓
• Identify signs and symptoms of infection.	✓	✓
• Demonstrate how to monitor for signs of infection.	✓	✓
• Describe to whom, how, and when to report signs of infection.	✓	✓
• Identify appropriate behaviors to take to prevent infection: <ul style="list-style-type: none"> • Maintain good hand hygiene technique, total body hygiene, and skin integrity. • Avoid fresh flowers, plants, garden work (soil), bird cages, and litter boxes. • Maintain a high-calorie, high-protein diet, with fluid intake of 3000 mL daily (unless fluids are restricted). • Avoid people with infections and crowds. • Perform deep breathing; use incentive spirometer every 4 hour while awake if mobility is restricted. • Provide adequate lubrication with gentle vaginal manipulation during sexual intercourse; avoid anal intercourse. 	✓	✓
• Describe appropriate actions to take should infection occur.	✓	✓

Chart 33-6 • Neutropenia Precautions**Nursing Diagnosis**

Risk for infection secondary to impaired immunocompetence due to:

- Diminished neutrophil count (see below) secondary to bone marrow invasion or hypocellularity secondary to disease or treatment
- Dysfunctional neutrophils (eg, secondary to myelodysplastic syndrome [MDS])
- Dysfunctional or diminished lymphocytes
- Hypogammaglobulinemia
- Diminished immune response or anergy
- Malnutrition
- Surgery or invasive procedures
- Antibiotic therapy (increased risk of superimposed infection)

Assessment**Patient**

Assess the following areas thoroughly every shift or visit (with spot checks throughout shift if the patient is hospitalized) and notify physician of any signs of infection or worsening of status:

- **Skin:** Check for tenderness, edema, breaks in skin integrity, moisture, drainage, lesions (especially under breasts, axillae, groin, skin folds, bony prominences, perineum); check all puncture sites (eg, intravenous sites) for signs and symptoms of inflammation/infection.
 - Skin and mucous membranes are the body's first line of defense against infection; loss of endothelial cell integrity allows organisms to enter the blood and lymph systems.
- **Oral mucosa:** Check for moisture, lesions, color (check palate, tongue, buccal mucosa, gums, lips, oropharynx).
- **Respiratory:** Check for presence of sinus pressure or tenderness, cough, sore throat; auscultate breath sounds; assess rate and depth of respiration, use of accessory muscles.
- **Gastrointestinal:** Check for abdominal discomfort/distention, nausea, change in bowel pattern; auscultate bowel sounds.
- **Genitourinary:** Check for dysuria, urgency, frequency; check urine for color, clarity, odor.
- **Neurologic:** Check for complaints of headache, neck stiffness, visual disturbances; assess level of consciousness, orientation, behavior.
- **Temperature:** Check every 4 hours or every visit; call primary health care provider if temperature is $>38^{\circ}\text{C}$ ($>101^{\circ}\text{F}$), fever is unresponsive to acetaminophen, or patient shows a decline in hemodynamic status.
 - Neutropenic, infected patients often do not exhibit the classic signs of inflammation/infection (ie, redness, cloudiness of any drainage); the only initial sign may be fever (and it often occurs later in the infectious process with neutropenia).

Diagnostic Studies

- Monitor complete blood count (CBC) and differential daily (especially absolute neutrophil count [ANC], lymphocyte count).
- Call physician if ANC is $<1000/\text{mm}^3$ or is significantly different from previous count, or whenever patient becomes symptomatic (eg, febrile).
- Monitor globulin, albumin, total protein levels.
- Monitor all culture and sensitivity reports.
- Monitor x-ray reports.

Nursing Interventions**Environment and Staff**

- Thorough hand hygiene must be performed by everyone before entering patient's room each and every time.
- Allow no one with a cold or sore throat to care for the patient or to enter room, or come in contact with patient at home.
- Care for neutropenic patients before caring for other patients (as much as possible).
- Use private room for patient if ANC is $<1000/\text{mm}^3$.
- Allow no fresh flowers or plants (stagnant water, risk of *Aspergillus* infection).
- Change water in containers every shift (include O_2 humidification systems every 24 hours).
- Ensure room is cleaned daily.

Dietary

- Provide low-microbial diet.*
- Encourage adequate hydration.

Patient

- Avoid suppositories, enemas, rectal temperatures.
- Practice deep breathing (with incentive spirometer) every 4 hours while awake.
- Ambulate; wear high-efficiency particulate air (HEPA) filter mask if neutropenia is severe.
- Prevent skin dryness with water-soluble lubricants, especially in high-risk areas (eg, lips, corners of mouth, elbows, feet, bony prominences).

Hygiene

- Provide meticulous total body hygiene daily (preferably with antimicrobial solution), including perineal care after every bowel movement.
- Provide thorough oral hygiene after meals and every 4 hours while awake; warm saline, or salt and soda solution, is effective; avoid use of lemon-glycerine swabs, commercial mouthwashes, and hydrogen peroxide.

Intravenous (IV) Therapy

- Avoid plastic cannulas for peripheral IVs when ANC is $<500/\text{mm}^3$ if possible; a central vascular access device is preferred for long-term or intensive IV therapy.
- Inspect IV sites every shift; monitor closely for any discomfort; erythema may not be present.
- Maintain meticulous IV site care.
- Cleanse skin with antimicrobial solution before venipuncture (unless patient is allergic).
- Moisture-vapor-permeable dressings are permissible with strict adherence to institutional protocol.
- Change IV tubing per institution policy, using aseptic technique.
- Administer antimicrobial agents on time.

Expected Patient Outcomes

- Patient demonstrates an absence of infection as evidenced by an absence of fever, chills, inflammation, drainage, cough, dyspnea, sore throat, dysuria, or urinary frequency.
- Patient demonstrates an absence of infection as evidenced by the presence of vital signs within normal limits, including intact neurologic status and intact skin.

Duration of Evaluation

Until patient is no longer neutropenic and any infection is resolved.

*Note that although it is certainly prudent to avoid uncooked eggs, seafood, and meats as well as unwashed fruits and vegetables, there is little evidence to support this guideline.

CHART NURSING RESEARCH PROFILE

33-7 The Effect of a Neutropenic Diet in the Outpatient Setting

DeMille, D., Deming, P., Lupinacci, P., et al. (2006). The effect of the neutropenic diet in the outpatient setting: A pilot study. *Oncology Nursing Forum*, 33(2), 337–343.

Purpose

Infection remains a serious complication for many patients who are neutropenic. In an attempt to decrease infections in patients receiving myelosuppressive chemotherapy, particularly in the context of hematologic malignancy, the neutropenic diet has been used. Although this diet has not been uniformly defined, it often prohibits ingestion of raw, fresh vegetables; fresh juices; raw eggs; and uncooked fish, poultry, and meat. The rationale for this diet is that it decreases the ingestion of potential pathogens (eg, *Pseudomonas*, *Escherichia coli*, *Klebsiella*, and *Proteus*) found on such foods, thereby reducing the possible transmission of organisms from the gastrointestinal tract to the bloodstream. The purpose of this study was twofold: (1) to assess patients' compliance with the neutropenic diet outside the hospital, and (2) to compare patients who complied with the diet with those who did not in terms of the rate of hospital admissions for febrile neutropenia and positive blood cultures from gram-negative rods.

Design

A convenience sample of 28 patients without neutropenia who were about to begin a type of chemotherapeutic

regimen associated with a high incidence of neutropenia was enrolled in this prospective, descriptive study. An investigator-developed questionnaire was used to assess each patient's knowledge regarding food safety and neutropenic diet. Information regarding these concepts was then provided and the questionnaire was readministered 6 and 12 weeks later. Medical records were examined to assess hospitalization admissions and blood culture results.

Seventy percent of the sample (16 of 23 who completed the study) were noncompliant with the neutropenic diet. There was no statistically significant difference in hospital admissions for febrile neutropenia for those who were compliant and those who were not. Similarly, there was no statistically significant difference between groups in incidence of blood cultures yielding gram-negative rods.

Nursing Implications

The use of a neutropenic diet is commonly advocated for cancer patients. Although problematic in its methodology and small sample size, this pilot study does not provide evidence to support these diet restrictions. This is one of few studies specifically designed to test the impact of a standard nursing intervention designed to prevent infection in neutropenic patients. Further studies are needed so that nursing interventions can be based on evidence, thereby enhancing patient outcomes.

cancers, advanced Hodgkin disease), and some protein-losing enteropathies (in which the lymphocytes within the intestines are lost). Although when lymphopenia is mild it is often without sequelae, when severe, it can result in bacterial infections (due to low B lymphocytes) or in opportunistic infections (due to low T lymphocytes).

LEUKEMIA

The term *leukocytosis* refers to an increased level of leukocytes in the circulation. Typically, only one specific cell type is increased. Because the proportions of several types of leukocytes (eg, eosinophils, basophils, monocytes) are small, only an increase in neutrophils or lymphocytes can be great enough to elevate the total leukocyte count. Although leukocytosis can be a normal response to increased need (eg, in acute infection), the elevation in leukocytes should decrease as the physiologic need decreases. A prolonged or progressively increasing elevation in leukocytes is abnormal and should be evaluated. A significant cause of persistent leukocytosis is hematologic malignancy.

Hematopoiesis is characterized by a rapid, continuous turnover of cells. Normally, production of specific blood cells from their stem cell precursors is carefully regulated according to the body's needs. If the mechanisms that control the production of these cells are disrupted, the cells can proliferate excessively. Hematopoietic malignancies are often classified by the cells involved. **Leukemia** is a neoplastic

proliferation of one particular cell type (granulocytes, monocytes, lymphocytes, or infrequently erythrocytes or megakaryocytes). The defect originates in the hematopoietic stem cell, the myeloid, or the lymphoid stem cell. The lymphomas are neoplasms of lymphoid tissue, usually derived from B lymphocytes. Multiple myeloma is a malignancy of the most mature form of B lymphocyte, the plasma cell.

The common feature of the leukemias is an unregulated proliferation of leukocytes in the bone marrow. In acute forms (or late stages of chronic forms), the proliferation of leukemic cells leaves little room for normal cell production. There can also be a proliferation of cells in the liver and spleen (extramedullary hematopoiesis). With acute forms, there can be infiltration of leukemic cells in other organs, such as the meninges, lymph nodes, gums, and skin. The cause of leukemia is not fully known, but there is some evidence that genetic influences and viral pathogenesis may be involved (American Cancer Society [ACS], 2008b; Sherbenou & Druker, 2007; Taylor, 2007). Bone marrow damage from radiation exposure or from chemicals such as benzene and alkylating agents (eg, melphalan [Alkeran]) can cause leukemia.

The leukemias are commonly classified according to the stem cell line involved, either lymphoid or myeloid. They are also classified as either acute or chronic, based on the time it takes for symptoms to evolve and the phase of cell development that is halted (ie, with few leukocytes differentiating beyond that phase).

In acute leukemia, the onset of symptoms is abrupt, often occurring within a few weeks. Leukocyte development is halted at the blast phase, so that most leukocytes are undifferentiated cells or are blasts. Acute leukemia progresses very rapidly; death occurs within weeks to months without aggressive treatment.

In chronic leukemia, symptoms evolve over a period of months to years, and the majority of leukocytes produced are mature. Chronic leukemia progresses more slowly; the disease trajectory can extend for years.

Acute Myeloid Leukemia

AML results from a defect in the hematopoietic stem cell that differentiates into all myeloid cells: monocytes, granulocytes (eg, neutrophils, basophils, eosinophils), erythrocytes, and platelets. All age groups are affected, although it infrequently occurs before age 40 and the incidence rises with age, with a peak incidence at age 67 years (ACS, 2008b). AML is the most common nonlymphocytic leukemia.

The prognosis is highly variable. Patient age is a significant factor; patients who are younger may survive for 5 years or more after diagnosis of AML. However, patients who are older or have a more undifferentiated form of AML tend to have a worse prognosis. The 5-year survival rate for patients with AML who are 65 years of age or younger is 35%; it drops to 4% for those older than 65 years of age (Leukemia & Lymphoma Society, 2007). The development of AML in people with preexisting MDS or in those who previously received alkylating agents for cancer (secondary AML) is also associated with a much worse prognosis; the leukemia tends to be more resistant to treatment, resulting in a much shorter duration of remission. With treatment, patients with secondary AML survive an average of less than 1 year, with death usually a result of infection or hemorrhage. Patients receiving supportive care also usually survive less than 1 year, dying of infection or bleeding.

Clinical Manifestations

Most signs and symptoms of AML result from insufficient production of normal blood cells. Fever and infection result from neutropenia, weakness and fatigue from anemia, and bleeding tendencies from thrombocytopenia. The proliferation of leukemic cells within organs leads to a variety of additional symptoms: pain from an enlarged liver or spleen, hyperplasia of the gums, and bone pain from expansion of marrow.

Assessment and Diagnostic Findings

AML develops without warning, with symptoms occurring over a period of weeks to months. The CBC shows a decrease in both erythrocytes and platelets. Although the total leukocyte count can be low, normal, or high, the percentage of normal cells is usually vastly decreased. A bone marrow analysis shows an excess of immature blast cells (more than 20%). AML can be further classified into seven different subgroups, based on cytogenetics, histology, and morphology of the blasts. The actual prognosis varies some-

what between subgroups and with the extent of cytogenetic abnormalities and genetic mutations. The clinical course and treatment differ substantially with only one subtype. Patients with acute promyelocytic leukemia (APL, or AML-M3) often have significantly more problems with bleeding, in that they have underlying coagulopathy and a higher incidence of disseminated intravascular coagulation (DIC).

Complications

Complications of AML include bleeding and infection, the major causes of death. The risk of bleeding correlates with the level of platelet deficiency (thrombocytopenia). The low platelet count can result in ecchymoses (bruises) and **petechiae** (pinpoint red or purple hemorrhagic spots on the skin; Fig. 33-5). Major hemorrhages also may develop when the platelet count drops to less than 10,000/mm³. The most common bleeding is GI, pulmonary, and intracranial. For undetermined reasons, fever and infection also increase the likelihood of bleeding.

Because of the lack of mature and normal granulocytes, patients with leukemia are always threatened by infection. The likelihood of infection increases with the degree and duration of neutropenia; neutrophil counts that persist at less than 100/mm³ increase the risk of systemic infections. As the duration of severe neutropenia increases, the patient's risk of developing fungal infections also increases. These fungal infections remain difficult to treat, despite the development of new antifungal agents, particularly if the patient has significant neutropenia.

Medical Management

Despite advances in understanding the biology of the AML, substantive advances in treatment response rates and survival rates have not occurred for decades, with the exception of advances made in treating APL (see later discussion). Even for those subtypes that have not benefited from advances in treatment, cure is still possible. The overall objective of treatment is to achieve complete remission, in which there is no evidence of residual leukemia in the bone marrow. Attempts

Figure 33-5 Petechiae and purpura on lower extremities of a thrombocytopenic patient. From Kelley, W. N. (1989). *Textbook of internal medicine*. Philadelphia: Lippincott Williams & Wilkins.

are made to achieve remission by the aggressive administration of chemotherapy, called induction therapy, which usually requires hospitalization for several weeks. Induction therapy typically involves high doses of cytarabine (Cytosar, Ara-C) and daunorubicin (Cerubidine) or mitoxantrone (Novantrone) or idarubicin (Idamycin); sometimes etoposide (VP-16, VePesid) is added to the regimen. The choice of agents is based on the patient's physical status and history of prior antineoplastic treatment.

Treatment of APL revolves around induction therapy using the differentiating agent all-trans retinoic acid (ATRA), which induces the promyelocytic blast cells to differentiate, thereby deterring the cells from proliferating. ATRA is typically combined with a conventional chemotherapeutic agent, usually an anthracycline drug. This regimen yields a very high response rate, and cure is possible.

The aim of induction therapy is to eradicate the leukemic cells, but this is also accompanied by the eradication of normal types of myeloid cells. Thus, the patient becomes severely neutropenic (an ANC of 0 is not uncommon), anemic, and thrombocytopenic (a platelet count of less than 10,000/mm³ is common). During this time, the patient is typically very ill, with bacterial, fungal, and occasionally viral infections; bleeding; and severe mucositis, which causes diarrhea and an inability to maintain adequate nutrition. Supportive care consists of administering blood products (PRBCs and platelets) and promptly treating infections. The use of granulocytic growth factors, either G-CSF (filgrastim [Neupogen]) or GM-CSF (sargramostim [Leukine]), can shorten the period of significant neutropenia by stimulating the bone marrow to produce leukocytes more quickly; these agents do not appear to increase the risk of producing more leukemic cells.

When the patient has recovered from the induction therapy (ie, the neutrophil and platelet counts have returned to normal and any infection has resolved), consolidation therapy (postremission therapy) is administered to eliminate any residual leukemia cells that are not clinically detectable and reduce the chance for recurrence. Multiple treatment cycles of various agents are used, usually containing some form of cytarabine. Frequently, the patient receives one cycle of treatment that is almost the same, if not identical, to the induction treatment but at lower dosages, therefore resulting in less toxicity.

Another aggressive treatment option is BMT or PBSCT. When a suitable tissue match can be obtained, the patient embarks on an even more aggressive regimen of chemotherapy (sometimes in combination with radiation therapy), with the treatment goal of destroying the hematopoietic function of the patient's bone marrow. The patient is then "rescued" with the infusion of the donor stem cells to reinitiate blood cell production. Patients who undergo PBSCT have a significant risk for infection, graft-versus-host disease (GVHD, in which the donor's lymphocytes [graft] recognize the patient's body as "foreign" and set up reactions to attack the "foreign" host), and other complications. The most appropriate use and timing of PBSCT remain unclear. Patients with a poorer prognosis may benefit from early PBSCT; those with a good prognosis may not need transplant at all. (See Chapter 16 for a discussion of nursing management in BMT.)

Another important option for the patient to consider is supportive care alone. In fact, supportive care may be the only option if the patient has significant comorbidity, such as extremely poor cardiac, pulmonary, renal, or hepatic function, and/or is extremely old. In such cases, aggressive antileukemia therapy is not used; occasionally, hydroxyurea (Hydrea) may be used briefly to control the increase of blast cells. Patients are more commonly supported with antimicrobial therapy and transfusions as needed. This treatment approach provides the patient with some additional time outside the hospital (eg, at home); however, death frequently occurs within months, typically from infection or bleeding. (Refer to Chapter 17 for a discussion of end-of-life care.)

Complications of Treatment

Massive leukemic cell destruction from chemotherapy results in the release of intracellular electrolytes and fluids into the systemic circulation. Increases in uric acid levels, potassium, and phosphate are seen; this process is referred to as tumor lysis syndrome (see Chapter 16). The increased uric acid and phosphorus levels make the patient vulnerable to renal stone formation and renal colic, which can progress to acute renal failure. Hyperkalemia and hypocalcemia can lead to cardiac dysrhythmias; hypotension; neuromuscular effects such as muscle cramps, weakness, and spasm/tetany; confusion; and seizures. Patients require a high fluid intake, alkalization of the urine, and prophylaxis with allopurinol to prevent crystallization of uric acid and subsequent stone formation. GI problems may result from the infiltration of abnormal leukocytes into the abdominal organs and from the toxicity of the chemotherapeutic agents. Anorexia, nausea, vomiting, diarrhea, and severe mucositis are common. Because of the profound myelosuppressive effects of chemotherapy, significant neutropenia and thrombocytopenia typically result in serious infection and increased risk of bleeding.

Nursing Management

Nursing management of the patient with acute leukemia is presented at the end of the discussion of leukemia in this chapter.

Chronic Myeloid Leukemia

Chronic myeloid leukemia (CML) arises from a mutation in the myeloid stem cell. Normal myeloid cells continue to be produced, but there is a pathologic increase in the production of forms of blast cells. Therefore, a wide spectrum of cell types exists within the blood, from blast forms through mature neutrophils. Because there is an uncontrolled proliferation of cells, the marrow expands into the cavities of long bones (eg, the femur), and cells are also formed in the liver and spleen (extramedullary hematopoiesis), resulting in enlargement of these organs that is sometimes painful. In 90% to 95% of patients with CML, a section of DNA is missing from chromosome 22 (the Philadelphia chromosome [Ph1]); it is translocated onto chromosome 9. The specific location of these changes is on the BCR gene of chromosome 22 and the ABL gene on chromosome 9.

When these two genes fuse (*BCR-ABL* gene), they produce an abnormal protein (a tyrosine kinase protein) that causes leukocytes to divide rapidly. This *BCR-ABL* gene is present in virtually all patients with this disease.

CML is uncommon in people younger than 20 years of age; the incidence increases with age (mean age is 67 years) (ACS, 2008a). Patients diagnosed with CML in the chronic phase have an overall median life expectancy exceeding 5 years. During that time, they have few symptoms and complications from the disease itself. Problems with infections and bleeding are rare. However, once the disease transforms to the acute phase (blast crisis), the median survival is typically less than 6 months (Schiffer, 2007).

Clinical Manifestations

The clinical picture of CML varies. Many patients are asymptomatic, and leukocytosis is detected by a CBC performed for some other reason. The leukocyte count commonly exceeds 100,000/mm³. Patients with extremely high leukocyte counts may be somewhat short of breath or slightly confused because of decreased capillary perfusion to the lungs and brain from leukostasis (the excessive volume of leukocytes inhibits blood flow through the capillaries). The patient may have an enlarged, tender spleen. The liver may also be enlarged. Some patients have insidious symptoms, such as malaise, anorexia, and weight loss. Lymphadenopathy is rare. There are three stages in CML: chronic, transformation, and accelerated or blast crisis. Patients develop more symptoms and complications as the disease progresses.

Medical Management

Advances in understanding of the pathology of CML at a molecular level have led to dramatic changes in its treatment. An oral formulation of a tyrosine kinase inhibitor, imatinib mesylate (Gleevec), works by blocking signals within the leukemia cells that express the *BCR-ABL* protein, thus preventing a series of chemical reactions that cause the cell to grow and divide. Imatinib therapy appears to be most useful in the chronic phase of the illness. It can induce complete remission at the cellular and even the molecular level. Imatinib is metabolized by the cytochrome P450 pathway, which means that drug–drug interactions are common. Also, antacids and grapefruit juice may limit drug absorption, and large doses of acetaminophen can cause hepatotoxicity.

In those instances where imatinib (at conventional doses) does not elicit a molecular remission, or when that remission is not maintained, other treatment options may be considered. The dosage of imatinib can be increased (with increased toxicity), another inhibitor of *BCR-ABL* can be used (eg, dasatinib [Sprycell]), or allogeneic transplant can be used. CML is a disease that can potentially be cured with BMT or PBSCT in otherwise healthy patients who are younger than 65 years of age. However, with the development of tyrosine kinase inhibitors such as imatinib and dasatinib, the timing of transplant has come into question. Patients who receive such transplants while still in the chronic phase of the illness tend to have a greater chance for cure than those who receive them in the acute phase. The use of imatinib therapy may decrease the need for

transplantation in CML; however, the long-term efficacy of imatinib as well as its effects on transplant morbidity, mortality, and risk of relapse remain unknown (Schiffer, 2007).

The transformation phase can be insidious or rapid; it marks the process of evolution (or transformation) to the acute form of leukemia (blast crisis). In the transformation phase, the patient may complain of bone pain and may report fevers (without any obvious sign of infection) and weight loss. Even with chemotherapy, the spleen may continue to enlarge. The patient may become more anemic and thrombocytopenic; an increased basophil level is detected by the CBC.

In the acute form of CML (blast crisis), treatment may resemble induction therapy for acute leukemia, using the same medications as for AML or acute lymphocytic leukemia. Patients whose disease evolves into a “lymphoid” blast crisis are more likely to be able to reenter a chronic phase after induction therapy. For those whose disease evolves into AML, therapy has been largely ineffective in achieving a second chronic phase. However, an increased dose of imatinib or dasatinib can be effective in the later stages of CML. Nonetheless, life-threatening infections and bleeding occur frequently in this phase.

In rare instances, when a purely palliative approach is desired, the therapeutic approach focuses on reducing the leukocyte count to a more normal level but does not alter cytogenetic changes. This goal can be achieved by using oral chemotherapeutic agents, typically hydroxyurea or busulfan (Myleran). In the case of an extreme leukocytosis at diagnosis (eg, leukocyte count greater than 300,000/mm³), a more emergent treatment may be required. In this instance, leukapheresis (in which the patient’s blood is removed and separated, with the leukocytes withdrawn and the remaining blood returned to the patient) can temporarily reduce the number of leukocytes. An anthracycline chemotherapeutic agent (eg, daunomycin [Cerubidine]) may also be used to bring the leukocyte count down quickly to a safer level, where more conservative therapy can be instituted.

Acute Lymphocytic Leukemia

Acute lymphocytic leukemia (ALL) results from an uncontrolled proliferation of immature cells (lymphoblasts) derived from the lymphoid stem cell. The cell of origin is the precursor to the B lymphocyte in approximately 75% of ALL cases; T-lymphocyte ALL occurs in approximately 25% of cases. The *BCR-ABL* translocation (see earlier discussion) is found in 20% of ALL blast cells. ALL is most common in young children, with boys affected more often than girls; the peak incidence is 4 years of age. After 15 years of age, it is relatively uncommon. ALL is responsive to treatment; complete remission rates are extremely high in children (98%) and 85% for adults (Pui & Evans, 2006). Increasing age appears to be associated with diminished survival; the 5-year event-free survival rate is almost 80% for children with ALL but drops to 40% for adults (Pui & Evans, 2006). Yet even if relapse occurs, resumption of induction therapy can often achieve a second complete remission. Moreover, BMT may be successful even after a second relapse, particularly in certain subsets of patients

(eg, those with Philadelphia chromosome–positive ALL [Ph+ ALL]) (Chim, Lie, Liang, et al., 2007).

Clinical Manifestations

Immature lymphocytes proliferate in the marrow and impede the development of normal myeloid cells. As a result, normal hematopoiesis is inhibited, resulting in reduced numbers of leukocytes, erythrocytes, and platelets. Leukocyte counts may be either low or high, but there is always a high proportion of immature cells. Manifestations of leukemic cell infiltration into other organs are more common with ALL than with other forms of leukemia and include pain from an enlarged liver or spleen and bone pain. The central nervous system is frequently a site for leukemic cells; thus, patients may exhibit headache and vomiting because of meningeal involvement. Other extranodal sites include the testes and breasts.

Medical Management

The expected outcome of treatment is complete remission. Due to the heterogeneity of the disease, treatment plans are based on genetic markers of the disease, as well as risk factors of the patient, primarily age (Pui & Evans, 2006). Because ALL frequently invades the central nervous system, preventive cranial irradiation or intrathecal chemotherapy (eg, methotrexate) or both is also a key part of the treatment plan.

Treatment protocols for ALL tend to be complex, using a wide variety of chemotherapeutic agents. Lymphoid blast cells are typically very sensitive to corticosteroids and to vinca alkaloids; therefore, these medications are an integral part of the initial induction therapy. Typically, an anthracycline is included, sometimes with asparaginase (Elspar). Once a patient is in remission, intensification therapy (consolidation) ensues. In the adult with ALL, allogeneic transplant may be used for intensification therapy. Transplant greatly improves long-term disease-free survival, although the risks of death or long-term morbidity are associated with the procedure. For those for whom transplant is not an option (or is reserved for relapse), a prolonged maintenance phase ensues, when lower doses of medications are given for up to 3 years. Despite its complexity, treatment can be provided in the outpatient setting in some circumstances until severe complications develop. Imatinib appears effective in patients with Philadelphia chromosome–positive ALL. Monoclonal antibodies, in which the antibody specific for the antigen expressed on the ALL blast cell is selected for treatment, are also under study (Pui & Evans, 2006). For example, the CD52 antigen is expressed on approximately 70% of ALL cells; thus, alemtuzumab (Campath), a monoclonal antibody with specific affinity for the CD52 antigen, may be effective therapy for this subset of patients.

Infections, especially viral infections, are common. The use of corticosteroids to treat ALL increases the patient's susceptibility to infection. Patients with ALL tend to have a better response to treatment than do patients with AML. BMT or PBSCT offers a chance for prolonged remission, or even cure, if the illness recurs after therapy.

Nursing Management

Nursing management of the patient with acute leukemia is presented at the end of the leukemia section in this chapter.

Chronic Lymphocytic Leukemia

CLL is a common malignancy of older adults; the average age at diagnosis is 72 years (ACS, 2007). CLL is the most common form of leukemia in the United States and Europe, affecting more than 120,000 people. It is rarely seen in Native Americans and infrequently among persons of Asian descent. On average, patients with CLL survive 15 years (early-stage CLL); this period may be as low as 3 to 4 years (late-stage CLL) (Montserrat, 2006).

Pathophysiology

CLL is typically derived from a malignant clone of B lymphocytes (T-lymphocyte CLL is rare). In contrast to the acute forms of leukemia, most of the leukemia cells in CLL are fully mature. It was initially hypothesized that these cells can escape apoptosis (programmed cell death), resulting in an excessive accumulation of the cells in the marrow and circulation. However, this hypothesis is now being questioned (Chiorazzi & Ferrarini, 2006). The disease is classified into three or four stages (two classification systems are in use). In the early stage, an elevated lymphocyte count is seen; it can exceed 100,000/mm³. Because the lymphocytes are small, they can easily travel through the small capillaries within the circulation, and the pulmonary and cerebral complications of leukocytosis (as seen with myeloid leukemias) typically are not found in CLL. Lymphadenopathy occurs as the lymphocytes are trapped within the lymph nodes. The nodes can become very large and are sometimes painful. Hepatomegaly and splenomegaly then develop.

In later stages, anemia and thrombocytopenia may develop. Autoimmune complications can also occur at any stage, as either autoimmune hemolytic anemia or idiopathic thrombocytopenic purpura. In the autoimmune process, the RES destroys the body's own erythrocytes or platelets.

More sophisticated prognostic markers have recently been identified (Montserrat, 2006). Beta₂-microglobulin, a protein found on the surface of lymphocytes, can be measured in the serum; an elevated level correlates with more advanced clinical stage and poorer prognosis. Cytogenetic analysis is also useful.

Clinical Manifestations

Many patients are asymptomatic and are diagnosed incidentally during routine physical examinations or during treatment for another disease. An increased lymphocyte count (lymphocytosis) is always present. The erythrocyte and platelet counts may be normal or, in later stages of the illness, decreased. Enlargement of lymph nodes (lymphadenopathy) is common; this can be severe and sometimes painful. The spleen can also be enlarged (splenomegaly).

Patients with CLL can develop "B symptoms," a constellation of symptoms including fevers, drenching sweats (especially at night), and unintentional weight loss. Patients with CLL have defects in their humoral and cell-mediated immune systems; therefore, infections are common. The defect in cellular immunity is evidenced by an absent or decreased reaction to skin sensitivity tests (eg, *Candida*, mumps), which is known as **anergy**. Life-threatening infections are common, particularly with advanced disease. Viral infections, such as

herpes zoster, can become widely disseminated. Defects in the complement system are also seen, which results in increased risk of developing infection with encapsulated organisms (eg, *Haemophilus influenzae*) (Moran, Browning, Buckby, et al., 2007).

Medical Management

A major paradigm shift has occurred in CLL therapy. For years, there appeared to be no survival advantage in treating CLL in its early stages. However, with the advent of more sensitive means of assessing therapeutic response, it has been demonstrated that achieving a complete remission and eradicating even minimal residual disease results in improved survival (Tam & Keating, 2007). Even if treatment is not initiated early in the course of the illness, it typically begins when symptoms are severe (drenching night sweats, painful lymphadenopathy) or when the disease progresses to later stages (with resultant anemia and thrombocytopenia).

The chemotherapy agents fludarabine (Fludara) and cyclophosphamide (Cytosan) are often given in combination with the monoclonal antibody rituximab (Rituxan). This regimen can result in remission that lasts for 5 years in 70% of patients. The major side effect of fludarabine is prolonged bone marrow suppression, manifested by prolonged periods of neutropenia, lymphopenia, and thrombocytopenia, which puts patients at risk for such infections as *Pneumocystis jirovecii*, *Listeria*, mycobacteria, herpes viruses, and cytomegalovirus (CMV). The monoclonal antibody alemtuzumab (Campath) is often used in combination with other chemotherapeutic agents when the disease is refractory to fludarabine, the patient has very poor prognostic markers, or it is necessary to eradicate residual disease after initial treatment (Tam & Keating, 2007). Alemtuzumab targets the CD52 antigen commonly found on CLL cells, and it is effective in clearing the marrow and circulation of these cells without affecting the stem cells. Because CD52 is present on both B and T lymphocytes, patients receiving alemtuzumab are at significant risk for infection; prophylactic use of antiviral agents and antibiotics (eg, trimethoprim/sulfamethoxazole [Bactrim, Septra]) is important and needs to continue for several months after treatment ends. Bacterial infections are common in patients with CLL, and IV treatment with immunoglobulin may be given to selected patients with recurrent infection.

findings may be subtle initially, a thorough, systematic assessment incorporating all body systems is essential. For example, a dry cough, mild dyspnea, and diminished breath sounds may indicate a pulmonary infection. However, the infection may not be seen initially on the chest x-ray; the absence of neutrophils delays the inflammatory response against the pulmonary infection, thus delaying the changes seen on x-ray. The platelet count can become dangerously low, leaving the patient at risk for significant bleeding. The specific body system assessments are delineated in the neutropenic precautions and bleeding precautions found in Charts 33-6 and 33-8, respectively. When serial assessments are performed, current findings are compared with previous findings to evaluate improvement or worsening.

The nurse also must closely monitor the results of laboratory studies. Flow sheets and spreadsheets are particularly useful in tracking the leukocyte count, ANC, hematocrit, platelet, creatinine and electrolyte levels, and hepatic function tests. Culture results need to be reported immediately so that appropriate antimicrobial therapy can begin or be modified.

Diagnosis

Nursing Diagnoses

Based on the assessment data, major nursing diagnoses for the patient with acute leukemia may include:

- Risk for infection and bleeding
- Risk for impaired skin integrity related to toxic effects of chemotherapy, alteration in nutrition, and impaired mobility
- Impaired gas exchange
- Impaired mucous membranes due to changes in epithelial lining of the GI tract from chemotherapy or prolonged use of antimicrobial medications
- Imbalanced nutrition, less than body requirements, related to hypermetabolic state, anorexia, mucositis, pain, and nausea
- Acute pain and discomfort related to mucositis, leukocyte infiltration of systemic tissues, fever, and infection
- Hyperthermia related to tumor lysis or infection
- Fatigue and activity intolerance related to anemia, infection, and deconditioning
- Impaired physical mobility due to anemia, malaise, discomfort, and protective isolation
- Risk for excess fluid volume related to renal dysfunction, hypoproteinemia, and need for multiple IV medications and blood products
- Diarrhea due to altered GI flora, mucosal denudation, and prolonged use of broad-spectrum antibiotics
- Risk for deficient fluid volume related to potential for diarrhea, bleeding, infection, and increased metabolic rate
- Self-care deficit due to fatigue, malaise, and protective isolation
- Anxiety due to knowledge deficit and uncertainty about future
- Disturbed body image related to change in appearance, function, and roles
- Grieving related to anticipatory loss and altered role functioning

NURSING PROCESS

THE PATIENT WITH ACUTE LEUKEMIA

Assessment

Although the clinical picture varies with the type of leukemia as well as the treatment implemented, the health history may reveal a range of subtle symptoms reported by the patient before the problem is detectable on physical examination. Weakness and fatigue are common manifestations, not only of the leukemia, but also of the resulting complications of anemia and infection. If the patient is hospitalized, the assessments should be performed daily, or more frequently as warranted. Because the physical

Chart 33-8 • Bleeding Precautions**Nursing Diagnosis**

Risk for injury/bleeding secondary to thrombocytopenia/ altered coagulation due to:

- Malignant invasion in bone marrow
- Bone marrow suppression resulting from chemotherapy (particularly alkylators, antitumor antibiotics, antimetabolites) and radiation therapy
- Hypersplenism
- Disseminated intravascular coagulation (DIC)
- Altered coagulation

Assessment**Patient**

Assess the following systems thoroughly every shift (with spot checks throughout the shift if patient is hospitalized), and notify physician if there is new onset of the following and/or worsening of status:

- *Integumentary:* Petechiae (usually located on trunk, legs), ecchymoses or hematomas, conjunctival hemorrhages, bleeding gums, bleeding at puncture sites (venipuncture, lumbar puncture, bone marrow)
- *Cardiovascular:* Hypotension, tachycardia, dizziness, epistaxis
- *Pulmonary:* Respiratory distress, tachypnea
- *Gastrointestinal:* Hemoptysis, abdominal distention, rectal bleeding
- *Genitourinary:* Vaginal or urethral bleeding; initiate pad count for menstruating patients
- *Neurologic:* Headache, blurred vision, mental status changes

Laboratory Tests

- Monitor complete blood count (CBC), platelets daily (at least); coagulation panel.
- Notify physician if platelet count is $<10,000/\text{mm}^3$ or if count has changed significantly from previous count (including coagulation), or whenever patient becomes symptomatic.
- Ensure patient's blood was human leukocyte antigen (HLA) typed before transfusions or chemotherapy begins if admitted for induction therapy (eg, for acute leukemia).
- Obtain 1-hour posttransfusion platelet count if prescribed.
- Test all urine, emesis, stools for occult blood.

Nursing Interventions**Prevent Complications**

- Avoid aspirin and aspirin-containing medications or other medications known to inhibit platelet function, if possible.

- Do not give intramuscular injections.
- Avoid indwelling catheters if at all possible.
- Take no rectal temperatures; do not give suppositories, enemas.
- Use stool softeners, oral laxatives to prevent constipation.
- Induce amenorrhea with oral contraceptives (do not administer the placebo pills).
- Use smallest possible needles when performing venipuncture.
- Apply pressure to venipuncture sites for 5 minutes or until bleeding has stopped.
- Permit no flossing of teeth and no commercial mouthwashes.
- Use only soft-bristled toothbrush for mouth care.
- Consider using toothettes for mouth care if platelet count is $<10,000/\text{mm}^3$, or if gums bleed.
- Lubricate lips with water-soluble lubricant every 2 hours while awake.
- Avoid suctioning if at all possible; if unavoidable, use only gentle suctioning.
- Discourage vigorous coughing or blowing of the nose.
- Use only electric razor for shaving.
- Pad side rails as needed.
- Prevent falls by ambulating with patient as necessary.

Control Bleeding

- Apply direct pressure.
- For epistaxis, position patient in high Fowler's position; apply ice pack to back of neck and direct pressure to nose.
- Notify physician for prolonged bleeding (eg, unable to stop within 10 minutes).
- Administer platelets, fresh-frozen plasma, packed red blood cells, as prescribed.

Evaluation and Expected Patient Outcomes

- Patient demonstrates an absence of bleeding as evidenced by absence of spontaneous petechiae, ecchymoses, epistaxis, hemoptysis, bleeding gums, conjunctival hemorrhage, vaginal bleeding, hematuria, heme-positive stool, blurred vision, orthostatic hypotension, and prolonged bleeding from puncture sites.
- Patient demonstrates an absence of bleeding as evidenced by the presence of vital signs within normal limits and intact neurologic status.

*Serious hemorrhage is unusual in mildly thrombocytopenic patients in absence of local lesions (peptic ulcer, bleeding from hemorrhoids, cystitis).

- Potential for spiritual distress
- Deficient knowledge about disease process, treatment, complication management, and self-care measures

Collaborative Problems/Potential Complications

Based on the assessment data, potential complications that may develop include:

- Infection
- Bleeding/DIC
- Renal dysfunction
- Tumor lysis syndrome

- Nutritional depletion
- Mucositis
- Depression and anxiety

Planning and Goals

The major goals for the patient may include absence of complications and pain, attainment and maintenance of adequate nutrition, activity tolerance, ability to provide self-care and to cope with the diagnosis and prognosis, positive body image, and an understanding of the disease process and its treatment.

Nursing Interventions

Preventing or Managing Infection and Bleeding

The nursing interventions related to diminishing the risk of infection and bleeding are delineated in Charts 33-6 and 33-8.

Managing Mucositis

Although emphasis is placed on the oral mucosa, the entire GI mucosa can be altered, not only by the effects of chemotherapy but also from prolonged administration of antibiotics. See Chapter 16 for assessment and management of mucositis.

Improving Nutritional Intake

The disease process can increase the patient's metabolic rate and nutritional requirements. (Sepsis further increases them.) Nutritional intake is often reduced because of pain and discomfort associated with stomatitis. Encouraging or providing mouth care before and after meals and the administration of analgesic agents before eating can help increase intake. If oral anesthetic agents are used, the patient must be warned to chew with extreme care to avoid inadvertently biting the tongue or buccal mucosa.

Nausea should not deter nutritional intake, because antiemetic therapy is highly effective. However, nausea can result from antimicrobial therapy, so some antiemetic therapy may still be required after the chemotherapy has been completed.

Small, frequent feedings of foods that are soft in texture and moderate in temperature may be better tolerated. Low-microbial diets may be prescribed (avoiding uncooked fruits or vegetables and those without a peelable skin), although there is little evidence to support this intervention (Zitella, Friese, Hauser, et al., 2006). Nutritional supplements are frequently used. Daily body weight (as well as intake and output measurements) is useful in monitoring fluid status. Both calorie counts and more formal nutritional assessments are useful. Parenteral nutrition is often required to maintain adequate nutrition.

Easing Pain and Discomfort

Recurrent fevers are common in acute leukemia; at times, they are accompanied by shaking chills (rigors), which can be severe. Myalgias and arthralgias can result. Acetaminophen is typically given to decrease fever, but it does so by increasing diaphoresis. Sponging with cool water may be useful, but cold water or ice packs should be avoided because the heat cannot dissipate from constricted blood vessels. Bedclothes need frequent changing as well. Gentle back and shoulder massage may provide comfort.

Mucositis can also cause significant discomfort. In addition to oral hygiene practices, PCA can be effective in controlling the pain (see Chapter 13). With the exception of severe mucositis, less pain is associated with acute leukemia than with many other forms of cancer. However, the amount of psychological suffering that the patient must endure can be immense. Patients often benefit from active listening.

Because patients with acute leukemia require hospitalization for extensive nursing care (either during induction or consolidation therapy or during resultant complications),

sleep deprivation frequently results. Nurses need to implement creative strategies that permit uninterrupted sleep for at least a few hours while still administering necessary medications on time.

Decreasing Fatigue and Deconditioning

Fatigue is a common and oppressive symptom. Nursing interventions should focus on assisting the patient to establish a balance between activity and rest. Patients with acute leukemia need to maintain some physical activity and exercise to prevent the deconditioning that results from inactivity. Use of a high-efficiency particulate air (HEPA) filter mask can permit the patient to ambulate outside the room despite severe neutropenia. Stationary bicycles may also be set up in the room; however, many patients lack the motivation or stamina to use them. At a minimum, patients should be encouraged to sit up in a chair while awake rather than staying in bed; even this simple activity can improve the patient's tidal volume and enhance circulation. Physical therapy can also be beneficial.

Maintaining Fluid and Electrolyte Balance

Febrile episodes, bleeding, and inadequate or overly aggressive fluid replacement can alter the patient's fluid status. Similarly, persistent diarrhea, vomiting, and long-term use of certain antimicrobial agents can cause significant deficits in electrolytes. Intake and output need to be measured accurately, and daily weights should also be monitored. The patient should be assessed for signs of dehydration as well as fluid overload, with particular attention to pulmonary status and the development of dependent edema. Laboratory test results, particularly electrolytes, blood urea nitrogen, creatinine, and hematocrit, should be monitored and compared with previous results. Replacement of electrolytes, particularly potassium and magnesium, is commonly required. Patients receiving amphotericin or certain antibiotics are at increased risk for electrolyte depletion.

Improving Self-Care

Because hygiene measures are so important in this patient population, they must be performed by the nurse when the patient cannot do so. However, the patient should be encouraged to do as much as possible to preserve mobility and function as well as self-esteem. Patients may have negative feelings because they can no longer care for themselves. Empathetic listening is helpful, as is realistic reassurance that these deficits are temporary. As the patient recovers, it is important to assist him or her to resume more self-care. Patients are usually discharged from the hospital with a vascular access device (eg, Hickman catheter, peripherally inserted central catheter [PICC]), and most patients can care for the catheter with adequate instruction and practice under observation.

Managing Anxiety and Grief

Being diagnosed with acute leukemia can be extremely frightening. In many instances, the need to begin treatment is emergent, and the patient has little time to process the fact that he or she has the illness before making decisions about therapy. Providing emotional support and discussing the uncertain future are crucial. The nurse also needs to assess how much information the patient wants to have regarding the

illness, its treatment, and potential complications. This desire should be reassessed at intervals, because needs and interest in information change throughout the course of the disease and treatment. Priorities must be identified so that procedures, assessments, and self-care expectations are adequately explained even to those who do not wish extensive information.

Many patients become depressed and begin to grieve for the losses they feel, such as normal family functioning, professional roles and responsibilities, and social roles, as well as physical functioning. The nurse can assist the patient to identify the source of the grief and encourage him or her to allow time to adjust to the major life changes produced by the illness. Role restructuring, in both family and professional life, may be required. Again, when possible, encouraging the patient to identify options and to take time making important decisions is helpful.

Discharge from the hospital can also provoke anxiety. Although most patients are eager to go home, they may lack confidence in their ability to manage potential complications and to resume their normal activity. Close communication between nurses across care settings can reassure patients that they will not be abandoned.

Encouraging Spiritual Well-Being

Because acute leukemia is a serious, potentially life-threatening illness, the nurse may offer support to enhance the patient's spiritual well-being. The patient's spiritual and religious practices should be assessed and pastoral services offered. Throughout the patient's illness, it is important that the nurse assist the patient to maintain hope. However, that hope should be realistic and will certainly change over the course of the illness. For example, the patient may initially hope to be cured, but with repeated relapses and a change to hospice or palliative care the same patient may hope for a quiet, dignified death. (Refer to Chapter 17 for a discussion of end-of-life care.)

Promoting Home and Community-Based Care

TEACHING PATIENTS SELF-CARE. Most patients cope better when they have an understanding of what is happening to them. Based on their education, literacy level, and interest, teaching of the patient and family should focus on the disease (including some pathophysiology), its treatment, and certainly the resulting significant risk of infection and bleeding (see Charts 33-6 and 33-8).

Management of a vascular access device can be taught to most patients or family members. Nurses in outpatient facilities or home care nurses may need to provide follow-up care for patients with vascular access devices.

CONTINUING CARE. Shortened hospital stays and outpatient care have significantly altered care for patients with acute leukemia. In many instances, when the patient is clinically stable but still requires parenteral antibiotics or blood products, these procedures can be performed in an outpatient setting. Nurses in these various settings must communicate regularly. They need to tell the patient which parameters are important to monitor and how to monitor them, and give the patient specific instructions about when to seek care from the physician or other health care

provider. The primary care provider is responsible for monitoring the patient who is cured or in sustained remission.

The patient and family need to have a clear understanding of the disease, the prognosis, and how to monitor for complications or recurrence. The nurse ensures that this information is provided. Should the patient no longer respond to therapy, it is important to respect the patient's choices about treatment, including measures to prolong life and other end-of-life measures. Advance directives, including living wills, provide patients with some measure of control during terminal illness.

Most patients in this stage choose to be cared for at home, and families often need support when considering this option. Coordination of home care services and instruction can help alleviate anxiety about managing the patient's care in the home. As the patient becomes weaker, the caregivers must assume more of the patient's care. In addition, caregivers often need to be encouraged to take care of themselves, allowing time for rest and accepting emotional support. Hospice staff can assist in providing respite for family members as well as care for the patient. Patients and families also need assistance to cope with changes in their roles and responsibilities. Anticipatory grieving is an essential task during this time (see Chapter 17).

In patients with acute leukemia, death typically occurs from infection or bleeding. Family members need to have information about these complications and the measures to take should either occur. Many family members cannot cope with the care required when a patient begins to bleed actively. It is important to delineate alternatives to keeping the patient at home, such as inpatient hospice units. Should another option be sought, family members who may feel guilty that they could not keep the patient at home will require support from the nurse.

Evaluation

Expected Patient Outcomes

Expected patient outcomes may include:

1. Shows no evidence of infection
2. Experiences no bleeding
3. Has intact oral mucous membranes
 - a. Participates in oral hygiene regimen
 - b. Reports no discomfort in mouth
4. Attains optimal level of nutrition
 - a. Maintains weight with increased food and fluid intake
 - b. Maintains adequate protein stores (eg, albumin, prealbumin)
5. Reports satisfaction with pain and comfort levels
6. Has less fatigue and increased activity
7. Maintains fluid and electrolyte balance
8. Participates in self-care
9. Copes with anxiety and grief
 - a. Discusses concerns and fears
 - b. Uses stress management strategies appropriately
 - c. Participates in decisions regarding end-of-life care
 - d. Discusses hope for peaceful death
10. Absence of complications

MYELOFIBROSIS

Myelofibrosis, also known as agnogenic myeloid metaplasia (AMM) or myelofibrosis with myeloid metaplasia (MMM), is a chronic myeloproliferative disorder that arises from neoplastic transformation of an early hematopoietic stem cell. The disease is characterized by marrow fibrosis or scarring, extramedullary hematopoiesis (typically involving the spleen and the liver), leukocytosis, thrombocytosis, and anemia. Some patients have diminished leukocyte, platelet, and erythrocyte counts (ie, pancytopenia). Patients with myelofibrosis have increased **angiogenesis** (formation of new blood vessels) within the marrow. Early forms of blood cells (including nucleated RBCs and megakaryocyte fragments) are frequently found in the circulation. Symptoms may result from an often profoundly enlarged spleen, causing discomfort and early satiety, fatigue, infection and bleeding (from pancytopenia), and cachexia.

Myelofibrosis is a disease of the elderly, with a median age at diagnosis of 65 years. Average survival ranges from 3 to 10 years based on the occurrence of such adverse prognostic indicators as pancytopenia, leukocytosis, presence of blast cells in the circulation, poor-risk cytogenetic results, and constitutional symptoms (eg, fever, night sweats, fatigue, cachexia) (Tefferi, Barosi, Mesa, et al., 2006; Hoffman & Rondelli, 2007). Common causes of death are heart or liver failure, portal hypertension, complications of marrow failure, and transformation to AML. AML is especially difficult to treat successfully in these cases; average survival rate posttransplant is 2.6 months (Mesa, Li, Ketterling, et al., 2005).

Medical Management

BMT or PBSCT is a useful treatment modality in younger, otherwise healthy people. For patients who are not candidates for transplant, medical management is directed toward palliation, reducing symptoms related to cytopenias, splenomegaly, and hypermetabolic state. Although one third of anemic patients respond to the combination of an androgen plus a corticosteroid, the primary treatment remains PRBC transfusion. Because of the prolonged requirement for these transfusions, iron overload is a common problem. Iron chelation therapy should be initiated in patients in whom survival is expected to exceed a few years. Hydroxyurea is often used to control high leukocyte and platelet counts and to reduce the size of the spleen.

Splenectomy may also be used to control the significant problems that result from a massively enlarged spleen. The mortality rate associated with this procedure is 6.7% (Mesa, Nagorney, Schwager, et al., 2006). Furthermore, a reactive thrombocytosis and leukocytosis can develop because the cells are no longer sequestered out of the circulation. Therefore, the decision to undergo splenectomy warrants careful consideration of the advantages and disadvantages.

Nursing Management

Splenomegaly can be profound in patients with myelofibrosis, with enlargement of the spleen that may extend to the pelvic rim. This condition is extremely uncomfortable and

can severely limit nutritional intake. Analgesic agents are often ineffective. Methods to reduce the size of the spleen are usually more effective in controlling pain. Splenomegaly, coupled with a hypermetabolic state, results in weight loss (often severe) and muscle wasting. Patients benefit from very small, frequent meals of foods that are high in calories and protein. Weakness, fatigue, and altered body image are other significant problems. Energy conservation methods and active listening are important nursing interventions. The patient needs to be educated about signs and symptoms of infection, bleeding, and thrombosis, as well as appropriate interventions if these occur.

LYMPHOMA

The lymphomas are neoplasms of cells of lymphoid origin. These tumors usually start in lymph nodes but can involve lymphoid tissue in the spleen, GI tract (eg, the wall of the stomach), liver, or bone marrow. They are often classified according to the degree of cell differentiation and the origin of the predominant malignant cell. Lymphomas can be broadly classified into two categories: Hodgkin lymphoma and non-Hodgkin lymphoma (NHL).

Hodgkin Lymphoma

Hodgkin lymphoma is a relatively rare malignancy that has an impressive cure rate. It is somewhat more common in men than women and has two peaks of incidence: one in the early 20s and the other after 50 years of age. Disease occurrence has a familial pattern: First-degree relatives have a higher-than-normal frequency of disease, but the actual incidence of this pattern is low. No increased incidence for nonblood relatives (eg, spouses) has been documented. Hodgkin lymphoma is seen more commonly in patients receiving chronic immunosuppressive therapy (eg, for renal transplant) and also in veterans of the military who were exposed to the herbicide Agent Orange.

Pathophysiology

Unlike other lymphomas, Hodgkin lymphoma is unicentric in origin in that it initiates in a single node. The disease spreads by contiguous extension along the lymphatic system. The malignant cell of Hodgkin lymphoma is the Reed-Sternberg cell, a gigantic tumor cell that is morphologically unique and is thought to be of immature lymphoid origin. It is the pathologic hallmark and essential diagnostic criterion. However, the tumor is very heterogeneous and may actually contain few Reed-Sternberg cells. Repeated biopsies may be required to establish the diagnosis.

The cause of Hodgkin lymphoma is unknown, but a viral etiology is suspected. Although fragments of the Epstein-Barr virus have been found in some Reed-Sternberg cells, the precise role of this virus in the development of Hodgkin lymphoma remains unknown.

Hodgkin lymphoma is customarily classified into five subgroups based on pathologic analyses that reflect the natural history of the malignancy and suggest the prognosis.

For example, when lymphocytes predominate, with few Reed-Sternberg cells and minimal involvement of the lymph nodes, the prognosis is much more favorable than when the lymphocyte count is low and the lymph nodes are virtually replaced by tumor cells of the most primitive type. Most patients with Hodgkin lymphoma have the types currently designated “nodular sclerosis” or “mixed cellularity.” The nodular sclerosis type tends to occur more often in young women, at an earlier stage but with a worse prognosis than the mixed cellularity subgroup, which occurs more commonly in men and causes more constitutional symptoms but has a better prognosis.

Clinical Manifestations

Hodgkin lymphoma usually begins as a painless enlargement of one or more lymph nodes on one side of the neck. The individual nodes are painless and firm but not hard. The most common sites for lymphadenopathy are the cervical, supraclavicular, and mediastinal nodes; involvement of the iliac or inguinal nodes or spleen is much less common. A mediastinal mass may be seen on chest x-ray; occasionally, the mass is large enough to compress the trachea and cause dyspnea. Pruritus is common; it can be extremely distressing, and the cause is unknown. Some patients experience brief but severe pain after drinking alcohol, usually at the site of the tumor. Again, the cause of this is unknown.

All organs are vulnerable to invasion by tumor cells. The symptoms result from compression of organs by the tumor, such as cough and pulmonary effusion (from pulmonary infiltrates), jaundice (from hepatic involvement or bile duct obstruction), abdominal pain (from splenomegaly or retroperitoneal adenopathy), or bone pain (from skeletal involvement). Herpes zoster infections are common. A cluster of constitutional symptoms has important prognostic implications. Referred to as “B symptoms,” they include fever (without chills), drenching sweats (particularly at night), and unintentional weight loss of more than 10% of body weight. B symptoms are found in 40% of patients and are more common in advanced disease.

A mild anemia is the most common hematologic finding. The leukocyte count may be elevated or decreased. The platelet count is typically normal, unless the tumor has invaded the bone marrow, suppressing hematopoiesis. The **erythrocyte sedimentation rate (ESR)** and the serum copper level are used by some clinicians to assess disease activity. Patients with Hodgkin lymphoma have impaired cellular immunity, as evidenced by an absent or decreased reaction to skin sensitivity tests (eg, *Candida*, mumps).

Assessment and Diagnostic Findings

Because many manifestations are similar to those occurring with infection, diagnostic studies are performed to rule out an infectious origin for the disease. The diagnosis is made by means of an excisional lymph node biopsy and the finding of the Reed-Sternberg cell. Once the diagnosis is confirmed and the histologic type is established, it is necessary to assess the extent of the disease, a process referred to as staging.

During the health history, the patient is assessed for any B symptoms. Physical examination requires a careful, systematic evaluation of the lymph node chains, as well as the size of the spleen and liver. A chest x-ray and a CT scan of

the chest, abdomen, and pelvis are crucial to identify the extent of lymphadenopathy within these regions. A positron emission tomography (PET) scan may be the most sensitive imaging test in identifying residual disease. Laboratory tests include CBC, platelet count, ESR, and liver and renal function studies. A bone marrow biopsy is performed if there are signs of marrow involvement, and some physicians routinely perform bilateral biopsies. Bone scans may be performed.

Medical Management

The general goal in the treatment of Hodgkin lymphoma is cure. Treatment is determined primarily by the stage of the disease, not the histologic type; however, extensive research is ongoing to target treatment regimens to histologic subtypes or prognostic features. Treatment of limited-stage Hodgkin lymphoma commonly involves a short course (2 to 4 months) of chemotherapy followed by radiation therapy to the specific involved area. This strategy has reduced the amount of radiation dosage, with subsequent decrease in long-term side effects (particularly second malignancies and late cardiovascular events) without decreasing the likelihood of controlling the disease (Gospodarowicz & Meyer, 2006). Combination chemotherapy with doxorubicin (Adriamycin), bleomycin (Blenoxane), vinblastine (Velban), and dacarbazine (DTIC), referred to as ABVD, is often considered the standard treatment for more advanced disease (stages III and IV and all stages with B symptoms). Other combinations of chemotherapy may afford higher response rates but result in more toxicity (Horning, 2007).

In addition, chemotherapy is often successful in obtaining remission even when relapse occurs. Transplant is used for advanced or refractory disease. Revised treatment approaches are aimed at diminishing the risk of complications without sacrificing the potential for cure.

Long-Term Complications of Therapy

Much is now known about the long-term effects of chemotherapy and radiation therapy. The complications of treatment are listed in Chart 33-9. Risk factors for other cancers should be assessed, and long-term surveillance is crucial. In large population-based studies of Hodgkin’s survivors, the reported actuarial risk of developing a second cancer was 21.9%. Lung cancer is the most common type of second malignancy, particularly following higher doses of thoracic radiation. However, breast cancer appears to be more common in women, particularly in those who were treated with thoracic radiation when younger than 30 years of age (Gospodarowicz & Meyer, 2006). Coronary artery disease is also common, and the risk increases over time.

A systematic review of seven quality-of-life studies of survivors of Hodgkin lymphoma (5 to 14 years since diagnosis) found that fatigue was a long-lasting effect of treatment that did not diminish over time. Mental fatigue was also higher compared with controls, and it appeared to be greater in older patients. In addition, lack of social support was an issue (Bloom, Petersen & Kang, 2007).

Nursing Management

The potential development of a second malignancy should be addressed with the patient when treatment decisions are made. However, it is also important to tell patients that

Chart 33-9 • Potential Long-Term Complications of Therapy for Hodgkin Lymphoma

Immune dysfunction
 Herpes infections (zoster and varicella)
 Pneumococcal sepsis
 Acute myeloid leukemia (AML)
 Myelodysplastic syndromes (MDS)
 Non-Hodgkin lymphoma
 Solid tumors
 Thyroid cancer
 Thymic hyperplasia
 Hypothyroidism
 Pericarditis (acute or chronic)
 Cardiomyopathy
 Pneumonitis (acute or chronic)
 Dyspnea on exertion
 Abnormalities in senses of taste, smell, and touch
 Abnormal sense of touch
 Abnormal balance, tremors, or weakness
 Avascular necrosis
 Growth retardation
 Infertility
 Decreased libido
 Dental caries
 Dry mouth
 Dysphagia

Hodgkin lymphoma is often curable. The nurse should encourage patients to reduce other factors that increase the risk of developing second cancers, such as use of tobacco and alcohol and exposure to environmental carcinogens and excessive sunlight. Screening for late effects of treatment (see Chart 33-9) is necessary. In addition, the nurse should provide education about relevant self-care strategies and disease management.

Non-Hodgkin Lymphomas

The non-Hodgkin lymphomas (NHLs) are a heterogeneous group of cancers that originate from the neoplastic growth of lymphoid tissue. As in CLL, the neoplastic cells are thought to arise from a single clone of lymphocytes; however, in NHL, the cells may vary morphologically. Most NHLs involve malignant B lymphocytes; only 5% involve T lymphocytes. In contrast to Hodgkin lymphoma, the lymphoid tissues involved are largely infiltrated with malignant cells. The spread of these malignant lymphoid cells occurs unpredictably, and true localized disease is uncommon. Lymph nodes from multiple sites may be infiltrated, as may sites outside the lymphoid system (extranodal tissue).

NHL is now the fifth most common type of cancer diagnosed in the United States. The incidence increases with each decade of life; the median age at diagnosis is 67 years (ACS, 2008c). Although no common etiologic factor has been identified, the incidence of NHL has increased in people with immunodeficiencies or autoimmune disorders; prior treatment for cancer; prior organ transplant; viral in-

fections (including Epstein-Barr virus and HIV); and exposure to pesticides, solvents, dyes, or defoliating agents, including Agent Orange. The prognosis varies greatly among the more than 30 subtypes of NHL. For example, diffuse large B-cell lymphoma, the most common form, accounts for 30% of all newly diagnosed lymphomas (80% of all aggressive types); 5-year survival rates are 26% to 73%. Follicular lymphoma, the second most common form, accounts for 22% of all new cases (70% of all indolent [less aggressive] types); median survival is 8 to 10 years (Sehn, 2006).

Clinical Manifestations

Symptoms are highly variable, reflecting the diverse nature of the NHLs. Lymphadenopathy is most common (66%); however, in indolent types of lymphomas, the lymphadenopathy can wax and wane. With early-stage disease, or with the types that are considered indolent, symptoms may be virtually absent or very minor, and the illness typically is not diagnosed until it progresses to a later stage, when the patient is symptomatic. At these stages (III or IV), lymphadenopathy is distinctly noticeable. One third of patients with NHLs have B symptoms (fever, drenching night sweats, and unintentional weight loss). Lymphomatous masses can compromise organ function. For example, a mass in the mediastinum can cause respiratory distress; abdominal masses can compromise the ureters, leading to renal dysfunction; and splenomegaly can cause abdominal discomfort, nausea, early satiety, anorexia, and weight loss. Involvement of the central nervous system with lymphoma is becoming increasingly common.

Assessment and Diagnostic Findings

The actual diagnosis of NHL is categorized into a highly complex classification system based on histopathology, immunophenotyping, and cytogenetic analyses of the malignant cells. The specific histopathologic type of the disease has important prognostic implications. Treatment also varies and is based on these features. Indolent types tend to have small cells that are distributed in a follicular pattern. Aggressive types tend to have large or immature cells distributed through the nodes in a diffuse pattern. Staging is typically based on data obtained from CT and PET scans, bone marrow biopsies, and occasionally cerebrospinal fluid analysis. The stage is based on the site of disease and its spread to other sites. For example, in stage I disease, only one area of involvement is detected; thus, stage I disease is highly localized and may respond well to localized therapy (eg, radiation therapy). In contrast, in stage IV disease at least one extranodal site is detected.

Although stage of disease is important, often it is not an accurate predictor of prognosis (Thieblemont & Coiffier, 2007). Two prognostic classification systems have been developed that are particularly useful in the elderly patient population, the International Prognostic Index (IPI) and, for follicular lymphomas, the Follicular Lymphoma International Prognostic Index (FLIPI). Age, performance status, lactate dehydrogenase levels, and extent of disease are scored to determine risk of failure or death from disease. Based on the IPI, 5-year overall survival rates range from 73% (low risk) to 26% (high risk) (Sehn, 2006).

Medical Management

Treatment is determined by the classification of disease, the stage of disease, prior treatment (if any), and the patient's ability to tolerate therapy. Tolerance to therapy is largely dictated by renal, hepatic, and cardiac function; the presence of concurrent diseases; functional status; and age. If the disease is not aggressive and is localized, radiation alone may be the treatment of choice. With aggressive types of NHL, aggressive combinations of chemotherapeutic agents are used; the combination of the monoclonal antibody rituximab with conventional chemotherapy (Cytosan, doxorubicin, vincristine, and prednisone [R-CHOP]) is now considered standard treatment for common lymphomas (Thieblemont & Coiffier, 2007). Central nervous system involvement is common with some aggressive forms of NHL; in this situation, cranial radiation or intrathecal chemotherapy is used in addition to systemic chemotherapy.

There is no standard therapy for follicular lymphoma (Morrison, 2007). "Watchful waiting" is often used in those with indolent disease. Rituximab or radiopharmaceutical agents (eg, tositumumab/iodine-131 [Bexxar] or ibritumomab tiuxetan [Zevalin]) are also used, although the latter agents cause technical difficulties with administration due to the radioactivity of the agent. More aggressive treatment (often R-CHOP) may provide a longer duration of remission in which additional treatment is not needed. Unfortunately, in most situations, relapse is commonly seen in patients with low-grade lymphomas. Treatment after relapse is controversial. BMT or PBSCT may be considered for patients younger than 60 years of age (see Chapter 16).

Nursing Management

Lymphoma is a highly complex constellation of diseases. When caring for patients with lymphoma, it is extremely important to know the specific disease type, stage of disease, treatment history, and current treatment plan. Most of the care for patients with Hodgkin lymphoma or NHL takes place in the outpatient setting, unless complications occur (eg, infection, respiratory compromise due to mediastinal mass). The most commonly used treatment methods are chemotherapy and radiation therapy. Chemotherapy causes systemic side effects (eg, myelosuppression, nausea, hair loss, risk of infection), whereas radiation therapy causes specific side effects that are limited to the area being irradiated. For example, patients receiving abdominal radiation therapy may experience nausea and diarrhea but not hair loss. Regardless of the type of treatment, all patients may experience fatigue.

The risk of infection is significant for these patients, not only from treatment-related myelosuppression but also from the defective immune response that results from the disease itself. Patients need to be taught to minimize the risks of infection, to recognize signs of possible infection, and to contact their health care provider if such signs develop (see Chart 33-5).

Additional complications depend on the location of the lymphoma. Therefore, it is important for the nurse to know the tumor location so that assessments can be targeted appropriately. For example, patients with lymphomatous masses in the upper chest should be assessed for superior

vena cava obstruction or airway obstruction, if the mass is near the bronchus or trachea.

Many lymphomas can be cured with current treatments. However, as survival rates increase, the incidence of second malignancies, particularly AML or MDS, also increases. Therefore, survivors should be screened regularly for the development of second malignancies.

MULTIPLE MYELOMA

Multiple myeloma is a malignant disease of the most mature form of B lymphocyte, the plasma cell. Plasma cells secrete immunoglobulins, proteins necessary for antibody production to fight infection. Myeloma is the second most common hematologic cancer in the United States (Katzel, Hari & Vesole, 2007). The median 5-year survival rate for newly diagnosed patients is 33% (Ries, Melbert, Krapcho, et al., 2007). Currently, prognosis is based on two simple markers, serum albumin (presumed to be a negative acute-phase reactant) and serum beta-2 microglobulin (presumed to be an indirect measure of tumor burden, defined as an approximation of the amount of cancer or the number of cancer cells in the body) (Gertz, 2007). Using this system, patients with a good prognosis have a median survival of 62 months, whereas those with a poor prognosis have a median survival of 29 months (Katzel, et al., 2007). Research is currently directed at identifying specific types of chromosomal abnormalities that will further determine prognosis and treatment (Gertz, 2007).

Pathophysiology

In multiple myeloma, the malignant plasma cells produce an increased amount of a specific immunoglobulin that is nonfunctional. Functional types of immunoglobulin are still produced by nonmalignant plasma cells, but in lower-than-normal quantity. The specific immunoglobulin secreted by the myeloma cells is detectable in the blood or urine and is referred to as the monoclonal protein, or M protein. This protein serves as a useful marker to monitor the extent of disease and the patient's response to therapy. It is commonly measured by serum or urine protein electrophoresis (Sammet, et al., 2005). The patient's total protein level is also typically elevated because of the production of M protein. Malignant plasma cells also secrete certain substances to stimulate the creation of new blood vessels (ie, angiogenesis) to enhance the growth of these clusters of plasma cell. Occasionally the plasma cells infiltrate other tissue, in which case they are referred to as plasmacytomas. Plasmacytomas can occur in the sinuses, spinal cord, and soft tissues.

Clinical Manifestations

The classic presenting symptom of multiple myeloma is bone pain, usually in the back or ribs. Bone pain is reported by two thirds of all patients at diagnosis. The bone pain associated with myeloma increases with movement and decreases with rest; patients may report that they have less pain on awakening but more during the day. In myeloma, a substance secreted by the plasma cells, osteoclast activating factor, and other substances (eg, interleukin-6 [IL-6]) are

involved in stimulating osteoclasts. Both mechanisms appear to be involved in the process of bone breakdown. Thus, lytic lesions as well as osteoporosis may be seen on bone x-rays but do not visualize on bone scans. The bone destruction can be severe enough to cause vertebral collapse and fractures, including spinal fractures, which can impinge on the spinal cord and result in spinal cord compression.

If the bone destruction is fairly extensive, excessive ionized calcium is lost from the bone and enters the serum; hypercalcemia may therefore develop (frequently manifested by excessive thirst, dehydration, constipation, altered mental status, confusion, and perhaps coma). Renal failure may also occur; the configuration of the circulating immunoglobulin molecule (particularly the shape of lambda light chains) can damage the renal tubules.

NURSING ALERT

Any elderly patient whose chief complaint is back pain and who has an elevated total protein level should be evaluated for possible myeloma.

As more and more malignant plasma cells are produced, the marrow has less space for erythrocyte production, and anemia may develop. This anemia is also caused to a great extent by a diminished production of erythropoietin by the kidney. In the late stage of the disease, a reduced number of leukocytes and platelets may also be seen because the bone marrow is infiltrated by malignant plasma cells.

Infection is a concern. Infections occur most commonly within the first 2 months of beginning therapy and in the setting of advanced, refractory disease. In multiple myeloma, in contrast to other hematologic malignancies, the incidence of infection does not appear to be related to the extent of neutropenia. Infections occurring at the beginning of treatment are often caused by *S. pneumoniae*; those that occur when the disease is advanced or in the setting of renal failure are most often caused by gram-negative bacilli or *Staphylococcus aureus* (Blade & Rosinol, 2007). Infection is frequently the cause of death from multiple myeloma.

Neurologic manifestations can also occur. Spinal cord compression is the most common, and other neurologic symptoms may be present (see Chapter 16 for nursing care). When the M protein is IgM, peripheral neuropathy is more likely. Nerve root compression, the presence of intracranial neoplastic cells, and meningeal involvement are quite rare.

When plasma cells secrete excessive amounts of immunoglobulin, the serum viscosity can increase. Hyperviscosity may be manifested by bleeding from the nose or mouth, headache, blurred vision, paresthesias, or heart failure. Thromboembolic events (blood clots) may occur in patients with myeloma; the incidence is thought to be 5% to 10% (Zonder, 2006).

Assessment and Diagnostic Findings

An elevated monoclonal protein spike in the serum (via serum protein electrophoresis), urine (via urine protein electrophoresis), or light chain (via serum free light chain analysis) is considered to be a major criterion in the diagnosis of multiple myeloma. Evidence of end-organ damage

is necessary to establish the diagnosis, using the acronym CRAB (elevated calcium, renal insufficiency, anemia, and/or bone lesions). The diagnosis of myeloma is confirmed by bone marrow biopsy; the presence of more than 10% plasma cells is the hallmark diagnostic criterion. Because the infiltration of the marrow by these malignant plasma cells is not uniform, the plasma cells may not be increased in a given sample (a false-negative result).

Medical Management

There is no cure for multiple myeloma. Even BMT or PB-SCT is considered to extend remission rather than provide a cure. However, for many patients, it is possible to control the illness and maintain their level of functioning quite well for several years or longer. For those who are not candidates for transplant, chemotherapy is the primary treatment. Pharmacotherapeutic advances have resulted in significant improvement in response rates; corticosteroids, particularly dexamethasone (Decadron), are often combined with other agents (eg, melphalan [Alkeran], thalidomide [Thalomid], lenalidomide [Revlimid], and bortezomib [Velcade]).

Radiation therapy is very useful in strengthening the bone at a specific lesion, particularly one at risk for bone fracture or spinal cord compression. It is also useful in relieving bone pain and reducing the size of plasma cell tumors that occur outside the skeletal system. However, because it is a nonsystemic form of treatment, it does not diminish the source of the bone conditions (ie, the production of malignant plasma cells). Therefore, radiation therapy is typically used in combination with systemic treatment such as chemotherapy.

When lytic lesions result in vertebral compression fractures, vertebroplasty is often performed. This procedure is performed under fluoroscopy. A hollow needle is positioned within the fractured vertebra, and when the precise location is confirmed, an orthopedic cement is infiltrated into the vertebra to stabilize the fracture and strengthen the vertebra. For most patients, relief from pain is almost immediate. This procedure has been enhanced by concomitant kyphoplasty, the use of a special inflatable balloon inserted into the vertebra to increase the height of the vertebra prior to injecting the cement.

Some bisphosphonates, such as pamidronate (Aredia) and zoledronic acid (Zometa), have been shown to strengthen bone in multiple myeloma by diminishing survival of osteoclasts, thus controlling bone pain and potentially preventing bone fracture. These agents are also effective in managing and preventing hypercalcemia. Some evidence suggests that bisphosphonates may act against the myeloma cells themselves by inhibiting a growth factor necessary for myeloma cell survival (Van den Wyngaert, Huizing, & Vermorcken, 2007). Researchers have found an increased incidence of osteonecrosis of the jaw in people with and without multiple myeloma who have been receiving long-term bisphosphonate therapy; the mandible and/or maxilla are affected. But there is yet no proof of this association between bisphosphonates and osteonecrosis, and the incidence of osteonecrosis appears to be low (2% to 13%) (Mehrotra & Ruggiero, 2006). Nonetheless, careful assessment for this complication should be conducted.

Prior to initiating bisphosphonate therapy, a thorough evaluation of the patient's dentition should be performed, including panoramic dental x-rays. Necessary repairs, including those to ensure that dentures fit properly, should also be performed.

When patients have signs and symptoms of hyperviscosity, plasmapheresis may be used to lower the immunoglobulin level. Symptoms may be more useful than serum viscosity levels in determining the need for this intervention.

Recent advances in the understanding of the process of angiogenesis have resulted in new therapeutic options. The sedative thalidomide (Thalomid), initially used as an antiemetic, has significant antimyeloma effects. It inhibits cytokines necessary for new vascular generation, such as vascular endothelial growth factor, and for myeloma cell growth and survival, such as IL-6 and tumor necrosis factor, by boosting the body's immune response against the tumor and by creating favorable conditions for apoptosis (programmed cell death) of the myeloma cells. Fatigue, dizziness, constipation, rash, and peripheral neuropathy are commonly encountered in patients treated with thalidomide, whereas myelosuppression is not. There is also an increased incidence of DVT; prophylactic anticoagulation should be used to prevent this complication. Strategies to achieve this may range from administration of low-dose aspirin to anticoagulation with warfarin or low-molecular-weight heparin (LMWH) (Zonder, 2006). Thalidomide is contraindicated in pregnancy because of associated severe birth defects. Thus, the patient must be counseled and agree to use approved methods of birth control prior to taking this drug. The thalidomide analog lenalidomide is also effective in myeloma. Side effects are quite different from those of thalidomide: myelosuppression is common, whereas sedation, neuropathy, and constipation are not. However, the drug is excreted by the kidneys, so careful monitoring of renal function is required and dose reduction may be necessary. It also requires concomitant anticoagulation, particularly when used in combination with dexamethasone.

The use of a proteasome inhibiting agent, bortezomib (Velcade), has been approved by the U.S. Food and Drug Administration (FDA) for initial therapy as well as for use in refractory disease. When combined with other medications, it can overcome resistance to those agents (Manochakian, Miller, Chanan-Khan, et al., 2007). Side effects include transient thrombocytopenia, orthostatic hypotension, nausea and vomiting, skin rash, neuropathy, and asthenia (ie, weakness, malaise, fatigue). Because neuropathy is potentially serious, the dosage needs to be decreased as soon as the neuropathy begins to interfere with function. Bortezomib is metabolized by the cytochrome P450 pathway, which means that a careful review of concurrent medications for drug–drug interaction is crucial.

Nursing Management

Pain management is very important in patients with multiple myeloma. NSAIDs can be very useful for mild pain or can be administered in combination with opioid analgesics. Because NSAIDs can cause gastritis and renal dysfunction, renal function must be carefully monitored and patients assessed for gastritis. The patient needs to be educated about activity restrictions (eg, lifting no more than 10 pounds, use

of proper body mechanics). Braces are occasionally needed to support the spinal column.

The patient also needs to be instructed about the signs and symptoms of hypercalcemia. Maintaining mobility and hydration are important to diminish exacerbations of this complication; however, the primary cause is the disease itself. Renal function should also be monitored closely. Renal failure can become severe, and dialysis may be needed. Maintaining high urine output (3 L/day) can be very useful in preventing or limiting this complication.

Because antibody production is impaired, infections, particularly bacterial infections, are common and can be life-threatening. The patient needs to be instructed in appropriate infection prevention measures (see Chart 33-5) and should be advised to contact the health care provider immediately if fever or other signs and symptoms of infection develop. The patient should receive pneumococcal and influenza vaccines. Prophylactic antibiotics are sometimes used. IVIG can be useful for patients with recurrent infections.

Many newer medications incur higher risks of thromboembolism formation. Other risk factors include decreased mobility, poor nutrition, and the presence of a vascular access device (eg, PICC). It is important to maintain mobility and to use strategies that enhance venous return (eg, anti-embolism stockings, avoid crossing the legs).

Gerontologic Considerations

The incidence of multiple myeloma increases with age; the disease rarely occurs in patients younger than 40 years of age. Because of the increasing older population, more patients are seeking treatment for this disease. Back pain, which is often a presenting symptom in this disease, should be closely investigated in older patients. BMT or PBSCT is an option that can prolong remission and potentially cure some patients, but it is unavailable to most older people because of concurrent diminished organ function (eg, kidney, lung, liver, heart) associated with aging.

BLEEDING DISORDERS

Failure of normal hemostatic mechanisms can result in bleeding, which may be severe. This bleeding is commonly provoked by trauma, but in certain circumstances it can occur spontaneously. When the source is platelet or coagulation factor abnormalities, the site of bleeding can be anywhere in the body. When the source is vascular abnormalities, the site of bleeding may be more localized. Some patients have simultaneous defects in more than one hemostatic mechanism.

The bone marrow may be stimulated to increase platelet production (thrombopoiesis). This may be a reactive response, as in a compensatory response to significant bleeding, or a more general response to increased hematopoiesis, as in iron deficiency anemia. Sometimes, the increase in platelets does not result from increased production but from a loss in platelet pooling within the spleen. The spleen typically holds about one third of the circulating platelets at any time. If the spleen is absent (eg, splenectomy), the platelet reservoir is also lost, and an abnormally high number of platelets enters the circulation. In time, the rate of thrombopoiesis slows to reestablish a more normal platelet level.

Clinical Manifestations

Signs and symptoms of bleeding disorders vary depending on the type of defect. A careful history and physical examination can be useful in determining the source of the hemostatic defect. Abnormalities of the vascular system give rise to local bleeding, usually into the skin. Because platelets are primarily responsible for stopping bleeding from small vessels, patients with platelet defects develop petechiae, often in clusters; these are seen on the skin and mucous membranes but also occur throughout the body (see Fig. 33-5). Bleeding from platelet disorders can be severe. Unless the platelet disorder is severe, bleeding can often be stopped promptly when local pressure is applied; it does not typically recur when the pressure is released.

In contrast, coagulation factor defects do not tend to cause superficial bleeding, because the primary hemostatic mechanisms are still intact. Instead, bleeding occurs deeper within the body (eg, subcutaneous or IM hematomas, hemorrhage into joint spaces). External bleeding diminishes very slowly when local pressure is applied; it often recurs several hours after pressure is removed. For example, severe bleeding may start several hours after a tooth extraction. Risk factors for bleeding are listed in Chart 33-4.

Medical Management

Management varies based on the underlying cause of the bleeding disorder. If bleeding is significant, transfusions of blood products are indicated. The specific blood product used is determined by the underlying defect and the extent of the blood loss. If fibrinolysis is excessive, hemostatic agents such as aminocaproic acid (Amicar) can be used to inhibit this process. This agent must be used with caution, because excessive inhibition of fibrinolysis can result in thrombosis. A patient scheduled for an invasive procedure, including a dental extraction, may need a transfusion prior to the procedure to minimize the risk of excessive bleeding.

Nursing Management

Patients who have bleeding disorders or who have the potential for development of such disorders as a result of disease or therapeutic agents must be taught to observe themselves

carefully and frequently for bleeding (Chart 33-10). They need to understand the importance of avoiding activities that increase the risk of bleeding, such as contact sports. It is necessary to examine the skin for petechiae and ecchymoses (bruises) and the nose and gums for bleeding. Hospitalized patients are monitored for bleeding by testing all drainage and excreta (feces, urine, emesis, and gastric drainage) for occult as well as obvious blood. Outpatients are often given fecal occult blood screening cards to detect occult blood in stools.

Primary Thrombocytopenia

Primary thrombocytopenia (also called essential thrombocytopenia) is a stem cell disorder within the bone marrow. A marked increase in platelet production occurs, with the platelet count consistently greater than $600,000/\text{mm}^3$. Platelet size may be abnormal, but platelet survival is typically normal. Occasionally, the platelet increase is accompanied by an increase in erythrocytes, leukocytes, or both; however, these cells are not increased to the extent that they are in polycythemia vera, CML, or myelofibrosis. Although the exact cause is unknown, primary thrombocytopenia is similar to other myeloproliferative disorders, particularly polycythemia vera. However, unlike the other myeloproliferative disorders, it rarely evolves into acute leukemia.

Primary thrombocytopenia, which affects women twice as often as men, tends to occur later in life (median age at diagnosis is 65 to 70 years). Survival does not appear to differ from the general population (Johansson, 2006), although conflicting findings have been reported (Brière, 2007).

Clinical Manifestations

Many patients with primary thrombocytopenia are asymptomatic; the illness is diagnosed as the result of finding an elevated platelet count on a CBC. Symptoms occur most often when the platelet count exceeds 1 million/ mm^3 . However, they do not always correlate with the extent to which the platelet count is elevated. When symptoms do

33-10

HOME CARE CHECKLIST

The Patient at Risk for Bleeding

At the completion of the home care instruction, the patient or caregiver will be able to:	PATIENT	CAREGIVER
• Describe the source and function of platelets and clotting factors.	✓	✓
• Verbalize the rationale for being at risk for bleeding.	✓	✓
• Identify medications and other substances to avoid (eg, aspirin-containing medications, alcohol).	✓	✓
• Demonstrate how to monitor for signs of bleeding.	✓	✓
• Describe to whom, how, and when to report signs of bleeding.	✓	✓
• Notify health care professional before having dental work.	✓	✓
• Describe appropriate ways to prevent bleeding (avoid use of suppositories, enemas, tampons; avoid constipation, vigorous sexual intercourse, anal sex; avoid contact sports; avoid or limit aggressive manual labor; use only electric razor for shaving and a soft-bristled toothbrush for teeth).	✓	✓
• Demonstrate appropriate actions to take should bleeding occur.	✓	✓

occur, they result primarily from hemorrhage or vascular occlusion. This occlusion can occur in large vessels (cerebrovascular, coronary, or peripheral arteries) and deep veins, as well as in the microcirculation. Microvascular vasoocclusive manifestations are most frequently seen in the form of erythromyalgia. The toxic effects of platelet substances include painful burning, warmth, and redness in a localized distal area of the extremities. Headaches are the most common neurologic manifestations; other manifestations include transient ischemic attacks and diplopia (Brière, 2007). More common forms of venous thromboembolism include DVT and pulmonary embolism. The spleen may also be enlarged but usually not to a significant extent.

In addition, because the platelets can be dysfunctional, minor or major hemorrhage may occur. Bleeding is commonly limited to recurrent skin manifestations (ecchymoses, hematomas, epistaxis, gum bleeding), although significant GI bleeding is also possible. Bleeding typically does not occur unless the platelet count exceeds 1.5 million/mm³. It results from a deficiency in von Willebrand factor (vWF) as the platelet count increases (Brière, 2007).

Assessment and Diagnostic Findings

The diagnosis of primary thrombocythemia is made by ruling out other potential disorders—either other myeloproliferative disorders or underlying illnesses that cause a reactive or secondary thrombocytosis (see below). Iron deficiency should be excluded, because a reactive increase in the platelet count often accompanies this deficiency. Occult malignancy should be excluded. The CBC shows markedly large and abnormal platelets; the platelet count is persistently elevated (greater than 600,000/mm³). Analysis of the bone marrow (by aspiration and biopsy) may not be particularly useful.

No data reliably predict the development of complications. Risk factors for the development of thrombotic complications include age older than 60 years and a history of prior thrombotic events. Major bleeding tends to occur when the platelet count is very high (greater than 1,500,000/mm³) and there is a prior history of major bleeding. A history of minor bleeding can also render the patient at risk for further hemorrhage if the platelet count exceeds 1,000,000/mm³ and the duration of disease exceeds 15 years (Brière, 2007). In contrast, patients who are younger than 40 years of age, have no previous history of a thrombotic or hemorrhagic event, and have platelet counts of less than 1,000,000/mm³ are considered to be at low risk for developing thrombotic or hemorrhagic complications.

Medical Management

The management of primary thrombocythemia is highly controversial. The risk of significant thrombotic or hemorrhagic complications may not be increased until the platelet count exceeds 1.5 million/mm³. A careful assessment of other risk factors, such as history of peripheral vascular disease, history of tobacco use, atherosclerosis, and prior thrombotic events, should be considered in developing the treatment plan.

In younger patients with no risk factors, low-dose aspirin therapy may be sufficient to prevent thrombotic complications. However, the use of aspirin can increase the risk of he-

morrhagic complications and is typically a contraindication in patients with a history of GI bleeding. Aspirin can relieve the neurologic symptoms (eg, headache), erythromyalgias, and visual symptoms of primary thrombocythemia.

In older patients and in those with concurrent risk factors, more aggressive measures may be necessary. Hydroxyurea is effective in lowering the platelet count. This agent is taken orally and causes minimal side effects other than dose-related leukopenia. (Its potential for leukogenesis diminishes its utility in younger patients with risk factors.) The medication anagrelide is more specific in lowering the platelet count than hydroxyurea but has more side effects. Severe headaches cause many patients to stop taking the medication. Tachycardia and chest pain may also occur, and anagrelide is contraindicated in patients with concurrent cardiac problems. Anagrelide is also carcinogenic.

Interferon-alfa-2b has been shown to lower platelet counts by an unknown mechanism. The medication is administered subcutaneously at varying frequency, commonly three times per week. Significant side effects, such as fatigue, weakness, memory deficits, dizziness, anemia, and liver dysfunction, limit its usefulness.

Rarely, the occlusive symptoms are so great that the platelet count must be reduced immediately. When necessary, platelet pheresis (see later discussion) can reduce the amount of circulating platelets, but only transiently. The extent to which symptoms and complications (eg, thromboses) are reduced by pheresis is unclear.

Nursing Management

Patients with primary thrombocythemia need to be instructed about the accompanying risks of hemorrhage and thrombosis. The patient is informed about signs and symptoms of thrombosis, particularly the neurologic manifestations, such as visual changes, numbness, tingling, and weakness. Risk factors for thrombosis are assessed, such as obesity, hypertension, hyperlipidemia, and smoking; measures to diminish these risk factors are encouraged. Patients taking aspirin should be informed about the increased risk of bleeding. Patients who are at risk for bleeding should be instructed about medications (eg, aspirin, NSAIDs) and other substances (eg, alcohol) that can alter platelet function. Patients taking interferon are taught to self-administer the medication and manage side effects. Patients taking hydroxyurea should have CBCs monitored; the dosage is adjusted based on the platelet and white blood cell count.

Secondary Thrombocytosis

Increased platelet production is the primary mechanism of secondary, or reactive, **thrombocytosis**. The platelet count is above normal, but, in contrast to primary thrombocythemia, an increase of more than 1 million/mm³ is rare. Platelet function is normal; the platelet survival time is normal or decreased. Consequently, symptoms associated with hemorrhage or thrombosis are rare. Many disorders or conditions can cause a reactive increase in platelets, including infection, chronic inflammatory disorders, iron deficiency, malignant disease, acute hemorrhage, and splenectomy (see previous discussion of primary thrombocythemia). Treatment is

Table 33-4 CAUSES AND MANAGEMENT OF THROMBOCYTOPENIA

Cause	Management
Decreased Platelet Production	
Hematologic malignancy, especially acute leukemias	Treat leukemia; platelet transfusion
Myelodysplastic syndrome (MDS)	Treat MDS; platelet transfusion
Metastatic involvement of bone marrow from solid tumors	Treat solid tumor
Aplastic anemia	Treat underlying condition
Megaloblastic anemia	Treat underlying anemia
Toxins	Remove toxin
Medications (eg, sulfa drugs, methotrexate)	Stop medication
Infection (esp. septicemia, viral infection, tuberculosis, chronic hepatitis C)	Treat infection
Alcohol	Refrain from alcohol consumption
Chemotherapy	Delay or decrease dose; growth factor; platelet transfusion
Increased Platelet Destruction	
Due to antibodies:	
Idiopathic thrombocytopenic purpura (ITP)	Treat condition
Lupus erythematosus	
Malignant lymphoma	
Chronic lymphocytic leukemia (CLL)	Treat CLL and/or treat as ITP
Medications	Stop medication
Due to infection:	
Bacteremia	Treat infection
Postviral infection	
Sequestration of platelets in an enlarged spleen	If thrombocytopenia is severe, splenectomy may be needed
Increased Platelet Consumption	
Disseminated intravascular coagulation (DIC)	Treat underlying condition triggering DIC; administer heparin, aminocaproic acid (EACA), blood products

aimed at the underlying disorder. With successful management, the platelet count usually returns to normal.

Thrombocytopenia

Thrombocytopenia (low platelet level) can result from various factors: decreased production of platelets within the bone marrow, increased destruction of platelets, or increased consumption of platelets. Causes and treatments are summarized in Table 33-4.

Clinical Manifestations

Bleeding and petechiae usually do not occur with platelet counts greater than $50,000/\text{mm}^3$, although excessive bleeding can follow surgery or other trauma. When the platelet count drops to less than $20,000/\text{mm}^3$, petechiae can appear, along with nasal and gingival bleeding, excessive menstrual bleeding, and excessive bleeding after surgery or dental extractions. When the platelet count is less than $5000/\text{mm}^3$, spontaneous, potentially fatal central nervous system or GI hemorrhage can occur. If the platelets are dysfunctional as a result of disease (eg, MDS) or medications (eg, aspirin), the risk of bleeding may be much greater even when the actual platelet count is not significantly reduced, because the function of the platelets is altered.

Assessment and Diagnostic Findings

A platelet deficiency that results from decreased production (eg, leukemia, MDS) can usually be diagnosed by examining the bone marrow via aspiration and biopsy. Numerous genetic causes of thrombocytopenia have been discovered, including autosomal dominant, autosomal recessive, and

X-linked mutations. If platelet destruction is the cause of thrombocytopenia, the marrow shows increased megakaryocytes and normal or even increased platelet production as the body attempts to compensate for the decreased platelets in circulation.

An important cause to exclude is “pseudothrombocytopenia.” Here, platelets aggregate and clump in the presence of ethylenediamine tetra-acetic acid (EDTA), the anticoagulant present in the tube used for CBC collection. This clumping is seen in 1:1000 people (Sekhon & Roy, 2006). A manual examination of the peripheral smear can easily determine platelet clumping as the cause of thrombocytopenia; newer cell counter machines can also detect this.

Medical Management

The management of secondary thrombocytopenia is usually treatment of the underlying disease. If platelet production is impaired, platelet transfusions may increase the platelet count and stop bleeding or prevent spontaneous hemorrhage. If excessive platelet destruction occurs, transfused platelets are also destroyed, and the platelet count does not increase. The most common cause of excessive platelet destruction is idiopathic thrombocytopenic purpura (see the following discussion). In some instances splenectomy can be a useful therapeutic intervention, but often it is not an option; for example, in patients in whom the enlarged spleen is due to portal hypertension related to cirrhosis, splenectomy may cause more bleeding disorders.

Nursing Management

The interventions for a patient with thrombocytopenia are listed in Chart 33-8.

Idiopathic Thrombocytopenic Purpura

Idiopathic thrombocytopenic purpura (ITP) is a disease that affects people of all ages, but it is more common among children and young women. There are two forms of ITP: acute and chronic. Acute ITP, which occurs predominantly in children, often appears 1 to 6 weeks after a viral illness. This form is self-limited; remission often occurs spontaneously within 6 months. Chronic ITP is often diagnosed by exclusion of other causes of thrombocytopenia.

Pathophysiology

In patients with ITP, antiplatelet autoantibodies that bind to the platelets are found in the blood. When the platelets are bound by the antibodies, the RES or tissue macrophage system ingests the platelets, destroying them. The body attempts to compensate for this destruction by increasing platelet production within the marrow. This mechanism appears to be complicated by the fact that thrombopoietin levels are not elevated in patients with ITP, and as such, platelet production may be diminished (Bussel, Kuter, George, et al., 2006).

As previously stated, viral illness may lead to ITP. Medications such as sulfa drugs as well as conditions such as systemic lupus erythematosus or pregnancy can also induce ITP.

Clinical Manifestations

Many patients have no symptoms, and the low platelet count (often less than $20,000/\text{mm}^3$; less than $5000/\text{mm}^3$ is not uncommon) is an incidental finding. Common physical manifestations are easy bruising, heavy menses, and petechiae on the extremities or trunk. Patients with simple bruising or petechiae (“dry purpura”) tend to have fewer complications from bleeding than those with bleeding from mucosal surfaces, such as the GI tract (including the mouth) and pulmonary system (eg, hemoptysis), which is termed *wet purpura*. Patients with wet purpura have a greater risk of intracranial bleeding than do those with dry purpura. Despite low platelet counts, the platelets are young and very functional. They adhere to endothelial surfaces and to one another, so spontaneous bleeding does not always occur. Thus, treatment may not be initiated unless bleeding becomes severe or life-threatening, or the platelet count is extremely low (less than $10,000/\text{mm}^3$).

Assessment and Diagnostic Findings

Patients may have an isolated decrease in platelets (less than $20,000/\text{mm}^3$ is common), but they may also have an increase in megakaryocytes within the marrow, as detected on bone marrow aspirate. Some patients are found to be infected with *H. pylori*, and eradicating the infection may improve platelet counts (Emilia, Luppi, Zucchini, et al., 2007). It is unclear why *H. pylori* and ITP are correlated. It is thought that *H. pylori* may cause an autoimmune reaction or that it binds vWF, both of which may result in accelerated platelet demise.

Medical Management

The primary goal of treatment is a “safe” platelet count. Because the risk of bleeding typically does not increase until the platelet count is less than $10,000/\text{mm}^3$, a patient whose

count exceeds $30,000/\text{mm}^3$ to $50,000/\text{mm}^3$ may be carefully observed without additional intervention. However, if the count is less than $20,000/\text{mm}^3$ or if bleeding occurs, the goal is to improve the patient’s platelet count rather than to cure the disease. The decision to treat should not be made merely on the basis of the patient’s platelet count, but also on his or her lifestyle and activity level. A person with a sedentary lifestyle can tolerate a low platelet count more safely than one with a more active lifestyle.

Treatment for ITP usually involves several approaches. If the patient is taking a medication known to be associated with ITP (eg, quinine, sulfa-containing medications), that medication must be stopped immediately. The mainstay of short-term therapy is the use of immunosuppressive agents. These agents block the binding receptors on macrophages so that the platelets are not destroyed. The corticosteroid prednisone is typically used, although dexamethasone (Decadron) is also effective (Sekhon & Roy, 2006). The immunosuppressant azathioprine (Imuran) may also be used. Platelet counts typically begin to rise within a few days after institution of corticosteroid therapy; this effect takes longer with azathioprine. Because of the associated side effects, patients cannot take high doses of corticosteroids indefinitely. The platelet count tends to drop once the corticosteroid dose is tapered. Some patients can be successfully maintained on low doses of prednisone.

IVIg is also commonly used to treat ITP. It is effective in binding the receptors on the macrophages; however, high doses are required, the drug is very expensive, and the effect is transient. Splenectomy is an alternative treatment but results in a sustained normal platelet count only 50% of the time; however, many patients can maintain a “safe” platelet count of more than $30,000/\text{mm}^3$ after removal of the spleen. Even those who do respond to splenectomy may have recurrences of severe thrombocytopenia months or years later. Patients who have undergone splenectomy are permanently at risk for sepsis and should receive pneumococcal (Pneumovax), *H. influenzae* B, and meningococcal vaccines, preferably 2 to 3 weeks before the splenectomy is performed. The pneumococcal vaccine should be repeated at 5- to 10-year intervals.

Other management options include the chemotherapy agent vincristine (Oncovin). Vincristine appears to work by blocking the receptors on the macrophages and therefore inhibiting platelet destruction; it may also stimulate thrombopoiesis. Certain monoclonal antibodies (eg, rituximab) may increase platelet counts, but the result is often temporary (Beardsley, 2006).

Another approach to the management of chronic ITP involves the use of anti-D (WinRho) in patients who are Rh (D) positive. The actual mechanism of action is unknown. One theory is that the anti-D binds to the patient’s erythrocytes, which are in turn destroyed by the body’s macrophages. The receptors in the RES may become saturated with the sensitized erythrocytes, diminishing removal of antibody-coated platelets. Anti-D produces a transient decreased hematocrit and increased platelet count in many, but not all, patients with ITP. Anti-D appears to be most effective in children with ITP and least effective in patients who have undergone splenectomy.

In addition, the thrombopoiesis-stimulating protein romiplostin (Nplate) has been successfully used to treat patients with chronic ITP (Bussel, et al., 2006). Side effects include headache, blistering of the oral mucosa, and ecchymoses. Further study is ongoing.

Despite extremely low platelet counts, platelet transfusions are usually avoided. Transfusions tend to be ineffective because the patient's antiplatelet antibodies bind with the transfused platelets, causing them to be destroyed. Platelet counts can actually drop further after platelet transfusion. Occasionally, transfusion of platelets may protect against catastrophic bleeding in patients with severe wet purpura. Aminocaproic acid, a fibrinolytic enzyme inhibitor that slows the dissolution of clots, may be useful for patients with significant mucosal bleeding refractory to other treatments.

Nursing Management

Nursing care includes an assessment of the patient's lifestyle to determine the risk of bleeding from activity. A careful medication history is also obtained, including use of over-the-counter medications, herbs, and nutritional supplements. The nurse must be alert for sulfa-containing medications and others that alter platelet function (eg, aspirin based or other NSAIDs). The nurse assesses for any history of recent viral illness and reports of headache or visual disturbances, which could be initial symptoms of intracranial bleeding. Patients who are admitted to the hospital with wet purpura and low platelet counts should have a neurologic assessment incorporated into their routine vital sign measurements. All injections or rectal medications should be avoided, and rectal temperature measurements should not be performed, because they can stimulate bleeding.

Patient teaching addresses signs of exacerbation of disease (eg, petechiae, ecchymoses); how to contact appropriate health care personnel; the name and type of medication inducing ITP (if appropriate); current medical treatment (medications, tapering schedule if relevant, side effects); and the frequency of monitoring the platelet count. The patient is instructed to avoid all agents that interfere with platelet function. The patient should avoid constipation, the Valsalva maneuver (eg, straining at stool), and vigorous flossing of the teeth. Electric razors should be used for shaving, and soft-bristled toothbrushes should replace stiff-bristled ones. The patient may also be counseled to refrain from vigorous sexual intercourse when the platelet count is less than $10,000/\text{mm}^3$. Patients who are receiving corticosteroids long term are at risk for complications including osteoporosis, proximal muscle wasting, cataract formation, and dental caries (see Chapter 42). Bone mineral density should be monitored, and these patients may benefit from calcium and vitamin D supplementation and bisphosphonate therapy to prevent significant bone disease.

Platelet Defects

Quantitative platelet defects are relatively common (thrombocytopenia), but qualitative defects can also occur. With qualitative defects, the number of platelets may be normal, but the platelets do not function normally. In the past, the bleeding time was most commonly used to evalu-

ate platelet function. Now a platelet function analyzer is often used; this method is particularly valuable for rapid and simple screening (Scharbert, Gebhardt, Sow, et al., 2007).

Aspirin may induce a functional platelet disorder. Even small amounts of aspirin reduce normal platelet aggregation, and the prolonged bleeding time lasts for several days after aspirin ingestion. Although this does not cause bleeding in most people, patients with a coagulation disorder (eg, hemophilia) or thrombocytopenia can have significant bleeding after taking aspirin, particularly if invasive procedures or trauma has occurred.

NSAIDs can also inhibit platelet function, but the effect is not as prolonged as with aspirin (about 5 days versus 7 to 10 days). Other causes of platelet dysfunction include end-stage renal disease, possibly from metabolic products affecting platelet function; MDS; multiple myeloma (due to abnormal protein interfering with platelet function); cardiopulmonary bypass; and herbs and other medications (Chart 33-11).

Clinical Manifestations

Bleeding may be mild or severe. Its extent is not necessarily correlated with the platelet count or with tests that measure coagulation (prothrombin time [PT], activated partial thromboplastin time [aPTT]). Ecchymoses are common, particularly on the extremities. Patients with platelet dysfunction may be at risk for significant bleeding after trauma or invasive procedures (eg, biopsy, dental extraction).

Medical Management

If the platelet dysfunction is caused by medication, its use should be stopped, if possible, particularly when bleeding occurs. If platelet dysfunction is marked, bleeding can often be prevented by transfusion of normal platelets before invasive procedures. Aminocaproic acid may be required to prevent significant bleeding after such procedures.

Nursing Management

Patients with significant platelet dysfunction need to be instructed to avoid substances that can diminish platelet function, such as certain over-the-counter medications, herbs, nutritional supplements, and alcohol. They also need to inform their health care providers (including dentists) of the underlying condition before any invasive procedure is performed, so that appropriate steps can be initiated to diminish the risk of bleeding. Bleeding precautions should be initiated as appropriate (see Chart 33-8).

Hemophilia

Two inherited bleeding disorders—hemophilia A and hemophilia B—are clinically indistinguishable, although they can be distinguished by laboratory tests. Hemophilia A is caused by a genetic defect that results in deficient or defective factor VIII. Hemophilia B (also called Christmas disease) stems from a genetic defect that causes deficient or defective factor IX. Hemophilia is a relatively rare disease; hemophilia A, which occurs in 1 of every 5000 births, is three times more common than hemophilia B. Both types of hemophilia are inherited as X-linked traits, so almost all affected people are males; females can be carriers but are

almost always asymptomatic. The disease occurs in all ethnic groups.

Hemophilia is recognized in early childhood, usually in the toddler age group. However, patients with mild hemophilia may not be diagnosed until they experience severe trauma (eg, a high-school football injury) or surgery.

Clinical Manifestations

Hemophilia is manifested by hemorrhages into various parts of the body; these hemorrhages can be severe and can occur even after minimal trauma. The frequency and severity of the bleeding depend on the degree of factor deficiency as well as the intensity of the precipitating trauma. For example, patients with a mild factor VIII deficiency (ie, 6% to 50% of normal levels) rarely develop hemorrhage spontaneously; hemorrhage tends to occur secondary to trauma. In contrast, spontaneous hemorrhages, particularly hemarthroses and hematomas, can frequently occur in patients with severe factor VIII deficiency (ie, less than 1% of normal levels). These patients require frequent factor VIII replacement therapy.

About 75% of all bleeding in patients with hemophilia occurs into joints. The most commonly affected joints are the knees, elbows, ankles, shoulders, wrists, and hips. Patients often note pain in a joint before they are aware of swelling and limitation of motion. Recurrent joint hemorrhages can result in damage so severe that chronic pain or ankylosis (fixation) of the joint occurs. Many patients with severe factor deficiency are crippled by the joint damage before they become adults. Hematomas can be superficial or deep hemorrhages into muscle or subcutaneous tissue. With severe factor VIII deficiency, hematomas can occur without known trauma and progressively extend in all directions. When the hematomas occur within muscle, particularly in the extremities, peripheral nerves can be compressed. Over time, this compression results in decreased sensation, weakness, and atrophy of the area involved.

Bleeding is not limited to the joints. Spontaneous hematuria and GI bleeding can occur. Bleeding is also common in mucous membranes, such as the nasal passages. The most dangerous site of hemorrhage is in the head (intracranial or

extracranial). Any head trauma requires prompt evaluation and treatment. Surgical procedures typically result in excessive bleeding at the surgical site. Because clot formation is poor, wound healing is also poor. Bleeding is most commonly associated with dental extraction.

Medical Management

In the past, the only treatment for hemophilia was infusion of fresh-frozen plasma, which had to be administered in such large quantities that patients experienced fluid volume overload. Now factor VIII and factor IX concentrates are available to all blood banks. Recombinant forms of these factors are made available and decrease the need for factor concentrates. Patients are given concentrates when they are actively bleeding or as a preventive measure before traumatic procedures (eg, lumbar puncture, dental extraction, surgery). The patient and family are taught how to administer the concentrate intravenously at home at the first sign of bleeding. It is crucial to initiate treatment as soon as possible so that bleeding complications can be avoided. A study of 133 patients with severe hemophilia evaluated the use of factor replacement at the initial sign of bleeding or as prophylaxis. Although patients assigned to the prophylaxis group used more clotting factors, they also experienced a significant reduction in the number of bleeding episodes (Khoriaty, Taher, Inati, et al., 2005).

Between 15% and 30% of patients with hemophilia A and between 2% and 5% of patients with hemophilia B develop antibodies (inhibitors) to factor concentrates (National Hemophilia Foundation, 2006). Although one third of such inhibitors are transient, their effects can be significant and induce partial or complete refractoriness to factor replacement, thus resulting in increased risk of bleeding. Patients may require plasmapheresis or concurrent immunosuppressive therapy, particularly in the setting of significant bleeding. Factor VIIa can be administered, although it is expensive and requires frequent administration because of its short half-life. Occasionally, tolerance to the antibody can be induced by repeated daily exposure to factor VIII. Patients receiving daily administration of factor VIII can take months or longer for tolerance to develop. Treatment success is optimal when antibody titers remain low; thus, it is important to identify rising titers and act promptly. Activated prothrombin complex concentrates can also be used to control bleeding (National Hemophilia Foundation, 2006). However, efficacy is unpredictable, and if infused too quickly, effective hemostasis is not achieved and bleeding persists; thrombosis is also a possible sequela. Patients with severe factor deficiency should be screened for antibodies, particularly before major surgery. Recombinant factor VIIa is approved by the FDA for patients with acquired antibodies to factors VIII and IX, but treatment is expensive and not always successful.

Aminocaproic acid inhibits fibrinolysis and therefore stabilizes the clot; it is very effective as an adjunctive measure after oral surgery and in treating mucosal bleeding. Another agent, desmopressin (DDAVP), induces a significant but transient rise in factor VIII levels; the mechanism for this response is unknown. In patients with mild forms of hemophilia A, desmopressin is extremely useful, significantly reducing the amount of blood products required.

However, desmopressin is not effective in patients with severe factor VIII deficiency.

Nursing Management

Most patients with hemophilia are diagnosed as children. They often require assistance in coping with the condition because it is chronic, places restrictions on their lives, and is an inherited disorder that can be passed to future generations. From childhood, patients are helped to cope with the disease and to identify the positive aspects of their lives. They are encouraged to be self-sufficient and to maintain independence by preventing unnecessary trauma that can cause acute bleeding episodes and temporarily interfere with normal activities. As they work through their feelings about the condition and progress to accepting it, they can assume more and more responsibility for maintaining optimal health.

Patients with mild factor deficiency may not be diagnosed until adulthood if they do not experience significant trauma or surgery as children. These patients need extensive teaching about activity restrictions and self-care measures to diminish the chance of hemorrhage and complications of bleeding. The nurse should emphasize safety at home and in the workplace.

Patients with hemophilia are instructed to avoid any agents that interfere with platelet aggregation, such as aspirin, NSAIDs, herbs, nutritional supplements, and alcohol. This restriction applies to over-the-counter medications such as cold remedies. Dental hygiene is very important as a preventive measure because dental extractions are hazardous. Applying pressure to a minor wound may be sufficient to control bleeding if the factor deficiency is not severe. Nasal packing should be avoided, because bleeding frequently resumes when the packing is removed. Splints and other orthopedic devices may be useful in patients with joint or muscle hemorrhages. All injections should be avoided; invasive procedures (eg, endoscopy, lumbar puncture) should be minimized or performed after administration of appropriate factor replacement. Patients with hemophilia should carry or wear medical identification.

During hemorrhagic episodes, the extent of bleeding must be assessed carefully. Patients who are at risk for significant compromise (eg, bleeding into the respiratory tract or brain) warrant close observation and systematic assessment for emergent complications (eg, respiratory distress, altered level of consciousness). If the patient has had recent surgery, the nurse frequently and carefully assesses the surgical site for bleeding. Frequent monitoring of vital signs is needed until the nurse is certain that there is no excessive postoperative bleeding.

Analgesic agents are commonly required to alleviate the pain associated with hematomas and hemorrhage into joints. Many patients report that warm baths promote relaxation, improve mobility, and lessen pain. However, during bleeding episodes, heat, which can accentuate bleeding, is avoided; applications of cold are used instead.

Although recent technology (ie, the formulation of heat-solvent or detergent-treated factor concentrates) has rendered factor VIII and IX preparations free of viruses such as HIV and hepatitis, many patients have already been exposed to these infections through previous transfusions.

These patients and their families may need assistance in coping with the diagnosis and the consequences of these infections.

Genetic testing and counseling should be provided to female carriers so that they can make informed decisions regarding having children and managing pregnancy.

Von Willebrand's Disease

Von Willebrand disease (vWD), a common bleeding disorder affecting males and females equally, is usually inherited as a dominant trait. The prevalence of this disease is estimated to be 1% to 2% of the population (National Hemophilia Foundation, 2006). The disease is caused by a deficiency of vWF, which is necessary for factor VIII activity. vWF is also necessary for platelet adhesion at the site of vascular injury. Although synthesis of factor VIII is normal, its half-life is shortened; therefore, factor VIII levels commonly are mildly low (15% to 50% of normal).

There are three types of vWD. Type 1, the most common, is characterized by decreases in structurally normal vWF. Type 2 shows variable qualitative defects based on the specific vWF subtype involved. Type 3 is very rare (less than 5% of cases) (Borel-Derlon, Federici, Roussel-Robert, et al., 2007) and is characterized by a severe vWF deficiency as well as significant deficiency of factor VIII.

Clinical Manifestations

Bleeding tends to be mucosal. Patients commonly have recurrent nosebleeds, easy bruising, heavy menses, prolonged bleeding from cuts, and postoperative bleeding. Massive soft tissue or joint hemorrhages are not often seen, unless the patient has severe type 3 vWD. As the laboratory values fluctuate (see Assessment and Diagnostic Findings), so does the bleeding. For example, a careful history of prior bleeding may show little problem with postoperative bleeding on one occasion but significant bleeding from a dental extraction at another time.

Assessment and Diagnostic Findings

Laboratory test results show a normal platelet count but a prolonged bleeding time and a slightly prolonged aPTT. These defects are not static, and laboratory test results can vary widely within the same patient over time. More important tests include the ristocetin cofactor, or vWF collagen binding assay, which measures vWF activity. Other tests include vWF antigen, factor VIII, and, for patients with suspected type 2 defects, vWF multimers.

Medical Management

The goal of treatment is to replace the deficient protein (eg, vWF or factor VIII) at the time of spontaneous bleeding or prior to an invasive procedure. Desmopressin (DDAVP), a synthetic vasopressin analogue, can be used to prevent bleeding associated with dental or surgical procedures or to manage mild bleeding after surgery in those individuals with mild vWD. DDAVP provides a transient increase in factor VIII coagulant activity and may also correct the bleeding time. It can be administered as an IV infusion or intranasally. With major surgery or invasive procedures, IV

administration is preferable. DDAVP is contraindicated in patients with unstable coronary artery disease, because it can induce platelet aggregation and cause MI. Side effects include headache, facial flushing, tachycardia, hyponatremia, and, rarely, seizures.

Replacement products include Humate-P and Alphanate, which are commercial concentrates of vWF and factor VIII. The dosage and frequency of administration of these agents depend on the patient's factor VIII levels and the extent of bleeding. Treatment may be necessary for up to 7 to 10 days after major surgery and 3 to 4 days postpartum. In patients with severe type 3 vWD, the prophylactic administration of these replacement agents has been very successful in preventing or limiting spontaneous bleeding (Berntorp, 2006; Lethagen, 2006). Antibody formation to these products usually occurs only in patients with type 3 vWD, after administration of high doses.

Other agents may be effective in reducing bleeding. Aminocaproic acid is useful in managing mild forms of mucosal bleeding. Estrogen–progesterone compounds may diminish the extent of menses. Platelet transfusions are useful when there is significant bleeding. Medications that interfere with platelet function (eg, aspirin) should be avoided.

ACQUIRED COAGULATION DISORDERS

Liver Disease

With the exception of factor VIII, most blood coagulation factors are synthesized in the liver. Therefore, hepatic dysfunction (due to cirrhosis, tumor, or hepatitis; see Chapter 39) can result in diminished amounts of the factors needed to maintain coagulation and hemostasis. Prolongation of the PT, unless it is caused by vitamin K deficiency, may indicate severe hepatic dysfunction. Although bleeding is usually minor (eg, ecchymoses), these patients are also at risk for significant bleeding, related especially to trauma or surgery. Transfusion of fresh-frozen plasma may be required to replace clotting factors and to prevent or stop bleeding. Patients may also have life-threatening hemorrhage from peptic ulcers or esophageal varices. In these cases, replacement with fresh-frozen plasma, PRBCs, and platelets is usually required.

Vitamin K Deficiency

The synthesis of many coagulation factors depends on vitamin K. Vitamin K deficiency is common in malnourished patients. Prolonged use of some antibiotics decreases the intestinal flora that produce vitamin K, depleting vitamin K stores. Administration of vitamin K (phytonadione [Mephyton], either orally or as a subcutaneous injection) can correct the deficiency quickly; adequate synthesis of coagulation factors is reflected by normalization of the PT.

Complications of Anticoagulant Therapy

Anticoagulants are used in the treatment or prevention of thrombosis. These agents, particularly warfarin or heparin, can cause bleeding, particularly if their use is not carefully monitored. If the PT or aPTT is longer than desired and bleeding has not occurred, the medication can be stopped or the dose decreased. Vitamin K is administered as an antidote for warfarin toxicity. Protamine sulfate is rarely needed for heparin toxicity, because the half-life of heparin is very short. With significant bleeding, fresh frozen plasma is needed to replace the vitamin K–dependent coagulation factors.

Disseminated Intravascular Coagulation

DIC is not a disease but a sign of an underlying condition. DIC may be triggered by sepsis, trauma, cancer, shock, abruptio placentae, toxins, or allergic reactions. The severity of DIC is variable, but it is potentially life-threatening.

Pathophysiology

In DIC, normal hemostatic mechanisms are altered. The inflammatory response generated by the underlying disease initiates the process of coagulation within the vasculature. The natural anticoagulant pathways within the body are simultaneously impaired, and the fibrinolytic system is suppressed so that a massive amount of tiny clots forms in the microcirculation. Initially, the coagulation time is normal. However, as the platelets and clotting factors are consumed to form microthrombi, coagulation fails. Thus, the paradoxical result of excessive clotting is bleeding.

The clinical manifestations of DIC are primarily reflected in compromised organ function or failure. Decline in organ function is usually a result of excessive clot formation (with resultant ischemia to all or part of the organ) or, less often, of bleeding. The excessive clotting triggers the fibrinolytic system to release fibrin degradation products, which are potent anticoagulants, furthering the bleeding. The bleeding is characterized by low platelet and fibrinogen levels; prolonged PT, aPTT, and thrombin time; and elevated fibrin degradation products (**D-dimers**) (Table 33-5).

The mortality rate can exceed 80% in patients who develop severe DIC with ischemic thrombosis and frank

hemorrhage. Identification of patients who are at risk for DIC and recognition of the early clinical manifestations of this syndrome can result in prompt medical intervention, which may improve the prognosis. However, the primary prognostic factor is the ability to treat the underlying condition that precipitated DIC.

Clinical Manifestations

Patients with frank DIC may bleed from mucous membranes, venipuncture sites, and the GI and urinary tracts. The bleeding can range from minimal occult internal bleeding to profuse hemorrhage from all orifices. Patients typically develop multiple organ dysfunction syndrome (MODS), and they may exhibit renal failure as well as pulmonary and multifocal central nervous system infarctions as a result of microthromboses, macrothromboses, or hemorrhages.

During the initial process of DIC, the patient may have no new symptoms, the only manifestation being a progressive decrease in the platelet count. As the thrombosis becomes more extensive, the patient exhibits signs and symptoms of thrombosis in the organs involved. Then, as the clotting factors and platelets are consumed to form these thrombi, bleeding occurs. Initially the bleeding is subtle, but it can develop into frank hemorrhage. Signs and symptoms, which depend on the organs involved, are listed in Chart 33-12.

Assessment and Diagnostic Findings

Clinically, the diagnosis of DIC is often established by a drop in platelet count, an increase in PT and aPTT, an elevation in fibrin degradation products, and measurement of one or more clotting factors and inhibitors (eg, antithrombin [AT]). Although each of these tests is useful in establishing the diagnosis of DIC, the specificity of each individual parameter is not great. The International Society of Thrombosis and Haemostasis has developed a highly sensitive and specific scoring system using the platelet count, fibrin degradation products, PT, and fibrinogen level to diagnose DIC (Levi, 2007). This system is also useful in predicting the severity of the disease and subsequent mortality (Voves, Wuillemin, & Zeerleder, 2006).

Medical Management

The most important management factor in DIC is treating the underlying cause; until the cause is controlled, the DIC will persist. Correcting the secondary effects of tissue ischemia by improving oxygenation, replacing fluids, correcting

Table 33-5 LABORATORY VALUES COMMONLY FOUND IN DISSEMINATED INTRAVASCULAR COAGULATION (DIC)*

Test	Function Evaluated	Normal Range	Changes in DIC
Platelet count	Platelet number	150,000–450,000/mm ³	↓
Prothrombin time (PT)	Extrinsic pathway	11–12.5 sec	↑
Partial thromboplastin time (activated) (aPTT)	Intrinsic pathway	23–35 sec	↑
Thrombin time (TT)	Clot formation	8–11 sec	↑
Fibrinogen	Amount available for coagulation	170–340 mg/dL	↓
D-dimer	Local fibrinolysis	0–250 ng/mL	↑
Fibrin degradation products (FDPs)	Fibrinolysis	0–5 μg/mL	↑
Euglobulin clot lysis	Fibrinolytic activity	≥2 h	≤1 h

*Because DIC is a dynamic condition, the laboratory values measured will change over time. Therefore, a progressive increase or decrease in a given laboratory value is likely to be more important than the actual value of a test at a single point in time.

CHART
33-12
Assessing for Recognizing Thrombosis and Bleeding in Disseminated Intravascular Coagulation (DIC)*

System	Signs and Symptoms of Microvascular Thrombosis	Signs and Symptoms of Microvascular and Frank Bleeding
Integumentary system (skin)	↓ Temperature, sensation; ↑ pain; cyanosis in extremities, nose, earlobes; focal ischemia, superficial gangrene	Petechiae, including periorbital and oral mucosa; bleeding: gums, oozing from wounds, previous injection sites, around catheters (IVs, tracheostomies); epistaxis; diffuse ecchymoses; subcutaneous hemorrhage; joint pain
Circulatory system	↓ Pulses; capillary filling time >3 sec	Tachycardia
Respiratory system	Hypoxia (secondary to clot in lung); dyspnea; chest pain with deep inspiration; ↓ breath sounds over areas of large embolism	High-pitched bronchial breath sounds; tachypnea; ↑ consolidation; signs and symptoms of acute respiratory distress syndrome
Gastrointestinal system	Gastric pain; “heartburn”	Hematemesis (heme⊕ [†] NG output) melena (heme⊕ stools → tarry stools → bright-red blood from rectum) retroperitoneal bleeding (abdomen firm and tender to palpation; distended; ↑ abdominal girth)
Renal system	↓ Urine output; ↑ creatinine, ↑ blood urea nitrogen	Hematuria
Neurologic system	↓ Alertness and orientation; ↓ pupillary reaction; ↓ response to commands; ↓ strength and movement ability	Anxiety; restlessness; ↓ mentation, altered level of consciousness; headache; visual disturbances; conjunctival hemorrhage

*Note: Signs of microvascular thrombosis are the result of an inappropriate activation of the coagulation system, causing thrombotic occlusion of small vessels within all body organs. As the clotting factors and platelets are consumed, signs of microvascular bleeding appear. This bleeding can quickly extend into frank hemorrhage. Treatment must be aimed at the disorder underlying the DIC; otherwise, the stimulus for the syndrome will persist.

[†]heme⊕, positive for hemoglobin.

electrolyte imbalances, and administering vasopressor medications is also important. If serious hemorrhage occurs, the depleted coagulation factors and platelets may be replaced to reestablish the potential for normal hemostasis and thereby diminish bleeding; however, decisions to provide transfusion support should not be solely based on the laboratory results. Cryoprecipitate is given to replace fibrinogen and factors V and VII; fresh-frozen plasma is administered to replace other coagulation factors.

A controversial treatment strategy is to interrupt the thrombosis process through the use of heparin infusion. Heparin may inhibit the formation of microthrombi and thus permit perfusion of the organs (skin, kidneys, or brain) to resume. Heparin use was traditionally reserved for patients in whom thrombotic manifestations predominated or in whom extensive blood component replacement failed to halt the hemorrhage or increased fibrinogen and other clotting levels. Heparin is now also used in less acute forms of DIC. The effectiveness of heparin can be determined by observing for normalization of the plasma fibrinogen concentration and diminishing signs of bleeding. Fibrinolytic inhibitors, such as aminocaproic acid, may be used with heparin.

Other therapies include recombinant activated protein C (APC, drotrecogin alfa [Xigris]), which is effective in diminishing inflammatory responses on the surface of the vessels as well as having anticoagulant properties. Bleeding is common, can occur at any site, and can be significant. AT infusions can

also be used for their anticoagulant and anti-inflammatory properties. Bleeding can be significant, particularly when administered in association with heparin, and the use of both agents may diminish their efficacy (Levi, de Jonge, & van der Poll, 2006). Some studies have demonstrated a decrease in mortality when recombinant APC is used, but similar benefit has not been seen after infusion of AT (Levi, 2007).

Nursing Management

Nurses need to be aware of which patients are at risk for DIC. Sepsis and acute promyelocytic leukemia are the most common causes of DIC. Patients need to be assessed thoroughly and frequently for signs and symptoms of thrombi and bleeding and monitored for any progression of these signs (see Chart 33-12).

Chart 33-13 describes care of the patient with DIC. Assessment and interventions should target potential sites of end-organ damage. As organs become ischemic from microthrombi, organ function diminishes; the kidneys, lungs, brain, and skin are particularly vulnerable. Lack of renal perfusion may result in acute tubular necrosis and renal failure, sometimes requiring dialysis. Placement of a large-bore dialysis catheter is extremely hazardous for this patient population and should be accompanied by adequate platelet and plasma transfusions. Hepatic dysfunction is also relatively common, reflected in altered liver function tests, depleted albumin stores, and diminished synthesis of clotting factors.

 CHART
33-13

PLAN OF NURSING CARE
The Patient With Disseminated Intravascular Coagulation (DIC)
NURSING DIAGNOSIS: Risk for deficient fluid volume related to bleeding

GOALS: Hemodynamic status maintained; urine output ≥ 30 mL/h

Nursing Interventions

1. Avoid procedures/activities that can increase intracranial pressure (eg, coughing, straining to have a bowel movement).
2. Monitor vital signs closely, including neurologic checks:
 - a. Monitor hemodynamics.
 - b. Monitor abdominal girth.
 - c. Monitor urine output.
3. Avoid medications that interfere with platelet function if possible (eg, ASA, NSAIDs, beta-lactam antibiotics).
4. Avoid rectal probes, rectal medications.
5. Avoid IM injections.
6. Monitor amount of external bleeding carefully
 - a. Monitor number of dressings, % of dressing saturated; time to saturate a dressing is more objective than "dressing saturated a moderate amount."
 - b. Assess suction output, all excreta for frank or occult blood.
 - c. Monitor pad counts in women with vaginal bleeding.
 - d. Females may receive progesterone to prevent menses.
7. Use low pressure with any suctioning needed.
8. Administer oral hygiene carefully.
 - a. Avoid lemon-glycerine swabs, hydrogen peroxide, commercial mouthwashes.
 - b. Use sponge-tipped swabs, salt/baking soda (bicarbonate of soda) mouth rinses.
9. Avoid dislodging any clots, including those around IV sites and injection sites.

Rationale

1. Prevents intracranial bleeding
2. Identifies signs of hemorrhage/shock quickly
3. Decreases problems with platelet aggregation and adhesion
4. Decreases chance for rectal bleeding.
5. Decreases chance for intramuscular bleeding
6.
 - a. Provides accurate, objective assessment of extent of bleeding
 - b. Identifies presence of or quantifies extent of bleeding
 - c. Quantifies extent of bleeding
 - d. Decreases chance for gynecologic source of hemorrhage
7. Prevents excessive trauma that could cause bleeding
8. Prevents excessive trauma that could cause bleeding. Glycerin and alcohol (in commercial mouthwashes) will dry mucosa, increasing risk for bleeding
9. Prevents excessive bleeding at sites

Expected Outcomes

- Level of consciousness (LOC) stable
- CVP 5–12 cm H₂O, systolic BP ≥ 70 mm Hg
- Urine output ≥ 30 mL/hour
- Decreased bleeding
- Decreased oozing
- Decreased ecchymoses
- Amenorrhea
- Absence of oral and bronchial bleeding
- Oral mucosa clean, moist, intact

NURSING DIAGNOSIS: Risk for impaired skin integrity related to ischemia or bleeding

GOALS: Skin integrity remains intact; oral mucosa remains intact

Nursing Interventions

1. Assess skin, with particular attention to bony prominences, skin folds.
2. Reposition carefully; use pressure-reducing mattress.
3. Perform careful skin care every 2 hours, emphasizing dependent areas, all bony prominences, perineum.

Rationale

1. Prompt identification of any area at risk for skin breakdown or showing early signs of breakdown can facilitate prompt intervention and thus prevent complications.
- 2–4. Meticulous skin care and use of measures to prevent pressure on bony prominences decrease the risk of skin trauma.

Expected Outcomes

- Skin integrity remains intact; skin is warm, and of normal color.
- Oral mucosa is intact, pink, moist, without bleeding.

Continued on following page

 CHART
33-13

PLAN OF NURSING CARE
The Patient With Disseminated Intravascular Coagulation (DIC) (Continued)

Nursing Interventions	Rationale	Expected Outcomes
4. Use lamb's wool between digits, around ears, as needed. 5. Use prolonged pressure after injection or procedure when such measures must be performed (at least 5 minutes). 6. Perform oral hygiene carefully (see above).	5. Initial platelet plug is very unstable and easily dislodged, which can lead to increased bleeding. 6. Meticulous care is needed to decrease trauma, bleeding, and risk of infection.	
NURSING DIAGNOSIS: Risk for imbalanced fluid volume related to excessive blood and/or factor component replacement GOALS: Absence of edema; absence of rales; intake not greater than output		
Nursing Interventions	Rationale	Expected Outcomes
1. Auscultate breath sounds every 2–4 hour. 2. Monitor extent of edema. 3. Monitor volume of IVs, blood products; decrease volume of IV medications if indicated. 4. Administer diuretics as prescribed.	1. Crackles can develop quickly. 2. Fluid may extend beyond intravascular system. 3. Helps prevent fluid overload 4. Decreases fluid volume	<ul style="list-style-type: none"> • Breath sounds clear • Absence of edema • Intake does not exceed output • Weight stable
NURSING DIAGNOSIS: Ineffective tissue perfusion related to microthrombi GOALS: Neurologic status remains intact; absence of hypoxemia; peripheral pulses remain intact; skin integrity remains intact; urine output remains ≥ 30 mL/h		
Nursing Interventions	Rationale	Expected Outcomes
1. Assess neurologic, pulmonary, integumentary systems. 2. Monitor response to heparin therapy. 3. Assess extent of bleeding. 4. Monitor fibrinogen levels. 5. Stop aminocaproic acid (EACA) if symptoms of thrombosis occur.	1. Initial signs of thrombosis can be subtle. 2. Response to heparin is most accurately reflected in fibrinogen level. 3. Objective measurements of all sites of bleeding are crucial to accurately assess extent of blood loss. 4. Response to heparin is most accurately reflected in fibrinogen level. 5. EACA should be used only in setting of extensive hemorrhage not responding to replacement therapy.	<ul style="list-style-type: none"> • Arterial blood gases, O₂ saturation, pulse oximetry, LOC within normal limits • Breath sounds clear • Absence of edema • Intake does not exceed output • Weight stable
NURSING DIAGNOSIS: Anxiety related to uncertainty or possible death GOALS: Fears verbalized/identified; realistic hope maintained		
Nursing Interventions	Rationale	Expected Outcomes
1. Identify previous coping mechanisms, if possible; encourage patient to use them as appropriate. 2. Explain all procedures and rationale for these in terms patient and family can understand. 3. Assist family in supporting patient. 4. Use services from behavioral medicine, chaplain as needed.	1. Identifying previous stressful situations can aid in recall of successful coping mechanisms. 2. Decreased knowledge and uncertainty can increase anxiety. 3. Family can be useful in assisting patient to use coping strategies and to maintain hope. 4. Additional professional intervention may be necessary, particularly if previous coping mechanisms are maladaptive or ineffective. Spiritual dimension should be supported.	<ul style="list-style-type: none"> • Previously used coping strategies identified and tried, to extent patient is able to do so • Patient indicates understanding of procedures and situation as condition permits

Respiratory function warrants careful monitoring and aggressive measures to diminish alveolar compromise. Suctioning should be performed as gently as possible to diminish the risk of additional bleeding. Central nervous system involvement can be manifested as headache, visual changes, and alteration in level of consciousness.

Thrombotic Disorders

Several conditions can alter balance within the normal hemostasis process and cause excessive thrombosis. Abnormalities that predispose a person to thrombotic events include decreased clotting inhibitors within the circulation (which enhances coagulation), altered hepatic function (which may decrease production of clotting factors or clearance of activated coagulation factors), lack of fibrinolytic enzymes, and tortuous or atherosclerotic vessels (which promote platelet aggregation). Thrombosis may occur as an initial manifestation of an occult malignancy or as a complication from a preexisting cancer. It can also be caused by more than one predisposing factor. Several inherited or acquired deficiency conditions, including hyperhomocysteinemia, AT deficiency, protein C deficiency, protein S deficiency, APC resistance, and factor V Leiden deficiency, can predispose a patient to repeated episodes of thrombosis; they are referred to as hypercoagulable states or thrombophilia. Table 33-6 lists

these disorders, their abnormal laboratory values, and the need for family testing.

Conditions that may result from thrombosis include MI (see Chapter 28), CVA (stroke, brain attack; see Chapter 62), and peripheral arterial occlusive disease (see Chapter 31). Anticoagulation therapy is necessary. The duration of therapy varies with the location and extent of the thrombosis, precipitating events (eg, trauma, immobilization), and concurrent risk factors (eg, use of oral contraceptives, tortuous blood vessels, history of thrombotic events). With some conditions, or with repeated thrombosis, life-long anticoagulant therapy is necessary.

Hyperhomocysteinemia

Increased plasma levels of homocysteine are a significant risk factor not only for venous thrombosis (eg, DVT, pulmonary embolism) but also for arterial thrombosis (eg, stroke, MI). Hyperhomocysteinemia can be hereditary, or it can result from a nutritional deficiency of folic acid and, to a lesser extent, of vitamins B₁₂ and B₆, because these vitamins are cofactors in homocysteine metabolism. For unknown reasons, people who are elderly, those with renal failure, and smokers may also have elevated levels of homocysteine in the absence of nutritional deficiencies of these vitamins. Although a simple fasting measurement of plasma homocysteine can serve as a useful screening test, people with genetically inherited hyperhomocysteinemia and those who are vitamin B₆ deficient may have normal or minimally elevated levels. A more sensitive method involves obtaining a second measurement 4 hours after the patient consumes methionine; the hyperhomocysteinemia is found twice as often when this method is used. In hyperhomocysteinemia, the endothelial lining of the vessel walls is denuded, which can precipitate thrombus formation. Patients who are found to have hyperhomocysteinemia should receive folic acid, vitamin B₆, and vitamin B₁₂ supplements and should understand the rationale for their use.

Table 33-6 HYPERCOAGULABLE STATES

Disorder	Abnormal Laboratory Value*
Inherited Disorders (Family Testing Recommended)	
Hyperhomocysteinemia	Homocysteine ↑ after methionine load
Antithrombin III (AT III) deficiency	AT III ↓
Protein C deficiency	Protein C activity ↓; must be measured off warfarin (Coumadin)
Activated protein C (APC) resistance	Must be measured off anticoagulant; <2× prolongation of PTT when APC added. Patients with APC resistance have a smaller increase in clotting time than normal (ie, the prolongation of clotting time is less than normal).
Factor V Leiden	Positive
Protein S deficiency	Protein S activity ↓; must be measured off warfarin (Coumadin)
Dysfibrinogenemia	↑ Thrombin time; ↑ reptilase time; ↓ functional fibrinogen; often requires special fibrinogen assays
Acquired Disorders (Family Testing Unnecessary)	
Anticardiolipin antibody	Positive
Cancer	Varied, depending on disorder
Lupus anticoagulant	Positive
Hyperhomocysteinemia	Homocysteine ↑ after methionine load
AT III deficiency	AT III ↓
Paroxysmal nocturnal hemoglobinuria	+ Hamm's test; acid hemolysis
Myeloproliferative disorders	Varied, depending on disorder
Nephrotic syndrome	Varied, depending on disorder
Cancer chemotherapy	Varied, depending on disorder

*Protein C and protein S are vitamin K–dependent proteins. Warfarin (Coumadin) interferes with the hepatic synthesis of vitamin K–dependent factors, which may decrease levels of protein C or protein S; therefore, protein C and protein S should be measured while the patient is off warfarin.

Antithrombin Deficiency

AT is a protein that inhibits thrombin and certain coagulation factors, and it may also play a role in diminishing inflammation within the endothelium of blood vessels. AT deficiency is a hereditary condition that can cause venous thrombosis, particularly when the AT level is less than 60% of normal. Patients with AT deficiency rarely develop thrombosis before puberty. By 50 years of age, two thirds of patients with AT deficiency have venous thrombosis. The most common sites for thrombosis are the deep veins of the leg and the mesentery. Recurrent thrombosis often occurs, particularly as the patient ages. Patients tend to exhibit heparin resistance; thus, they may require greater amounts of heparin to achieve adequate anticoagulation. Patients with AT deficiency should be encouraged to have their family members tested for the deficiency.

AT deficiency can also be acquired by four mechanisms: accelerated consumption of AT (as in DIC), reduced synthesis of AT (as in hepatic dysfunction), increased excretion

of AT (as in nephrotic syndrome), and medication induced (eg, estrogens, L-asparaginase).

Protein C Deficiency

Protein C is an enzyme that, when activated, inhibits coagulation. When levels of protein C are deficient, the risk of thrombosis increases, and thrombosis can often occur spontaneously. People who are deficient in protein C are often without symptoms until their 20s; the risk of having a thrombotic event then increases, with a median age at first thrombosis ranging from 30 to 45 years. A rare but significant complication of anticoagulation management in patients with protein C deficiency is warfarin-induced skin necrosis. This complication appears to result from progressive thrombosis in the capillaries within the skin. The extent of the necrosis can be extreme. Prompt cessation of warfarin, treatment with vitamin K, and infusions of heparin and fresh-frozen plasma are crucial to arrest the pathophysiologic process and reverse the effects of the warfarin. Treatment with purified protein C concentrate is sometimes indicated.

Protein S Deficiency

Protein S is another natural anticoagulant normally produced by the liver. APC requires protein S to inactivate certain clotting factors. When the level of protein S is deficient, this inactivation process is diminished, and the risk of thrombosis can be increased. Like patients with protein C deficiency, those with protein S deficiency have a greater risk of recurrent venous thrombosis early in life, as early as 15 years of age. More than 50% of these thromboses are spontaneous. Thromboses most commonly occur in the axillary, mesenteric, and cerebral veins. Warfarin-induced skin necrosis is possible. Acquired protein S deficiency can also occur. Pregnancy, DIC, liver disease, nephritic syndrome, HIV infection, and the use of L-asparaginase have all been associated with reduced protein S levels.

Activated Protein C Resistance and Factor V Leiden Mutation

APC resistance is a common condition that can occur with other hypercoagulable states. APC is an anticoagulant, and resistance to APC increases the risk of venous thrombosis. A molecular defect in the factor V gene has been identified in most (90%) patients with APC resistance. This factor V Leiden mutation is the most common cause of inherited hypercoagulability in Caucasians, but its incidence appears to be much lower in other ethnic groups. Factor V Leiden mutation synergistically increases the risk of thrombosis in patients with other risk factors (eg, use of oral contraceptives, hyperhomocysteinemia, increased age). People who are homozygous for the factor V Leiden mutation are at extremely high risk of thrombosis and need anticoagulation for life, whereas those who are heterozygous for the mutation may need anticoagulation for only several months after a thrombotic event.

Acquired Thrombophilia

Etiology

Antiphospholipid Syndrome

Antibodies to phospholipids are common acquired causes of thrombophilia (hypercoagulable states). The most common of these are either lupus or anticardiolipin antibodies. Both of these antibodies can be transient, resulting from infection or certain medications. In addition, the occurrence of elevated antiphospholipid antibodies becomes increasingly prevalent with age (Rand, 2007). Most thrombotic events are venous, but arterial thrombosis can occur in up to one third of the cases. Patients who persistently test positive for either antibody and who have had a thrombotic event are at significant risk of recurrent thrombosis (greater than 50%). Recurrent thromboses tend to be of the same type—that is, venous thrombosis after an initial venous thrombosis, arterial thrombosis after an initial arterial thrombosis. Thrombi typically occur in large vessels.

Malignancy

Another common acquired cause of thrombophilia is cancer, particularly stomach, pancreatic, lung, and ovarian cancers. The type of thrombosis that results is unusual. Rather than DVT or pulmonary embolism, the thrombosis occurs in unusual sites, such as the portal, hepatic, or renal vein or the inferior vena cava. Migratory superficial thrombophlebitis or nonbacterial thrombotic endocarditis can also occur. In these patients, anticoagulation can be difficult to manage, and the thrombosis can progress despite standard doses of anticoagulants. LMWH appears to be a more effective anticoagulant than warfarin in treating this patient population (Korte, 2008).

Medical Management

The primary method of treating thrombotic disorders is anticoagulation. However, in thrombophilic conditions, when to treat (prophylaxis or not) and how long to treat (lifelong or not) can be controversial. Anticoagulation therapy is not without risks; the most significant risk is bleeding. The most common anticoagulant medications are identified in the following section.

Pharmacologic Therapy

Along with administering anticoagulant therapy, concerns include minimizing any risk factors that predispose a patient to thrombosis. When risk factors (eg, immobility after surgery, pregnancy) cannot be avoided, prophylactic anticoagulation may be necessary.

Unfractionated Heparin Therapy

Heparin is a naturally occurring anticoagulant that enhances AT III and inhibits platelet function. To prevent thrombosis, heparin is typically given as a subcutaneous injection, two or three times daily. To treat thrombosis, heparin is usually administered intravenously. The therapeutic effect of heparin is monitored by serial measurements of the aPTT; the dose is adjusted to maintain the range at 1.5 to 2.5 times the laboratory control. Oral forms

are being evaluated in clinical trials (Stone, Tonnessen & Money, 2007).

Heparin-Induced Thrombocytopenia. Heparin-induced thrombocytopenia (HIT) is a significant complication of heparin-based therapy. HIT involves the formation of antibodies against the heparin–platelet complex. The actual incidence of HIT is unknown, but it has been shown to occur in as many as 5% of patients receiving heparin (Ahmed, Majeed & Powell, 2007; Levy & Hursting, 2007). The type of heparin used, duration of therapy (beyond 4 days), and surgery appear to be risk factors for developing HIT: Bovine preparations are more likely to lead to HIT than porcine preparations, and LMWH formulations carry a lower risk. Prolonged use of heparin (beyond 4 days) and surgery are also risk factors (Ahmed, et al., 2007). Neither the dose nor the route of administration (IV versus subcutaneous) is a risk. A decline in platelet count is a hallmark sign that typically occurs after 4 to 14 days of heparin therapy; therefore, the platelet count should be monitored in any patient beginning heparin therapy. The platelet count can drop significantly, usually by 50% of baseline. The antibodies typically disappear in 2 to 3 months.

Interestingly, affected patients are at increased risk for thrombosis, either venous, arterial, or both, and the thrombosis can range from DVT to MI or CVA, or to ischemic damage to an extremity, necessitating amputation. The risk of fatal thrombosis is 20% to 30% (Ahmed, et al., 2007).

Heparin-associated thrombocytopenia (previously known as HIT-1) is actually more common than HIT. The platelet count declines slightly (rarely less than 100,000/mm³) within 2 to 3 days after heparin is initiated and it returns to a normal level within 4 days after the heparin is stopped (Ahmed, et al., 2007). The incidence is thought to be as high as 10% of heparin-treated patients, and there is no association with thrombosis.

Treatment of HIT includes prompt cessation of heparin and initiation of an alternative means of anticoagulation. If the heparin is stopped without providing additional anticoagulation, the patient is at increased risk for developing new thrombi. Two inhibitors of thrombin, lepirudin (Refludan) and argatroban, are FDA-approved anticoagulants for the treatment of HIT. Oral anticoagulation with warfarin can be initiated only after the platelet count has recovered.

Low-Molecular-Weight Heparin Therapy

LMWHs (eg, dalteparin [Fragmin], enoxaparin [Lovenox]) are special forms of heparin that have more selective effects on coagulation. Based on their biochemical properties, LMWHs have a longer half-life and a less variable anticoagulant response than unfractionated heparin. These differences permit LMWHs to be safely administered only once or twice daily, without the need for laboratory monitoring for dose adjustments. The incidence of HIT is much lower when an LMWH is used; however, LMWH is 100% cross-reactive with HIT antibodies and therefore contraindicated in HIT. In certain conditions, the use of an LMWH has allowed anticoagulation therapy to be moved entirely to the outpatient setting. Many cases of uncomplicated DVT are being managed outside the hospital. LMWHs are also used as “bridge therapy” when patients receiving anticoagulation

therapy (warfarin) require a major invasive procedure such as surgery (Dunn, 2006; du Breuil & Umland, 2007). In this situation, warfarin is stopped 2 to 3 days preoperatively and a LMWH is used in its place until the procedure is performed. After the procedure, warfarin therapy is resumed. If the LMWH is resumed after the procedure, it is discontinued when a therapeutic level of warfarin is achieved.

Warfarin (Coumadin) Therapy

Coumarin anticoagulants (warfarin [Coumadin]) are antagonists of vitamin K and therefore interfere with the synthesis of vitamin K–dependent clotting factors. Coumarin anticoagulants bind to albumin, are metabolized in the liver, and have an extremely long half-life. Typically, a patient with a venous thromboembolus is initially treated with both heparin (either unfractionated or an LMWH) and warfarin. When the international normalized ratio (INR), which is a standard method of reporting PT, reaches the desired therapeutic range, the heparin is stopped. The dosage required to maintain the therapeutic range (typically an INR of 2.0 to 3.0) varies widely among patients and even within the same patient, depending on the diagnosis and the rationale for anticoagulation. Frequent monitoring of the INR is extremely important so that the dosage of warfarin can be adjusted as needed.

Warfarin is affected by many medications; consultation with a pharmacist is important to assess the extent to which concurrently administered medications, herbs, and nutritional supplements may interact with warfarin. It is also affected by many foods, so patients need dietary instruction and may benefit from consultation with a dietitian. In particular, foods with high vitamin K content antagonize the effects of warfarin. Some of these foods include spinach, broccoli, and lettuce. Chart 33-14 lists agents that interact with warfarin.

Nursing Management

Patients with thrombotic disorders should avoid activities that lead to circulatory stasis (eg, immobility, crossing the legs). Exercise, especially ambulation, should be performed frequently throughout the day, particularly during long trips by car or plane. Anti-embolism stockings are often prescribed and patients often need assistance in learning how to use them properly. Surgery further increases the risk of thrombosis. Medications that alter platelet aggregation, such as low-dose aspirin, may be prescribed. Some patients require lifelong therapy with anticoagulants such as warfarin. No evidence supports the use of bed rest as a therapeutic intervention in people with DVT (du Breuil & Umland, 2007).

In addition, patients with thrombotic disorders, particularly those with thrombophilia, should be assessed for concurrent risk factors for thrombosis and should avoid them if possible. For example, use of tobacco and nicotine products should be avoided. In many instances, younger patients with thrombophilia may not require prophylactic anticoagulation; however, with concomitant risk factors (eg, pregnancy), increasing age, or subsequent thrombotic events, prophylactic or long-term anticoagulation therapy may be required. Being able to provide the health care provider with an accurate health history can be extremely useful and can help guide the selection of appropriate therapeutic interventions. Patients with hereditary disorders should encourage their siblings and children to be tested for the disorder.

**CHART
33-14**
PHARMACOLOGY**Agents That Interact With Warfarin (Coumadin)**

Although warfarin (Coumadin), an anticoagulant medication, is commonly used to treat and prevent thrombosis, many drug–drug and drug–food interactions are associated with its use. A careful medication history (including over-the-counter medications, herbs, and other substances, such as vitamins and minerals) is important when oral anticoagulation therapy is prescribed. Consultation with a pharmacist is recommended to assess the extent to which concurrent medications may affect the anticoagulant and for appropriate dosage adjustments. The following list contains a few examples of agents that interact with warfarin.

Agents That Inhibit Warfarin Function

Azathioprine
 Barbiturates
 Carbamazepine
 Cholestyramine
 Corticosteroids
 Cyclosporine
 Dicloxacillin
 Digitalis
 Estrogens
 Ethanol
 Glutethimide
 Griseofulvin
 Haloperidol
 Herbal medicines: coenzyme Q, ginseng, St. John's wort
 Nafcillin
 Oral contraceptives
 Phenytoin
 Rifampin
 Spironolactone
 Sucralfate
 Trazodone

Agents That Potentiate Warfarin Function

Acetaminophen
 Allopurinol
 Amiodarone
 Anabolic steroids
 Anti-inflammatory agents, including nonsteroidal anti-inflammatory drugs

Antimalarial agents
 Aspirin
 Broad-spectrum antibiotics
 Chloral hydrate
 Chloramphenicol
 Cimetidine
 Colchicine
 Clofibrate
 Chlorpromazine
 Danazol
 Disulfiram
 Erythromycin
 Ethacrynic acid
 Feprazole
 Fluconazole
 Herbal medicines:
 Danshen, devil's claw, dong quai, feverfew, garlic, ginkgo, ginseng, papain
 Vitamin C (in very large doses)
 Vitamin E (in very large doses)
 Isoniazid
 Lovastatin
 Mefenamic acid
 Methotrexate
 Metronidazole
 Miconazole
 Omeprazole
 Oral hypoglycemic agents
 Oxyphenbutazone
 Phenytoin
 Probenecid
 Propranolol
 Propylthiouracil
 Quinidine
 Quinine
 Salicylates
 Sulfinpyrazone
 Sulfonamides (long-acting)
 Tamoxifen
 Thyroxine
 Triclofos
 Tricyclic antidepressants

When a patient with a thrombotic disorder is hospitalized, frequent assessments should be performed for signs and symptoms of beginning thrombus formation, particularly in the legs (DVT) and lungs (pulmonary embolism). Ambulation or range-of-motion exercises as well as the use of anti-embolism stockings should be initiated promptly to decrease stasis. Prophylactic anticoagulants are commonly prescribed.

THERAPIES FOR BLOOD DISORDERS**Splenectomy**

The surgical removal of the spleen (splenectomy) is sometimes necessary. Splenectomy may be required after trauma to the abdomen. Severe hemorrhage can occur if the spleen is ruptured because the spleen is very vascular. Splenectomy is also a possible treatment for hematologic disorders. For

example, an enlarged spleen may be the site of excessive destruction of blood cells. If either of these conditions occurs, splenectomy is performed as an emergency procedure. In addition, some patients with grossly enlarged spleens develop severe thrombocytopenia as a result of platelets being sequestered in the spleen. Splenectomy removes the “trap,” and platelet counts may normalize over time.

In general, the mortality rate after splenectomy is low. Laparoscopic splenectomy can be performed in selected patients, with a resultant decrease in postoperative morbidity. Complications that may result from surgery are atelectasis, pneumonia, abdominal distention, and abscess formation. Although young children are at the highest risk after splenectomy, all age groups are vulnerable to overwhelming lethal infections and should receive the pneumococcal vaccine (Pneumovax) before undergoing splenectomy, if possible.

Table 33-7 TYPES OF APHERESIS*

Procedure	Purpose	Examples of Clinical Use
Platelet pheresis	Remove platelets	Extreme thrombocytosis, essential thrombocythemia (temporary measure); single-donor platelet transfusion
Leukapheresis	Remove WBCs (can be specific to neutrophils or lymphocytes)	Extreme leukocytosis (eg, AML, CML) (very temporary measure); harvest WBCs for transfusion
Erythrocytapheresis (RBC exchange)	Remove RBCs	RBC dyscrasias (eg, sickle cell disease); RBCs replaced via transfusion
Plasmapheresis (plasma exchange)	Remove plasma proteins	Hyperviscosity syndromes; treatment for some renal and neurologic diseases (eg, Goodpasture's syndrome, TTP, Guillain-Barré, myasthenia gravis)
Stem cell harvest	Remove circulating stem cells	Transplantation (donor harvest or autologous)

*Therapeutic apheresis can be used to treat a wide variety of conditions. When it is used to treat a disease that causes an increase in a specific cell type with a short life in circulation (ie, WBCs, platelets), the reduction in those cells is temporary. However, this temporary reduction permits a margin of safety while waiting for a longer-lasting treatment modality (eg, chemotherapy) to take effect. Apheresis can also be used to obtain stem cells for transplantation, either from a matched donor (allogenic) or from the patient (autologous).

AML, acute myeloid leukemia; CML, chronic myeloid leukemia; RBC, red blood cell; WBC, white blood cell; TTP, thrombotic thrombocytopenic purpura.

The patient is instructed to seek prompt medical attention if even relatively minor symptoms of infection occur. Often, patients with high platelet counts have even higher counts after splenectomy (more than 1 million/mm³), which can predispose them to serious thrombotic or hemorrhagic problems. However, this increase is transient and usually does not warrant additional treatment.

Therapeutic Apheresis

Apheresis is a Greek word meaning separation. In therapeutic apheresis (or pheresis), blood is taken from the patient and passed through a centrifuge, where a specific component is separated from the blood and removed (Table 33-7). The remaining blood is then returned to the patient. The entire system is closed, so the risk of bacterial contamination is low. When platelets or leukocytes are removed, the decrease in these cells within the circulation is temporary. However, the temporary decrease provides a window of time until suppressive medications (eg, chemotherapy) can have therapeutic effects. Sometimes plasma is removed rather than blood cells—typically so that specific, abnormal proteins within the plasma are transiently lowered until a long-term therapy can be initiated.

Apheresis is also used to obtain larger amounts of platelets from a donor than can be provided from a single unit of whole blood. A unit of platelets obtained in this way is equivalent to 6 to 8 units of platelets obtained from six to eight separate donors via standard blood donation methods. Platelet donors can have their platelets apheresed as often as every 14 days. Leukocytes can be obtained similarly, typically after the donor has received growth factors (G-CSF, GM-CSF) to stimulate the formation of additional leukocytes and thereby increase the leukocyte count. The use of these growth factors also stimulates the release of stem cells within the circulation. Apheresis is used to harvest these stem cells (typically over a period of several days) for use in PBSCT.

Therapeutic Phlebotomy

Therapeutic phlebotomy is the removal of a certain amount of blood under controlled conditions. Patients with elevated hematocrits (eg, those with polycythemia vera) or excessive iron absorption (eg, hemochromatosis) can usually be managed by periodically removing 1 unit (about 500 mL) of whole blood. Eventually this process can produce iron defi-

ciency, leaving the patient unable to produce as many erythrocytes. The actual procedure for therapeutic phlebotomy is similar to that for blood donation (see later discussion).

Blood Component Therapy

A single unit of whole blood contains 450 mL of blood and 50 mL of an anticoagulant, which can be processed and dispensed for administration. However, it is more appropriate, economical, and practical to separate that unit of whole blood into its primary components: erythrocytes, platelets, and plasma (leukocytes are rarely used; see later discussion). Because the plasma is removed, a unit of PRBCs is very concentrated (hematocrit approximately 70%).

Each component must be processed and stored differently to maximize the longevity of the viable cells and factors within it; each individual blood component has a different storage life. PRBCs are stored at 4°C (39.2°F). With special preservatives, they can be stored safely for up to 42 days before they must be discarded. In contrast, platelets must be stored at room temperature because they cannot withstand cold temperatures, and they last for only 5 days before they must be discarded. To prevent clumping, platelets are gently agitated while stored. Plasma is immediately frozen to maintain the activity of the clotting factors within; it lasts for 1 year if it remains frozen. Alternatively, plasma can be further pooled and processed into blood derivatives, such as albumin, immune globulin, factor VIII, and factor IX. Table 33-8 describes each blood component and how it is commonly used.

Special Preparations

Factor VIII concentrate (antihemophilic factor) is a lyophilized, freeze-dried concentrate of pooled fractionated human plasma. It is used in treating hemophilia A. Factor IX concentrate (prothrombin complex) is similarly prepared and contains factors II, VII, IX, and X. It is used primarily for treatment of factor IX deficiency (hemophilia B). Factor IX concentrate is also useful in treating congenital factor VII and factor X deficiencies. Recombinant forms of factor VIII, such as Humate-P or Alphanate, are also useful. Because they contain vWF, these agents are used in vWD as well as in hemophilia A, particularly when patients develop factor VIII inhibitors.

Plasma albumin is a large protein molecule that usually stays within vessels and is a major contributor to plasma

Table 33-8 BLOOD AND BLOOD COMPONENTS COMMONLY USED IN TRANSFUSION THERAPY*

	Composition	Indications and Considerations
Whole blood	Cells and plasma, hematocrit about 40%	Volume replacement and oxygen-carrying capacity; usually used only in significant bleeding (>25% blood volume lost)
Packed red blood cells (PRBCs)	RBCs with little plasma (hematocrit about 75%); some platelets and WBCs remain	↑ RBC mass Symptomatic anemia: platelets in the unit are not functional; WBCs in the unit may cause reaction and are not functional
Platelets—random	Platelets (5.5×10^{10} platelets/unit) Plasma; some RBCs, WBCs	Bleeding due to severe ↓ platelets Prevent bleeding when platelets $<5000\text{--}10,000/\text{mm}^3$ Survival ↓ in presence of fever, chills, infection Repeated treatment → ↓ survival due to alloimmunization
Platelets—single donor	Platelets (3×10^{11} platelets/unit) 1 unit is equivalent to 6–8 units of random platelets	Used for repeated treatment: ↓ alloimmunization risk by limiting exposure to multiple donors
Plasma	Plasma; all coagulation factors Complement	Bleeding in patients with coagulation factor deficiencies; plasmapheresis
Granulocytes	Neutrophils ($>1 \times 10^{10}$ /unit); lymphocytes; some RBCs and platelets	Severe neutropenia in selected patients; controversial
Lymphocytes (WBCs)	Lymphocytes (number varies)	Stimulate graft-versus-host disease effect
Cryoprecipitate	Fibrinogen ≥ 150 mg/bag, AHF (VIII:C) 80–110 units/bag, von Willebrand factor; fibronectin	von Willebrand disease Hypofibrinogenemia Hemophilia A
AHF	Factor VIII	Hemophilia A
Factor IX concentrate	Factor IX	Hemophilia B (Christmas disease)
Factor IX complex	Factors II, VII, IX, X	Hereditary factor VII, IX, X deficiency; hemophilia A with factor VII inhibitors
Albumin	Albumin 5%, 25%	Hypoproteinemia; burns; volume expansion by 5% to ↑ blood volume; 25% → ↓ hematocrit
Intravenous gamma-globulin	IgG antibodies	Hypogammaglobulinemia (in CLL, recurrent infections); ITP; primary immunodeficiency states
Antithrombin III concentrate (AT III)	AT III (trace amounts of other plasma proteins)	AT III deficiency with or at risk for thrombosis

*The composition of each type of blood component is described as well as the most common indications for using a given blood component. RBCs, platelets, and fresh-frozen plasma are the blood products most commonly used. When transfusing these blood products, it is important to realize that the individual product is always “contaminated” with very small amounts of other blood products (eg, WBCs mixed in a unit of platelets). This contamination can cause some difficulties, particularly isosensitization, in certain patients.

AHF, antihemophilic factor; CLL, chronic lymphocytic leukemia; ITP, idiopathic thrombocytopenic purpura; RBCs, red blood cells; WBC, white blood cells.

oncotic pressure. This protein is used to expand the blood volume of patients in hypovolemic shock and, rarely, to increase the concentration of circulating albumin in patients with hypoalbuminemia.

Immune globulin is a concentrated solution of the antibody IgG; it contains very little IgA or IgM. It is prepared from large pools of plasma. The IV form (IVIG) is used in various clinical situations to replace inadequate amounts of IgG in patients who are at risk for recurrent bacterial infection (eg, those with CLL, those receiving BMT or PBSCT). It is also used in certain autoimmune disorders, such as ITP. Both albumin and IVIG, in contrast to all other fractions of human blood, cells, or plasma, can survive being subjected to heating at 60°C (140°F) for 10 hours to free them of the viral contaminants that may be present (Chart 33-15).

PROCURING BLOOD AND BLOOD PRODUCTS

Blood Donation

To protect both the donor and the recipients, all prospective donors are examined and interviewed before they are allowed to donate their blood. The intent of the interview is to assess the general health status of the donor and to identify risk factors that might harm a recipient of the donor's blood. Donors should be in good health and without any of the following:

- A history of viral hepatitis at any time in the past, or a history of close contact with a patient who had hepatitis or was undergoing dialysis within 6 months.
- A history of receiving a blood transfusion or an infusion of any blood derivative (other than serum albumin) within 12 months
- Previous transfusion in the United Kingdom, Gibraltar, or Falkland Islands. People who received these transfusions are not allowed to donate blood in the United States because they may have an increased likelihood of transmitting Creutzfeldt-Jakob disease.
- A cumulative total stay since 1980 in the United Kingdom of more than 3 months or in any other European country exceeding 6 months, because the likelihood of transmitting Creutzfeldt-Jakob disease may be increased
- A history of untreated syphilis or malaria, because these diseases can be transmitted by transfusion even years later. A person who has been free of symptoms and off therapy for 3 years after malaria may be a donor.
- A history or evidence of drug abuse in which illicit drugs were self-injected, because many IV/injection drug users are carriers of hepatitis and because the risk of HIV is high in this group
- A history of possible exposure to HIV. The population at risk includes people who engage in anal sex, people with multiple sexual partners, IV/injection drug users,

Chart 33-15 • Diseases Transmitted by Blood Transfusion

Hepatitis (Viral Hepatitis B, C)

- Greater risk from pooled blood products and blood of paid donors than from volunteer donors
- Screening test detects most hepatitis B and C
- Transmittal risk estimated at 1:10,000

AIDS (HIV and HTLV)

- Donated blood screened for antibodies to HIV
- Transmittal risk estimated at 1:670,000
- People with high-risk behaviors (multiple sex partners, anal sex, IV/injection drug use) and people with signs and symptoms that suggest AIDS should not donate blood

Cytomegalovirus (CMV)

- Transmittal risk greater for premature newborns with CMV antibody-negative mothers and for immunocompromised recipients who are CMV negative (eg, those with acute leukemia, organ or tissue transplant recipients)
- Blood products rendered "leukocyte reduced" help reduce transmission of virus

Graft-Versus-Host Disease (GVHD)

- Occurs only in severely immunocompromised recipients (eg, Hodgkin disease, bone marrow transplantation)
- Transfused lymphocytes engraft in recipient and attack host lymphocytes or body tissues; signs and symptoms are fever, diffuse reddened skin rash, nausea, vomiting, diarrhea
- Preventive measures include irradiating blood products to inactivate donor lymphocytes (no known radiation risks to transfusion recipient) and processing donor blood with leukocyte reduction filters

Creutzfeldt-Jakob Disease (CJD)

- Rare, fatal disease causing irreversible brain damage
- No evidence of transmittal by transfusion, but hemophiliacs and others are concerned that transmittal is possible
- All blood donors must be screened for positive family history of CJD
- Potential donors who spent 3 months or more in the United Kingdom or 6 months or more in Europe since 1980 cannot donate blood; blood products from a donor who develops CJD are recalled

sexual partners of people at risk for HIV, and people with hemophilia.

- A skin infection, because of the possibility of contaminating the phlebotomy needle, and subsequently the blood itself
- A recent history of asthma, urticaria, or allergy to medications, because hypersensitivity can be transferred passively to the recipient
- Pregnancy, because of the nutritional demands of pregnancy on the mother
- A history of tooth extraction or oral surgery within 72 hours, because such procedures are frequently associated with transient bacteremia
- A history of untreated exposure to infectious disease within the past 3 weeks, because of the risk of transmission to the recipient

- Recent immunizations, because of the risk of transmitting live organisms (2-week waiting period for live, attenuated organisms; 1 month for rubella, mumps, varicella; 1 year for rabies)
- A history of recent tattoo, because of the risk of bloodborne infections (eg, hepatitis, HIV)
- Cancer, because of the uncertainty about transmission of the disease. People who have a history of a non-hematologic cancer treated with surgery or radiation and who are without evidence of recurrence for at least 5 years are eligible to donate.
- A diagnosis of hemochromatosis (although this exclusion varies among blood centers)
- A history of whole blood donation within the past 56 days

Potential donors should be asked whether they have consumed any aspirin or aspirin-containing medications within the past 3 days. Although aspirin use does not render the donor ineligible, the platelets obtained may be dysfunctional and therefore not useful; aspirin use within 48 to 72 hours contraindicates platelet donation. Aspirin does not affect the erythrocytes or plasma obtained from the donor.

All donors are expected to meet the following minimal requirements:

- Body weight should exceed 50 kg (110 pounds) for a standard 450-mL donation. Donors weighing less than 50 kg donate proportionately less blood. People younger than 17 years of age are disqualified from donation.
- The oral temperature should not exceed 37.5°C (99.6°F).
- The pulse rate should be regular and between 50 and 100 bpm.
- The systolic arterial blood pressure should be 90 to 180 mm Hg, and the diastolic pressure should be 50 to 100 mm Hg.
- The hemoglobin level should be at least 12.5 g/dL for women and 13.5 g/dL for men.

Directed Donation

At times, friends and family of a patient wish to donate blood for that person. These blood donations are termed directed donations. These donations are not any safer than those provided by random donors, because directed donors may not be as willing to identify themselves as having a history of any of the risk factors that disqualify a person from donating blood.

Standard Donation

Phlebotomy consists of venipuncture and blood withdrawal. Standard precautions are used. Donors are placed in a semi-recumbent position. The skin over the antecubital fossa is carefully cleansed with an antiseptic preparation, a tourniquet is applied, and venipuncture is performed. Withdrawal of 450 mL of blood usually takes less than 15 minutes. After the needle is removed, donors are asked to hold the involved arm straight up, and firm pressure is applied with sterile gauze for 2 to 3 minutes or until bleeding stops. A firm bandage is then applied. The donor remains recumbent until he or she feels able to sit up, usually within a few minutes. Donors who experience weakness or faintness should rest for a longer period. The donor then receives food and fluids and is asked to remain another 15 minutes.

The donor is instructed to leave the dressing on and to avoid heavy lifting for several hours, to avoid smoking for 1 hour, to avoid drinking alcoholic beverages for 3 hours, to increase fluid intake for 2 days, and to eat healthy meals for at least 2 weeks. Specimens from this donated blood are tested to detect infections and to identify the specific blood type (see later discussion).

Autologous Donation

A patient's own blood may be collected for future transfusion; this method is useful for many elective surgeries where the potential need for transfusion is high (eg, orthopedic surgery). Preoperative donations are ideally collected 4 to 6 weeks before surgery. Iron supplements are prescribed during this period to prevent depletion of iron stores. Typically, 1 unit of blood is drawn each week; the number of units obtained varies with the type of surgical procedure to be performed (ie, the amount of blood anticipated to be transfused). Phlebotomies are not performed within 72 hours of surgery. Individual blood components can also be collected.

The primary advantage of autologous transfusions is the prevention of viral infections from another person's blood. Other advantages include safe transfusion for patients with a history of transfusion reactions, prevention of alloimmunization, and avoidance of complications in patients with alloantibodies. It is the policy of the American Red Cross that autologous blood is transfused only to the donor. If the blood is not required, it can be frozen until the donor needs it in the future (for up to 10 years). The blood is never returned to the general donor supply of blood products to be used by another person.

Needless autologous donation (ie, performed when the likelihood of transfusion is small) is discouraged because it is expensive, takes time, and uses resources inappropriately. Moreover, in an emergency situation, the autologous units available may be inadequate, and the patient may still require additional units from the general donor supply. Furthermore, although autologous transfusion can eliminate the risk of viral contamination, the risk of bacterial contamination is the same as that in transfusion from random donors.

Contraindications to donation of blood for autologous transfusion are acute infection, severely debilitating chronic disease, hemoglobin level less than 11 g/dL, hematocrit less than 33%, unstable angina, and acute cardiovascular or cerebrovascular disease. A history of poorly controlled epilepsy may be considered a contraindication in some centers.

Intraoperative Blood Salvage

This transfusion method provides replacement for patients who cannot donate blood before surgery and for those undergoing vascular, orthopedic, or thoracic surgery. During a surgical procedure, blood lost into a sterile cavity (eg, hip joint) is suctioned into a cell-saver machine. The whole blood or PRBCs are washed, often with saline solution; filtered; and then returned to the patient as an IV infusion. Salvaged blood cannot be stored, because bacteria cannot be completely removed from the blood and it cannot be used when it is contaminated with bacteria. The use of intraoperative blood salvage has decreased the need for autologous blood donation.

Hemodilution

This transfusion method may be initiated before or after induction of anesthesia. About 1 to 2 units of blood are removed from the patient through a venous or arterial line and simultaneously replaced with a colloid or crystalloid solution. The blood obtained is then reinfused after surgery. The advantage of this method is that the patient loses fewer erythrocytes during surgery, because the added IV solutions dilute the concentration of erythrocytes and lower the hematocrit. However, patients who are at risk for myocardial injury should not be further stressed by hemodilution. The efficacy of hemodilution has not been consistently demonstrated in clinical research, and further study is warranted (Toy, Beattie, Gould, et al., 2008).

Complications of Blood Donation

Excessive bleeding at the donor's venipuncture site is sometimes caused by a bleeding disorder but more often results from a technique error: laceration of the vein, excessive tourniquet pressure, or failure to apply enough pressure after the needle is withdrawn.

Fainting is common after blood donation and may be related to emotional factors, a vasovagal reaction, or prolonged fasting before donation. Because of the loss of blood volume, hypotension and syncope may occur when the donor assumes an erect position. A donor who appears pale or complains of faintness should immediately lie down or sit with the head lowered below the knees. He or she should be observed for another 30 minutes.

Anginal chest pain may be precipitated in patients with unsuspected coronary artery disease. Seizures can occur in donors with epilepsy, although the incidence is very low. Both angina and seizures require further medical evaluation and treatment.

Blood Processing

Samples of the unit of blood are always taken immediately after donation so that the blood can be typed and tested. Each donation is tested for antibodies to HIV 1 and 2, hepatitis B core antibody (anti-HBc), hepatitis C virus (HCV), human T-cell lymphotropic virus type I (anti-HTLV-I/II), hepatitis B surface antigen (HbsAG), and syphilis. Negative reactions are required for the blood to be used, and each unit of blood is labeled to certify the results. Nucleic acid amplification testing has increased the ability to detect the presence of HCV, HIV, and West Nile virus infections, because it directly tests for genomic nucleic acids of the viruses rather than for the presence of antibodies to the viruses. This testing significantly shortens the "window" of inability to detect HIV and HCV from a donated unit, further ensuring the safety of the blood; the risk of transmission of HIV or HCV is now estimated at 0.7 and 3.6 in 1 million units of blood transfused, respectively (Stollings & Oyen, 2006). Blood is also screened for CMV; if it tests positive for CMV, it can still be used, except in recipients who are negative for CMV and who are immunocompromised (eg, BMT or PBSCT recipients).

Equally important to viral testing is accurate determination of the blood type. More than 200 antigens have been identified on the surface of RBC membranes. Of these, the most important for safe transfusion are the ABO and Rh systems. The ABO system identifies which sugars are present

on the membrane of a person's erythrocytes: A, B, both A and B, or neither A nor B (type O). To prevent a significant reaction, the same type of PRBCs should be transfused. Previously, it was thought that in an emergency situation in which the patient's blood type was not known, type O blood could be safely transfused. This practice is no longer recommended.

The Rh antigen (also called D) is present on the surface of erythrocytes in 85% of the population (Rh positive). Those who lack the D antigen are called Rh negative. PRBCs are routinely tested for the D antigen as well as ABO. Patients should receive PRBCs with a compatible Rh type.

The majority of transfusion reactions (other than those due to procedural error) are due to the presence of donor leukocytes within the blood component unit (PRBCs or platelets); the recipient may form antibodies to the antigens present on these leukocytes. PRBC components typically have 1 to 3×10^9 leukocytes remaining in each unit. Leukocytes from the blood product are frequently filtered to diminish the likelihood of developing reactions and refractoriness to transfusions, particularly in patients who have chronic transfusion needs. The process of leukocyte filtration renders the blood component "leukocyte poor" (ie, leukopoor). Filtration can occur at the time the unit is collected from the

donor and processed, which achieves better results but is more expensive, or at the time the blood component is transfused by attaching a leukocyte filter to the blood administration tubing. Many centers advocate routinely using leukopoor filtered blood components for people who have or are likely to develop chronic transfusion requirements.

When a patient is immunocompromised, as in the case of bone or stem cell transplant, any donor lymphocytes must be removed from the blood components. In this situation, the blood component is exposed to low amounts of radiation (25 Gy) that kill any lymphocytes within the blood component. Irradiated blood products are highly effective in preventing transfusion-associated GVHD, which is fatal in most cases. Irradiated blood products have a shorter shelf life.

TRANSFUSION

Administration of blood and blood components requires knowledge of correct administration techniques and possible complications. It is very important to be familiar with the agency's policies and procedures for transfusion therapy. Methods for transfusing blood components are presented in Charts 33-16 and 33-17.

Chart 33-16 • Transfusion of Packed Red Blood Cells (PRBCs)

Preprocedure

1. Confirm that the transfusion has been prescribed.
2. Check that patient's blood has been typed and cross-matched.
3. Verify that patient has signed a written consent form per institution or agency policy.
4. Explain the procedure to the patient. Instruct patient in signs and symptoms of transfusion reaction (itching, hives, swelling, shortness of breath, fever, chills).
5. Take patient's temperature, pulse, respiration, and blood pressure to establish a baseline and auscultate lungs; assess for jugular venous distention to serve as a baseline for comparison during transfusion.
6. Use hand hygiene and wear gloves in accordance with standard precautions.
7. Use a 20-gauge or larger needle for insertion in a large vein. Use special tubing that contains a blood filter to screen out fibrin clots and other particulate matter. Do not vent the blood container.

Procedure

1. Obtain the PRBCs from the blood bank *after* the intravenous line is started. (Institution policy may limit release to only 1 unit at a time.)
2. Double-check the labels with another nurse or physician to make sure that the ABO group and Rh type agree with the compatibility record. Check to see that the number and type on the donor blood label and on the patient's medical record are correct. Check the patient's identification by asking the patient's name and checking the identification wristband.
3. Check the blood for gas bubbles and any unusual color or cloudiness. (Gas bubbles may indicate bacterial growth. Abnormal color or cloudiness may be a sign of hemolysis.)

4. Make sure PRBC transfusion is initiated within 30 minutes after removal of the PRBCs from the blood bank refrigerator.
5. For first 15 minutes, run the transfusion slowly—no faster than 5 mL/min. Observe the patient carefully for adverse effects. If no adverse effects occur during the first 15 minutes, increase the flow rate unless the patient is at high risk for circulatory overload.
6. Monitor closely for 15 to 30 minutes to detect signs of reaction. Monitor vital signs at regular intervals per institution or agency policy; compare results with baseline measurements. Increase frequency of measurements based on patient's condition. Observe the patient frequently throughout the transfusion for any signs of adverse reaction, including restlessness, hives, nausea, vomiting, torso or back pain, shortness of breath, flushing, hematuria, fever, or chills. Should any adverse reaction occur, stop infusion immediately, notify physician, and follow the agency's transfusion reaction standard.
7. Note that administration time does not exceed 4 hours because of the increased risk of bacterial proliferation.
8. Be alert for signs of adverse reactions: circulatory overload, sepsis, febrile reaction, allergic reaction, and acute hemolytic reaction.
9. Change blood tubing after every 2 units transfused, to decrease chance of bacterial contamination.

Postprocedure

1. Obtain vital signs and compare with baseline measurements.
2. Dispose of used materials properly.
3. Document procedure in patient's medical record, including patient assessment findings and tolerance to procedure.
4. Monitor patient for response to and effectiveness of the procedure.

Note: Never add medications to blood or blood products; if blood is too thick to run freely, normal saline may be added to the unit. If blood must be warmed, use an in-line blood warmer with a monitoring system.

Chart 33-17 • Transfusion of Platelets or Fresh-Frozen Plasma (FFP)**Preprocedure**

1. Confirm that the transfusion has been prescribed.
2. Verify that patient has signed a written consent form per institution policy.
3. Explain the procedure to the patient. Instruct patient in signs and symptoms of transfusion reaction (itching, hives, swelling, shortness of breath, fever, chills).
4. Take patient's temperature, pulse, respiration, and blood pressure to establish a baseline and auscultate breath sounds to establish a baseline for comparison during transfusion.
5. Use hand hygiene and wear gloves in accordance with standard precautions.
6. Use a 22-gauge or larger needle for placement in a large vein, if possible. Use appropriate tubing per institution policy (platelets often require different tubing from that used for other blood products).

Procedure

1. Obtain the platelets or FFP from the blood bank (only *after* the intravenous line is started.)
2. Double-check the labels with another nurse or physician to make sure that the ABO group matches the compatibility record (not usually necessary for platelets; here only if compatible platelets are ordered). Check to see that the number and type on the donor blood label and on the patient's chart are correct. Check the patient's identification by asking the patient's name and checking the identification wristband.
3. Check the blood product for any unusual color or clumps (excessive redness indicates contamination with larger amounts of red blood cells).

4. Make sure platelets or FFP units are administered immediately after they are obtained.
5. Infuse each unit of FFP over 30 to 60 minutes per patient tolerance; infuse each unit of platelets as fast as patient can tolerate to diminish platelet clumping during administration. Observe the patient carefully for adverse effects, including circulatory overload. Decrease rate of infusion if necessary.
6. Observe the patient closely throughout the transfusion for any signs of adverse reaction, including restlessness, hives, nausea, vomiting, torso or back pain, shortness of breath, flushing, hematuria, fever, or chills. Should any adverse reaction occur, stop infusion immediately, notify physician, and follow the agency's transfusion reaction standard.
7. Monitor vital signs at end of transfusion per institution policy; compare results with baseline measurements.
8. Flush line with saline after transfusion to remove blood component from tubing.

Postprocedure

1. Obtain vital signs and compare with baseline measurements.
2. Dispose of used materials properly.
3. Document procedure in patient's medical record, including patient assessment findings and tolerance to procedure.
4. Monitor patient for response to and effectiveness of procedure. A platelet count may be ordered 1 hour after platelet transfusion to facilitate this evaluation.

Note: FFP requires ABO but not Rh compatibility. Platelets are not typically cross-matched for ABO compatibility. Never add medications to blood or blood products.

Setting

Although most blood transfusions are performed in the acute care setting, patients with chronic transfusion requirements often can receive transfusions in other settings. Free-standing infusion centers, ambulatory care clinics, physicians' offices, and even patients' homes may be appropriate settings for transfusion. Typically, patients who need chronic transfusions but are otherwise stable physically are appropriate candidates for outpatient therapy. Verification and administration of the blood product are performed as in a hospital setting. Although most blood products can be transfused in the outpatient setting, the home is typically limited to transfusions of PRBCs and factor components (eg, factor VIII for patients with hemophilia).

Pretransfusion Assessment**Patient History**

Patient history is an important component of the pretransfusion assessment to determine the history of previous transfusions as well as previous reactions to transfusion. The history should include the type of reaction, its manifestations, the interventions required, and whether any preventive interventions were used in subsequent transfusions. It is important to assess the number of pregnancies a woman has had, because a high number can increase her risk of reaction

due to antibodies developed from exposure to fetal circulation. Other concurrent health problems should be noted, with careful attention to cardiac, pulmonary, and vascular disease.

Physical Assessment

A systematic physical assessment and measurement of baseline vital signs are important before transfusing any blood product. The respiratory system should be assessed, including careful auscultation of the lungs and the patient's use of accessory muscles. Cardiac system assessment should include careful inspection for any edema as well as other signs of cardiac failure (eg, jugular venous distention). The skin should be observed for rashes, petechiae, and ecchymoses. The sclera should be examined for icterus. In the event of a transfusion reaction, a comparison of findings can help differentiate between types of reactions.

Patient Teaching

Reviewing the signs and symptoms of a transfusion reaction is crucial for patients who have not received a previous transfusion. Even for patients who have received prior transfusions, a brief review of the signs and symptoms of transfusion reactions is advised. Signs and symptoms of a reaction include fever, chills, respiratory distress, low back pain, nausea, pain at the IV site, or anything "unusual." Although a

thorough review is very important, it is also important to reassure the patient that the blood is carefully tested against the patient's own blood (cross-matched) to diminish the likelihood of any untoward reaction. Similarly, the patient can be reassured about the very low possibility of contracting HIV from the transfusion; this fear persists among many people.

Complications

Any patient who receives a blood transfusion may develop complications from that transfusion. When explaining the reasons for the transfusion, it is important to include the risks and benefits and what to expect during and after the transfusion. Patients must be informed that, although it has been tested carefully, the supply of blood is not completely risk-free. Nursing management is directed toward preventing complications, promptly recognizing complications if they develop, and promptly initiating measures to control complications. The following sections describe the most common or potentially severe transfusion-related complications.

Febrile Nonhemolytic Reaction

A febrile nonhemolytic reaction is caused by antibodies to donor leukocytes that remain in the unit of blood or blood component; it is the most common type of transfusion reaction, accounting for more than 90% of reactions. It occurs more frequently in patients who have had previous transfusions (exposure to multiple antigens from previous blood products) and in Rh-negative women who have borne Rh-positive children (exposure to an Rh-positive fetus raises antibody levels in the untreated mother). These reactions occur in 3% of PRBC transfusions and 20% of platelet transfusions. More than 10% of patients with chronic transfusion requirements develop this type of reaction.

The diagnosis of a febrile nonhemolytic reaction is made by excluding other potential causes, such as a hemolytic reaction or bacterial contamination of the blood product. The signs and symptoms of a febrile nonhemolytic transfusion reaction are chills (minimal to severe) followed by fever (more than 1°C elevation). The fever typically begins within 2 hours after the transfusion is begun. Although the reaction is not life-threatening, the fever, and particularly the chills and muscle stiffness, can be frightening to the patient.

This reaction can be diminished, even prevented, by further depleting the blood component of donor leukocytes; this is accomplished by a leukocyte reduction filter. Antipyretics can be given to prevent fever, but routine premedication is not advised because it can mask the beginning of a more serious transfusion reaction.

Acute Hemolytic Reaction

The most dangerous, and potentially life-threatening, type of transfusion reaction occurs when the donor blood is incompatible with that of the recipient. Antibodies already present in the recipient's plasma rapidly combine with antigens on donor erythrocytes, and the erythrocytes are destroyed in the circulation (ie, intravascular hemolysis). The most rapid hemolysis occurs in ABO incompatibility. This reaction can occur after transfusion of as little as 10 mL of PRBCs. Rh incompatibility often causes a less severe reaction. The most common causes of acute hemolytic re-

action are errors in blood component labeling and patient identification that result in the administration of an ABO-incompatible transfusion.

Symptoms consist of fever, chills, low back pain, nausea, chest tightness, dyspnea, and anxiety. As the erythrocytes are destroyed, the hemoglobin is released from the cells and excreted by the kidneys; therefore, hemoglobin appears in the urine (hemoglobinuria). Hypotension, bronchospasm, and vascular collapse may result. Diminished renal perfusion results in acute renal failure, and DIC may also occur.

The reaction must be recognized promptly and the transfusion discontinued immediately. Blood and urine specimens must be obtained and analyzed for evidence of hemolysis. Treatment goals include maintaining blood volume and renal perfusion and preventing and managing DIC.

Acute hemolytic transfusion reactions are preventable. Meticulous attention to detail in labeling blood samples and blood components and accurately identifying the recipient cannot be overemphasized.

Allergic Reaction

Some patients develop urticaria (hives) or generalized itching during a transfusion. The cause of these reactions is thought to be a sensitivity reaction to a plasma protein within the blood component being transfused. Symptoms of an allergic reaction are urticaria, itching, and flushing. The reactions are usually mild and respond to antihistamines. If the symptoms resolve after administration of an antihistamine (eg, diphenhydramine [Benadryl]), the transfusion may be resumed. Rarely, the allergic reaction is severe, with bronchospasm, laryngeal edema, and shock. These reactions are managed with epinephrine, corticosteroids, and vasopressor support, if necessary.

Giving the patient antihistamines before the transfusion may prevent future reactions. For severe reactions, future blood components are washed to remove any remaining plasma proteins. Leukocyte filters are not useful to prevent such reactions, because the offending plasma proteins can pass through the filter.

Circulatory Overload

If too much blood is infused too quickly, hypervolemia can occur. This condition can be aggravated in patients who already have increased circulatory volume (eg, those with heart failure). PRBCs are safer to use than whole blood. If the administration rate is sufficiently slow, circulatory overload may be prevented. For patients who are at risk for, or already in, circulatory overload, diuretics are administered after the transfusion or between units of PRBCs. Patients receiving fresh-frozen plasma or even platelets may also develop circulatory overload. The infusion rate of these blood components must also be titrated to the patient's tolerance.

Signs of circulatory overload include dyspnea, orthopnea, tachycardia, and sudden anxiety. Jugular vein distention, crackles at the base of the lungs, and an increase in blood pressure can also occur. If the transfusion is continued, pulmonary edema can develop, as manifested by severe dyspnea and coughing of pink, frothy sputum.

If fluid overload is mild, the transfusion can often be continued after slowing the rate of infusion and administering diuretics. However, if the overload is severe, the patient is

placed in an upright position with the feet in a dependent position, the transfusion is discontinued, and the physician is notified. The IV line is kept patent with a very slow infusion of normal saline solution or a saline or heparin lock device to maintain access to the vein in case IV medications are necessary. Oxygen and morphine may be needed to treat severe dyspnea (see Chapter 30).

Bacterial Contamination

The incidence of bacterial contamination of blood components is very low; however, administration of contaminated products puts the patient at great risk. Contamination can occur at any point during procurement or processing but often results from organisms on the donor's skin. Many bacteria cannot survive in the cold temperatures used to store PRBCs, but some organisms can do so. Platelets are at greater risk of contamination because they are stored at room temperature. Recently, blood centers have developed rapid methods of culturing platelet units (Eder, Kennedy, Dy, et al., 2007), thereby diminishing the risk of using a contaminated platelet unit for transfusion.

Preventive measures include meticulous care in the procurement and processing of blood components. When PRBCs or whole blood is transfused, it should be administered within a 4-hour period, because warm room temperatures promote bacterial growth. A contaminated unit of blood product may appear normal, or it may have an abnormal color.

The signs of bacterial contamination are fever, chills, and hypotension. These signs may not occur until the transfusion is complete, occasionally not until several hours after the transfusion. If the condition is not treated immediately with fluids and broad-spectrum antibiotics, septic shock can occur. Even with aggressive management, including vasopressor support, the mortality rate is high.

As soon as the reaction is recognized, any remaining transfusion is discontinued, and the IV line is kept open with normal saline solution. The physician and the blood bank are notified, and the blood container is returned to the blood bank for testing and culture. Sepsis is treated with IV fluids and antibiotics; corticosteroids and vasopressors are often also necessary (see Chapter 15).

Transfusion-Related Acute Lung Injury

Transfusion-related acute lung injury (TRALI) is a potentially fatal, idiosyncratic reaction that occurs in less than 1 in 5000 transfusions, but as detection improves, the re-

ported incidence will likely increase. TRALI is now the most common transfusion-related cause of death reported to the FDA (Barrett & Kam, 2006; Triulzi, 2006; Cherry, Steciuk, Reddy, et al., 2008).

The underlying pathophysiologic mechanism for TRALI is unknown but is thought to involve antibodies in the donor's plasma that react to the leukocytes in the recipient's blood. Occasionally, the reverse occurs, and antibodies present in the recipient's plasma agglutinate the antigens on the few remaining leukocytes in the blood component being transfused (Barrett & Kam, 2006; Triulzi, 2006). Another theory suggests that an initial insult to the patient's vascular endothelium causes neutrophils to aggregate at the injured endothelium. Various substances within the transfused plasma (lipids, cytokines) then activate these neutrophils (Barrett & Kam, 2006). The end result of this process is interstitial and intra-alveolar edema, as well as extensive sequestration of WBCs within the pulmonary capillaries (Barrett & Kam, 2006; Cherry, et al., 2008).

Onset is abrupt (usually within 6 hours of transfusion, often within 2 hours). Signs and symptoms include acute shortness of breath, hypoxia (arterial oxygen saturation [SaO₂] less than 90%), hypotension, fever, and eventual pulmonary edema. Diagnostic criteria include hypoxemia, bilateral pulmonary infiltrates (seen on chest x-ray), and no evidence of cardiac cause for the pulmonary edema (Cherry, et al., 2008). Aggressive supportive therapy (eg, oxygen, intubation, fluid support) may prevent death.

Although TRALI can occur with the transfusion of any blood component, it is far more likely to occur when plasma and, to a lesser extent, platelets are transfused. One commonly used preventive strategy involves limiting the frequency and amount of blood products transfused. Another entails obtaining plasma and possibly platelets only from either men or from women who have never been pregnant (and, consequently, are less likely to have developed offending antibodies) (Estep, Bucci, Farmer, et al., 2008). The efficacy of this approach and its impact on the availability of these blood components remain unclear.

Delayed Hemolytic Reaction

Delayed hemolytic reactions usually occur within 14 days after transfusion, when the level of antibody has been increased to the extent that a reaction can occur. The hemolysis of the erythrocytes is extravascular via the RES and occurs gradually.

Table 33-9 COMMON COMPLICATIONS RESULTING FROM LONG-TERM PRBC TRANSFUSION THERAPY*

Complication	Manifestation	Management
Infection	Hepatitis (B, C)	May immunize against hepatitis B; treat hepatitis C; monitor hepatic function
Iron overload	Cytomegalovirus (CMV) Heart failure Endocrine failure (diabetes, hypothyroidism, hypoparathyroidism, hypogonadism)	WBC filters to protect against CMV Prevent by chelation therapy
Transfusion reaction	Sensitization Febrile reactions	Diminish by RBC phenotyping, using WBC-filtered products Diminish by using WBC-filtered products

*Patients with long-term transfusion therapy requirements are at risk not only for the transfusion reactions discussed in the text but also for the complications noted above. In many cases, the use of WBC-filtered (eg, leukocyte-poor) blood products is standard for patients who receive long-term PRBC transfusion therapy. An aggressive chelation program initiated early in the course of therapy can prevent problems with iron overload.
PRBC, packed red blood cells; RBC, red blood cell; WBC, white blood cell.

33-18

PHARMACOLOGY

Pharmacologic Alternatives to Blood Transfusions

Growth Factors

Recombinant technology has provided a means to produce hematopoietic growth factors necessary for the production of blood cells within the bone marrow. By increasing the body's production of blood cells, transfusions and complications resulting from diminished blood cells (eg, infection from neutropenia) may be avoided. However, the successful use of growth factors requires functional bone marrow. Moreover, the safety of these products has been questioned and the U.S. Food and Drug Administration is limiting their use in some patient populations.

Erythropoietin

Erythropoietin (epoetin alfa Epogen, Procrit) is an effective alternative treatment for patients with chronic anemia secondary to diminished levels of erythropoietin, as in chronic renal disease. This medication stimulates erythropoiesis. It also has been used for patients who are anemic from chemotherapy or zidovudine (AZT) therapy and for those who have diseases involving bone marrow suppression, such as myelodysplastic syndrome (MDS). The use of erythropoietin can also enable a patient to donate several units of blood for future use (eg, preoperative autologous donation). The medication can be administered intravenously or subcutaneously, although plasma levels are better sustained with the subcutaneous route. Side effects are rare, but erythropoietin can cause or exacerbate hypertension. If the anemia is corrected too quickly or is overcorrected, the elevated hematocrit can cause headache and, potentially, seizures. Thrombosis has been noted in some patients whose hemoglobins were raised to a high level and thus, it is recommended that a target hemoglobin level of 12 g/dL be used. These adverse effects are rare except for patients with renal failure. Serial complete blood counts (CBCs) should be performed to evaluate the response to the medication. The dose and frequency of administration are titrated to the hematocrit.

Granulocyte Colony-Stimulating Factor (G-CSF)

G-CSF (filgrastim [Neupogen]) is a cytokine that stimulates the proliferation and differentiation of myeloid stem cells;

a rapid increase in neutrophils is seen within the circulation. G-CSF is effective in improving transient but severe neutropenia after chemotherapy or in some forms of MDS. It is particularly useful in preventing bacterial infections that would be likely to occur with neutropenia. G-CSF is administered subcutaneously on a daily basis. The primary side effect is bone pain; this probably reflects the increase in hematopoiesis within the marrow. Serial CBCs should be performed to evaluate the response to the medication and to ensure that the rise in white blood cells is not excessive. The effect of G-CSF on myelopoiesis is short; the neutrophil count drops once the medication is stopped.

Granulocyte-Macrophage Colony-Stimulating Factor (GM-CSF)

GM-CSF (sargramostim [Leukine]) is a cytokine that is naturally produced by a variety of cells, including monocytes and endothelial cells. It works either directly or synergistically with other growth factors to stimulate myelopoiesis. GM-CSF is not as specific to neutrophils as is G-CSF; thus, an increase in erythroid (red blood cell) and megakaryocytic (platelet) production may also be seen. GM-CSF serves the same purpose as G-CSF. However, it may have a greater effect on macrophage function and therefore may be more useful against fungal infections, whereas G-CSF may be better used to fight bacterial infections. GM-CSF is also administered subcutaneously. Side effects include bone pain, fevers, and myalgias.

Thrombopoietin

Thrombopoietin (TPO) is a cytokine that is necessary for the proliferation of megakaryocytes and subsequent platelet formation. Unfortunately, clinical studies were stopped due to antibody formation. A second-generation thrombopoietic growth factor (romiplostin [Nplate]) that is nonimmunogenic was recently approved for the treatment of idiopathic thrombocytopenia purpura.

Signs and symptoms of a delayed hemolytic reaction are fever, anemia, increased bilirubin level, decreased or absent haptoglobin, and possibly jaundice. Rarely, there is hemoglobinuria. Generally, these reactions are not dangerous, but it is important to recognize them, because subsequent transfusions with blood products containing these antibodies may cause a more severe hemolytic reaction. However, recognition is also difficult, because the patient may not be in a health care setting to be tested for this reaction, and even if the patient is hospitalized, the reaction may be too mild to be recognized clinically. Because the amount of antibody present can be too low to detect, it is difficult to prevent delayed hemolytic reactions. Fortunately, the reaction is usually mild and requires no intervention.

Disease Acquisition

Despite advances in donor screening and blood testing, certain diseases can still be transmitted by transfusion of blood components (see Chart 33-15).

Complications of Long-Term Transfusion Therapy

The complications that have been described represent a real risk to any patient any time a blood component is administered. However, patients with long-term transfusion requirements (eg, those with MDS, thalassemia, aplastic anemia, sickle cell anemia) are at greater risk for infection transmission and for becoming more sensitized to donor antigens, simply because they are exposed to more units of blood and, consequently, more donors. A summary of complications associated with long-term transfusion therapy is given in Table 33-9.

Iron overload is a complication unique to people who have had long-term PRBC transfusions. One unit of PRBCs contains 250 mg of iron. Patients with chronic transfusion requirements can quickly acquire more iron than they can use, leading to iron overload. Over time, the excess iron deposits in body tissues and can cause organ damage, particularly in the liver, heart, testes, and pancreas. Promptly initiating a program of iron chelation therapy can prevent end-organ damage from iron toxicity (see Myelodysplastic Syndrome,

Nursing Management, and Hereditary Hemochromatosis, Nursing Management).

Nursing Management for Transfusion Reactions

If a transfusion reaction is suspected, the transfusion must be immediately stopped and the physician notified. A thorough patient assessment is crucial, because many complications have similar signs and symptoms. The following steps are taken to determine the type and severity of the reaction:

- Stop the transfusion. Maintain the IV line with normal saline solution through new IV tubing, administered at a slow rate.
- Assess the patient carefully. Compare the vital signs with baseline, including oxygen saturation. Assess the patient's respiratory status carefully. Note the presence of adventitious breath sounds, use of accessory muscles, extent of dyspnea, and changes in mental status, including anxiety and confusion. Note any chills, diaphoresis, jugular vein distention, and reports of back pain or urticaria.
- Notify the physician of the assessment findings, and implement any treatments prescribed. Continue to monitor the patient's vital signs and respiratory, cardiovascular, and renal status.
- Notify the blood bank that a suspected transfusion reaction has occurred.
- Send the blood container and tubing to the blood bank for repeat typing and culture. The identifying tags and numbers are verified.

If a hemolytic transfusion reaction or bacterial infection is suspected, the nurse does the following:

- Obtains appropriate blood specimens from the patient
- Collects a urine sample as soon as possible to detect hemoglobin in the urine
- Documents the reaction according to the institution's policy

Pharmacologic Alternatives to Blood Transfusions

Pharmacologic agents that stimulate production of one or more types of blood cells by the marrow are commonly used (Chart 33-18).

Researchers continue to seek a blood substitute that is practical and safe. Manufacturing artificial blood is problematic, given the myriad functions of blood components. Research findings from a recent trial of an artificial blood product were disappointing; the use of this product was associated with cardiovascular toxicity and regulatory approval is not likely (Estep, et al., 2008). The search for an efficacious artificial blood remains elusive.

PERIPHERAL BLOOD STEM CELL TRANSPLANTATION AND BONE MARROW TRANSPLANTATION

PBSCT and BMT are therapeutic modalities that offer the possibility of cure for some patients with hematologic disorders such as severe aplastic anemia, some forms of

leukemia, and thalassemia. These are discussed in detail in Chapter 16.

CRITICAL THINKING EXERCISES

EBP 1 You are working in a hematology-oncology clinic. The laboratory reports a critical laboratory result for one of your patients with possible MDS: The leukocyte count is $1800/\text{mm}^3$ with 40% neutrophils. What other laboratory results would be important to review or consider? The patient is also anemic (hemoglobin 8.2 mg/dL) and platelets are $65,000/\text{mm}^3$. What observations will you include in your assessment of this patient? Determine the extent to which this patient is neutropenic. What medical treatments would you anticipate? How would you educate the patient about neutropenia precautions? What evidence exists to support your educational interventions? What is the strength of that evidence?

EBP 2 You are caring for a 32-year-old woman who has had repeated hospitalizations for sickle cell crisis. What is the evidence base that indicates which factors should be assessed to determine the patient's educational, coping, and pain management needs? What is the strength of that evidence? Identify the evidence base that supports concepts that you will incorporate into the patient's discharge plan.

3 A 63-year-old man presents to the emergency department with unilateral swelling and pain of the left lower extremity. He reports this is the third time he has had a blood clot (DVT). How would you determine if he is at risk for having a hypercoagulable disorder? What would you include in your history to help you? How would you respond if he asks you if he will "ever get off Coumadin"? What would you include in your patient education to aid him in adhering to lifelong anticoagulation? What would your interventions be to decrease the risk of postphlebotic syndrome?

4 You are caring for a patient who is septic and is now receiving a transfusion of 2 units of PRBCs. The patient's temperature spikes to 38.5°C (101.3°F) after half of the second unit has been transfused. What are the possible causes of the fever? How would you differentiate the cause as sepsis versus a transfusion reaction? What are the appropriate nursing interventions? What are the potential causes of transfusion reaction? How are they manifested?

Digestive and Gastrointestinal Function

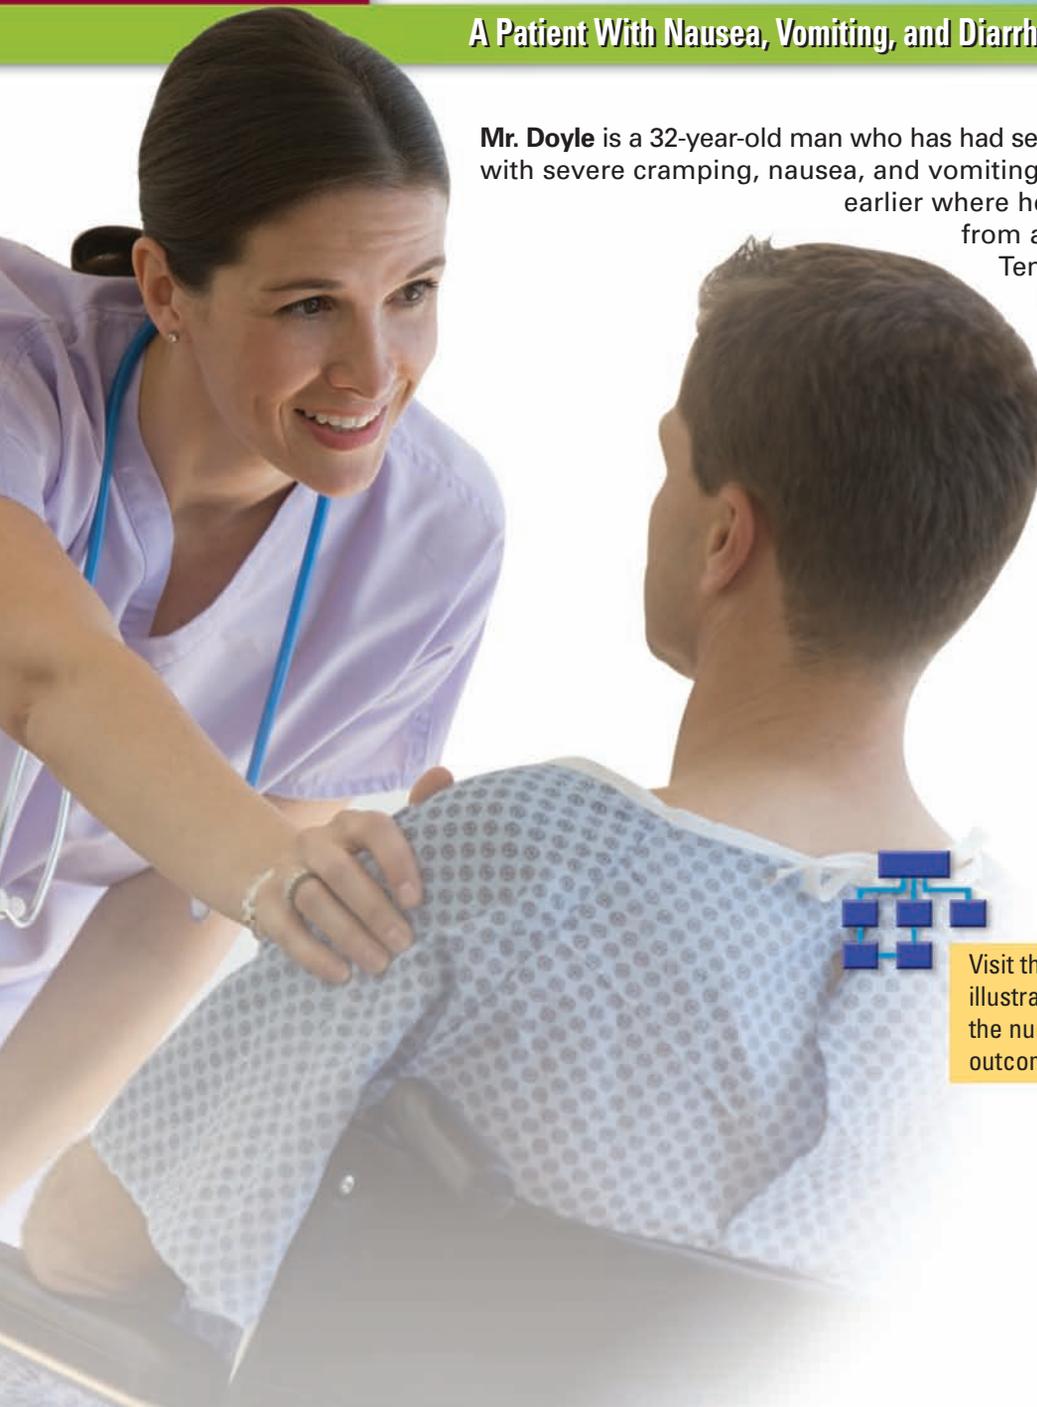

Case Study • Applying Concepts From NANDA, NIC, and NOC

A Patient With Nausea, Vomiting, and Diarrhea

Mr. Doyle is a 32-year-old man who has had several episodes of bloody diarrhea with severe cramping, nausea, and vomiting after attending a party 12 hours earlier where he drank eggnog and ate foods from a buffet table. Vital signs are: Temp 103°F; HR 108; B/P 118/80; Resp 20. Because Mr. Doyle is a kidney transplant recipient and is on immunosuppressive medications, he is admitted to the hospital; his diagnosis is salmonellosis.

Visit thePoint to view a concept map that illustrates the relationships that exist between the nursing diagnoses, interventions, and outcomes for the patient's clinical problems.

Nursing Classifications and Languages

NANDA NURSING DIAGNOSES	NIC NURSING INTERVENTIONS	NOC NURSING OUTCOMES
		Return to functional baseline status, stabilization of, or improvement in:
NAUSEA —Unpleasant wavelike sensation in the back of the throat, epigastrium, or abdomen that may lead to the urge or need to vomit	NAUSEA MANAGEMENT —Prevention and alleviation of nausea	SYMPTOM SEVERITY —Severity of perceived adverse changes in physical, emotional, and social functioning
DIARRHEA —Passage of loose, unformed stools	DIARRHEA MANAGEMENT —Prevention and alleviation of diarrhea	COMFORT LEVEL —Extent of physical and psychological ease
RISK FOR DEFICIENT FLUID VOLUME —At risk for experiencing vascular, cellular, or intracellular dehydration	FLUID/ELECTROLYTE MANAGEMENT —Regulation and prevention of complications from altered fluid and/or electrolyte levels VOMITING MANAGEMENT —Prevention and alleviation of vomiting	HYDRATION —Adequate water in the intracellular and extracellular compartments of the body

chapter 34

Assessment of Digestive and Gastrointestinal Function

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

- 1 Describe the structure and function of the organs of the gastrointestinal (GI) tract.
- 2 Describe the mechanical and chemical processes involved in digesting and absorbing foods and eliminating waste products.
- 3 Use assessment parameters appropriate for determining the status of GI function.
- 4 Describe the appropriate preparation, teaching, and follow-up care for patients who are undergoing diagnostic testing of the GI tract.

GLOSSARY

absorption: phase of the digestive process that occurs when small molecules, vitamins, and minerals pass through the walls of the small and large intestine and into the bloodstream

achalasia: absence of peristalsis of the lower esophagus resulting in difficulty swallowing, regurgitation, and sometimes pain

amylase: an enzyme that aids in the digestion of starch

anus: last section of the GI tract; outlet for waste products from the system

chyme: mixture of food with saliva, salivary enzymes, and gastric secretions that is produced as the food passes through the mouth, esophagus, and stomach

digestion: phase of the digestive process that occurs when digestive enzymes and secretions mix with ingested food and when proteins, fats, and sugars are broken down into their component smaller molecules

GLOSSARY (Continued)

dyspepsia: indigestion; upper abdominal discomfort associated with eating

elimination: phase of digestive process that occurs after digestion and absorption, when waste products are evacuated from the body

esophagus: collapsible tube connecting the mouth to the stomach, through which food passes as it is ingested

fibroscopy (gastrointestinal): intubation of a part of the GI system with a flexible, lighted tube to assist in diagnosis and treatment of diseases of that area

hydrochloric acid: acid secreted by the glands in the stomach; mixes with chyme to break it down into absorbable molecules and to aid in the destruction of bacteria

ingestion: phase of the digestive process that occurs when food is taken into the GI tract via the mouth and esophagus

intrinsic factor: a gastric secretion that combines with vitamin B₁₂ so that the vitamin can be absorbed

large intestine: the portion of the GI tract into which waste material from the small intestine passes as absorption continues and elimination begins; consists of several parts—ascending segment, transverse segment, descending segment, sigmoid colon, and rectum

lipase: an enzyme that aids in the digestion of fats

pepsin: a gastric enzyme that is important in protein digestion

small intestine: longest portion of the GI tract, consisting of three parts—duodenum, jejunum, and ileum—through which food mixed with all secretions and enzymes passes as it continues to be digested and begins to be absorbed into the bloodstream

stomach: distensible pouch into which the food bolus passes to be digested by gastric enzymes

trypsin: enzyme that aids in the digestion of protein

Abnormalities of the gastrointestinal (GI) tract are numerous and represent every type of major pathology that can affect other organ systems, including bleeding, perforation, obstruction, inflammation, and cancer. Congenital, inflammatory, infectious, traumatic, and neoplastic lesions have been encountered in every portion and at every site along the length of the GI tract. As with all other organ systems, the GI tract is subject to circulatory disturbances, faulty nervous system control, and aging.

Apart from the many organic diseases to which the GI tract is susceptible, many extrinsic factors can interfere with its normal function and produce symptoms. Stress and anxiety, for example, often find their chief expression in indigestion, anorexia, or motor disturbances of the intestines, sometimes producing constipation or diarrhea. In addition to the state of mental health, physical factors such as fatigue and an inadequate or abruptly changed dietary intake can markedly affect the GI tract. When assessing and instructing the patient, the nurse should consider the variety of mental and physical factors that affect the function of the GI tract.

Anatomic and Physiologic Overview

Anatomy of the Gastrointestinal System

The GI tract is a 23- to 26-foot-long (7 m to 7.9 m) pathway that extends from the mouth to the esophagus, stomach, small and large intestines, and rectum to the terminal structure, the **anus** (Fig. 34-1). The **esophagus** is located in the mediastinum anterior to the spine and posterior to the trachea and heart. This hollow muscular tube, which is approximately 25 cm (10 in) in length, passes through the diaphragm at an opening called the diaphragmatic hiatus.

The remaining portion of the GI tract is located within the peritoneal cavity. The **stomach** is situated in the left upper portion of the abdomen under the left lobe of the liver and the diaphragm, overlaying most of the pancreas (see Fig. 34-1). A hollow muscular organ with a capacity of approximately 1500 mL, the stomach stores food during eating, secretes digestive fluids, and propels the partially digested food, or chyme, into the small intestine. The gastroesophageal junction is the inlet to the stomach. The stomach has four anatomic regions: the cardia (entrance), fundus, body, and pylorus (outlet). Circular smooth muscle in the wall of the pylorus forms the pyloric sphincter and controls the opening between the stomach and the small intestine.

The **small intestine** is the longest segment of the GI tract, accounting for about two thirds of the total length. It folds back and forth on itself, providing approximately 7000 cm (70 m) of surface area for secretion and **absorption**, the process by which nutrients enter the bloodstream through the intestinal walls. It has three sections: The most proximal section is the duodenum, the middle section is the jejunum, and the distal section is the ileum. The ileum terminates at the ileocecal valve. This valve, or sphincter, controls the flow of digested material from the ileum into the cecal portion of the large intestine and prevents reflux

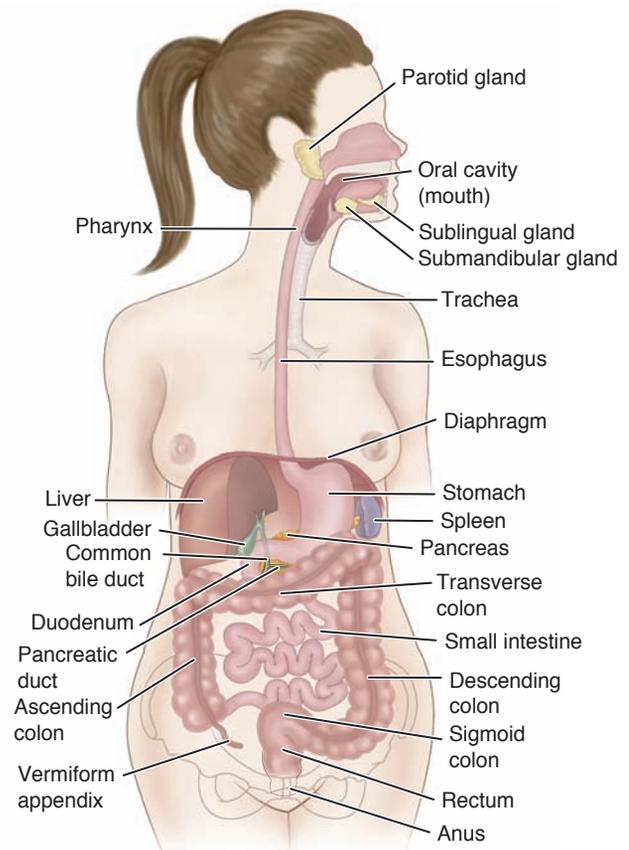

Figure 34-1 Organs of the digestive system and associated structures.

of bacteria into the small intestine. Attached to the cecum is the vermiform appendix, an appendage that has little or no physiologic function. Emptying into the duodenum at the ampulla of Vater is the common bile duct, which allows for the passage of both bile and pancreatic secretions.

The **large intestine** consists of an ascending segment on the right side of the abdomen, a transverse segment that extends from right to left in the upper abdomen, and a descending segment on the left side of the abdomen. The sigmoid colon, the rectum, and the anus complete the terminal portion of the large intestine. A network of striated muscle that forms both the internal and the external anal sphincters regulates the anal outlet.

The GI tract receives blood from arteries that originate along the entire length of the thoracic and abdominal aorta and veins that return blood from the digestive organs and the spleen. This portal venous system is composed of five large veins: the superior mesenteric, inferior mesenteric, gastric, splenic, and cystic veins, which eventually form the venae portae that enters the liver. Once in the liver, the blood is distributed throughout and collected into the hepatic veins that then terminate in the inferior vena cava. Of particular importance are the gastric artery and the superior and inferior mesenteric arteries. Oxygen and nutrients are supplied to the stomach by the gastric artery and to the intestine by the mesenteric arteries (Fig. 34-2). Venous blood is returned from the small intestine, cecum, and ascending and transverse portions of the colon by the superior mesenteric vein, which corresponds with

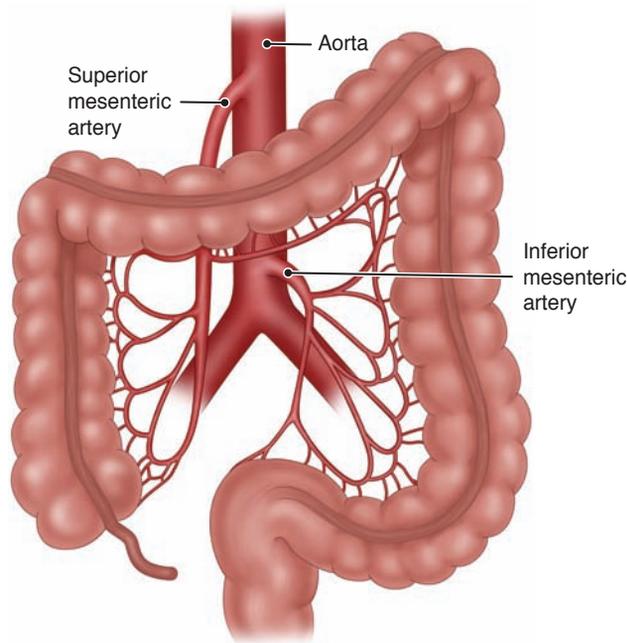

Figure 34-2 Anatomy and blood supply of the large intestine.

the distribution of the branches of the superior mesenteric artery. Blood flow to the GI tract is about 20% of the total cardiac output and increases significantly after eating.

Both the sympathetic and parasympathetic portions of the autonomic nervous system innervate the GI tract. In general, sympathetic nerves exert an inhibitory effect on the GI tract, decreasing gastric secretion and motility and causing the sphincters and blood vessels to constrict. Parasympathetic nerve stimulation causes peristalsis and increases secretory activities. The sphincters relax under the influence of parasympathetic stimulation except for the sphincter of the upper esophagus and the external anal sphincter, which are under voluntary control.

Function of the Digestive System

All cells of the body require nutrients. These nutrients are derived from the intake of food that contains proteins, fats, carbohydrates, vitamins, minerals, and cellulose fibers and other vegetable matter, some of which has no nutritional value. Primary functions of the GI tract are the following:

- The breakdown of food particles into the molecular form for **digestion**
- The absorption into the bloodstream of small nutrient molecules produced by digestion
- The **elimination** of undigested unabsorbed foodstuffs and other waste products

After food is ingested, it is propelled through the GI tract, coming into contact with a wide variety of secretions that aid in its digestion, absorption, or elimination from the GI tract.

Chewing and Swallowing

The process of digestion begins with the act of chewing, in which food is broken down into small particles that can be

swallowed and mixed with digestive enzymes. Eating—or even the sight, smell, or taste of food—can cause reflex salivation. Approximately 1.5 L of saliva is secreted daily from the parotid, submaxillary, and sublingual glands. Ptyalin, or salivary amylase, is an enzyme that begins the digestion of starches. Water and mucus, also contained in saliva, help lubricate the food as it is chewed, thereby facilitating swallowing.

Swallowing begins as a voluntary act that is regulated by the swallowing center in the medulla oblongata of the central nervous system (CNS). As a bolus of food is swallowed, the epiglottis moves to cover the tracheal opening and prevent aspiration of food into the lungs. Swallowing, which propels the bolus of food into the upper esophagus, thus ends as a reflex action. The smooth muscle in the wall of the esophagus contracts in a rhythmic sequence from the upper esophagus toward the stomach to propel the bolus of food along the tract. During this process of esophageal peristalsis, the lower esophageal sphincter relaxes and permits the bolus of food to enter the stomach. Subsequently, the lower esophageal sphincter closes tightly to prevent reflux of stomach contents into the esophagus.

Gastric Function

The stomach, which stores and mixes food with secretions, secretes a highly acidic fluid in response to the presence or anticipated **ingestion** of food. This fluid, which can total 2.4 L/day, can have a pH as low as 1 and derives its acidity from **hydrochloric acid** (HCl) secreted by the glands of the stomach. The function of this gastric secretion is twofold: to break down food into more absorbable components and to aid in the destruction of most ingested bacteria. **Pepsin**, an important enzyme for protein digestion, is the end product of the conversion of pepsinogen from the chief cells (Table 34-1). **Intrinsic factor**, also secreted by the gastric mucosa, combines with dietary vitamin B₁₂ so that the vitamin can be absorbed in the ileum. In the absence of intrinsic factor, vitamin B₁₂ cannot be absorbed, and pernicious anemia results (see Chapter 33).

Peristaltic contractions in the stomach propel the stomach's contents toward the pylorus. Because large food particles cannot pass through the pyloric sphincter, they are churned back into the body of the stomach. In this way, food in the stomach is mechanically broken down into smaller particles. Food remains in the stomach for a variable length of time, from 30 minutes to several hours, depending on the volume, osmotic pressure, and chemical composition of the gastric contents. Peristalsis in the stomach and contractions of the pyloric sphincter allow the partially digested food to enter the small intestine at a rate that permits efficient absorption of nutrients. This partially digested food mixed with gastric secretions is called **chyme**. Hormones, neuroregulators, and local regulators found in the gastric secretions control the rate of gastric secretions and influence gastric motility (Table 34-2).

Small Intestine Function

The digestive process continues in the duodenum. Duodenal secretions come from the accessory digestive organs—the pancreas, liver, and gallbladder—and the glands in the wall of the intestine itself. These secretions contain digestive enzymes: amylase, lipase, and bile. Pancreatic secretions have an alkaline pH due to their high concentration of bicarbonate.

Table 34-1 THE MAJOR DIGESTIVE ENZYMES AND SECRETIONS

Enzyme/Secretion	Enzyme Source	Digestive Action
Action of Enzymes That Digest Carbohydrates		
Ptyalin (salivary amylase)	Salivary glands	Starch→dextrin, maltose, glucose
Amylase	Pancreas and intestinal mucosa	Starch→dextrin, maltose, glucose Dextrin→maltose, glucose
Maltase	Intestinal mucosa	Maltose→glucose
Sucrase	Intestinal mucosa	Sucrose→glucose, fructose
Lactase	Intestinal mucosa	Lactose→glucose, galactose
Action of Enzymes/Secretions That Digest Protein		
Pepsin	Gastric mucosa	Protein→polypeptides
Trypsin	Pancreas	Proteins and polypeptides→polypeptides, dipeptides, amino acids
Aminopeptidase	Intestinal mucosa	Polypeptides→dipeptides, amino acids
Dipeptidase	Intestinal mucosa	Dipeptides→amino acids
Hydrochloric acid	Gastric mucosa	Protein→polypeptides, amino acids
Action of Enzymes Secretions That Digest Fat (Triglyceride)		
Pharyngeal lipase	Pharynx mucosa	Triglycerides→fatty acids, diglycerides, monoglycerides
Steapsin	Gastric mucosa	Triglycerides→fatty acids, diglycerides, monoglycerides
Pancreatic lipase	Pancreas	Triglycerides→fatty acids, diglycerides, monoglycerides
Bile	Liver and gallbladder	Fat emulsification

This alkalinity neutralizes the acid entering the duodenum from the stomach. Digestive enzymes secreted by the pancreas include **trypsin**, which aids in digesting protein; **amylase**, which aids in digesting starch; and **lipase**, which aids in digesting fats. These secretions drain into the pancreatic duct, which empties into the common bile duct at the ampulla of Vater. Bile, secreted by the liver and stored in the gallbladder, aids in emulsifying ingested fats, making them easier to digest and absorb. The sphincter of Oddi, found at the confluence

of the common bile duct and duodenum, controls the flow of bile. Hormones, neuroregulators, and local regulators found in these intestinal secretions control the rate of intestinal secretions and also influence GI motility. Intestinal secretions total approximately 1 L/day of pancreatic juice, 0.5 L/day of bile, and 3 L/day of secretions from the glands of the small intestine. Tables 34-1 and 34-2 give further information about the actions of digestive enzymes and GI regulatory substances.

Table 34-2 THE MAJOR GASTROINTESTINAL REGULATORY SUBSTANCES

Substance	Stimulus for Production	Target Tissue	Effect on Secretions	Effect on Motility
Neuroregulators				
Acetylcholine	Sight, smell, chewing food, stomach distention	Gastric glands, other secretory glands, gastric and intestinal muscle	Increased gastric acid	Generally increased; decreased sphincter tone
Norepinephrine	Stress, other various stimuli	Secretory glands, gastric and intestinal muscle	Generally inhibitory	Generally decreased; increased sphincter tone
Hormonal Regulators				
Gastrin	Stomach distention with food	Gastric glands	Increased secretion of gastric juice, which is rich in HCl	Increased motility of stomach, decreased time required for gastric emptying Relaxation of ileocecal sphincter Excitation of colon Constriction of gastroesophageal sphincter
Cholecystokinin	Fat in duodenum	Gallbladder Pancreas	Release of bile into duodenum Increased production of enzyme-rich pancreatic secretions	
Secretin	pH of chyme in duodenum below 4–5	Stomach Pancreas	Inhibits gastric secretion somewhat Inhibits gastric secretion somewhat Increased production of bicarbonate-rich pancreatic juice	Inhibits stomach contractions
Local Regulator				
Histamine	Unclear; substances in food	Gastric glands	Increased gastric acid production	

Two types of contractions occur regularly in the small intestine: segmentation contractions and intestinal peristalsis. *Segmentation contractions* produce mixing waves that move the intestinal contents back and forth in a churning motion. *Intestinal peristalsis* propels the contents of the small intestine toward the colon. Both movements are stimulated by the presence of chyme.

Food, ingested as fats, proteins, and carbohydrates, is broken down into absorbable particles (constituent nutrients) by the process of digestion. Carbohydrates are broken down into disaccharides (eg, sucrose, maltose, and galactose) and monosaccharides (eg, glucose, fructose). Glucose is the major carbohydrate that tissue cells use as fuel. Proteins are a source of energy after they are broken down into amino acids and peptides. Ingested fats become monoglycerides and fatty acid through emulsification, which makes them smaller and easier to absorb. Chyme stays in the small intestine for 3 to 6 hours, allowing for continued breakdown and absorption of nutrients.

Small, fingerlike projections called villi line the entire intestine and function to produce digestive enzymes as well as to absorb nutrients. Absorption is the primary function of the small intestine. Vitamins and minerals are absorbed essentially unchanged. Absorption begins in the jejunum and is accomplished by active transport and diffusion across the intestinal wall into the circulation. Nutrients are absorbed at specific locations in the small intestine and duodenum, whereas fats, proteins, carbohydrates, sodium, and chloride are absorbed in the jejunum. Vitamin B₁₂ and bile salts are absorbed in the ileum. Magnesium, phosphate, and potassium are absorbed throughout the small intestine.

Colonic Function

Within 4 hours after eating, residual waste material passes into the terminal ileum and slowly into the proximal portion of the right colon through the ileocecal valve. With each peristaltic wave of the small intestine, the valve opens briefly and permits some of the contents to pass into the colon.

Bacteria, a major component of the contents of the large intestine, assist in completing the breakdown of waste material, especially of undigested or unabsorbed proteins and bile salts. Two types of colonic secretions are added to the residual material: an electrolyte solution and mucus. The electrolyte solution is chiefly a bicarbonate solution that acts to neutralize the end products formed by the colonic bacterial action, whereas the mucus protects the colonic mucosa from the interluminal contents and provides adherence for the fecal mass.

Slow, weak peristalsis moves the colonic contents along the tract. This slow transport allows for efficient reabsorption of water and electrolytes, which is the primary function of the colon. Intermittent strong peristaltic waves propel the contents for considerable distances. This generally occurs after another meal is eaten, when intestine-stimulating hormones are released. The waste materials from a meal eventually reach and distend the rectum, usually in about 12 hours. As much as one fourth of the waste materials from a meal may still be in the rectum 3 days after the meal was ingested.

Waste Products of Digestion

Feces consist of undigested foodstuffs, inorganic materials, water, and bacteria. Fecal matter is about 75% fluid and 25% solid material. The composition is relatively unaffected by alterations in diet because a large portion of the fecal mass is of nondietary origin, derived from the secretions of the GI tract. The brown color of the feces results from the breakdown of bile by the intestinal bacteria. Chemicals formed by intestinal bacteria are responsible in large part for the fecal odor. Gases formed contain methane, hydrogen sulfide, and ammonia, among others. The GI tract normally contains approximately 150 mL of these gases, which are either absorbed into the portal circulation and detoxified by the liver or expelled from the rectum as flatus.

Elimination of stool begins with distention of the rectum, which initiates reflex contractions of the rectal musculature and relaxes the normally closed internal anal sphincter. The internal sphincter is controlled by the autonomic nervous system; the external sphincter is under the conscious control of the cerebral cortex. During defecation, the external anal sphincter voluntarily relaxes to allow colonic contents to be expelled. Normally, the external anal sphincter is maintained in a state of tonic contraction. Thus, defecation is seen to be a spinal reflex (involving the parasympathetic nerve fibers) that can be inhibited voluntarily by keeping the external anal sphincter closed. Contracting the abdominal muscles (straining) facilitates emptying of the colon. The average frequency of defecation in humans is once daily, but this varies among people.

Gerontologic Considerations

Although an increased prevalence of several common GI disorders occurs in the elderly population, aging per se appears to have minimal direct effect on most GI functions, in large part because of the functional reserve of the GI tract. Normal physiologic changes of the GI system that occur with aging are identified in Table 34-3. Careful assessment and monitoring of signs and symptoms related to these changes are imperative. Although irritable bowel symptoms decrease with aging, there seems to be an increase in many GI disorders of function and motility. The gastroenterologist frequently encounters elderly patients who report dysphagia, anorexia, dyspepsia, and disorders of colonic function (Salles, 2007).

Assessment of the Gastrointestinal System

Health History

A focused GI assessment begins with a complete history. Information about abdominal pain, dyspepsia, gas, nausea and vomiting, diarrhea, constipation, fecal incontinence, jaundice, and previous GI disease is obtained.

Common Symptoms

Pain

Pain can be a major symptom of GI disease. The character, duration, pattern, frequency, location, distribution of

Table 34-3 AGE-RELATED CHANGES IN THE GASTROINTESTINAL SYSTEM	
Structural Changes	Implications
Oral Cavity and Pharynx <ul style="list-style-type: none"> • Injury/loss or decay of teeth • Atrophy of taste buds • ↓ Saliva production • Reduced ptyalin and amylase in saliva 	Difficulty chewing and swallowing
Esophagus <ul style="list-style-type: none"> • ↓ Motility and emptying • Weakened gag reflex • ↓ Resting pressure of lower esophageal sphincter 	Reflux and heartburn
Stomach <ul style="list-style-type: none"> • Degeneration and atrophy of gastric mucosal surfaces with ↓ production of HCl • ↓ Secretion of gastric acids and most digestive enzymes • ↓ Gastric motility and emptying 	Food intolerances, malabsorption, or decrease in vitamin B ₁₂ absorption
Small Intestine <ul style="list-style-type: none"> • Atrophy of muscle and mucosal surfaces • Thinning of villi and epithelial cells 	↓ Motility and transit time, which lead to complaints of indigestion and constipation
Large Intestine <ul style="list-style-type: none"> • ↓ Mucus secretion • ↓ Elasticity of rectal wall • ↓ Tone of internal anal sphincter • Slower and duller nerve impulses in rectal area 	↓ Motility and transit time, which lead to complaints of indigestion and constipation ↓ Absorption of nutrients (dextrose, fats, calcium, and iron) Fecal incontinence

↓, decreased; HCl, hydrochloric acid.

referred pain (Fig. 34-3), and time of the pain vary greatly depending on the underlying cause. Other factors such as meals, rest, activity, and defecation patterns may directly affect this pain.

Dyspepsia

Dyspepsia, upper abdominal discomfort associated with eating (commonly called *indigestion*), is the most common symptom of patients with GI dysfunction. Indigestion is an

imprecise term that refers to a host of upper abdominal or epigastric symptoms such as pain, discomfort, fullness, bloating, early satiety, belching, heartburn, or regurgitation; it occurs in approximately 25% of the adult population. Typically, fatty foods cause the most discomfort because they remain in the stomach for digestion longer than proteins or carbohydrates. Salads and coarse vegetables as well as highly seasoned foods may also cause considerable GI distress.

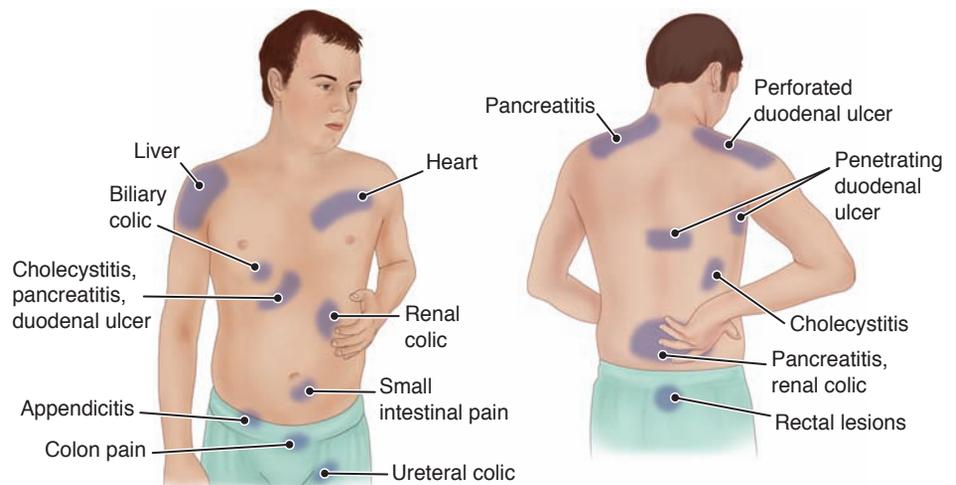

Figure 34-3 Common sites of referred abdominal pain.

Intestinal Gas

The accumulation of gas in the GI tract may result in belching (expulsion of gas from the stomach through the mouth) or flatulence (expulsion of gas from the rectum). Usually, gases in the small intestine pass into the colon and are released as flatus. Patients often complain of bloating, distention, or feeling “full of gas” with excessive flatulence as a symptom of food intolerance or gallbladder disease.

Nausea and Vomiting

Nausea is a vague, uncomfortable sensation of sickness or “queasiness” that may or may not be followed by vomiting. It can be triggered by odors, activity, medications, or food intake. The emesis, or vomitus, may vary in color and content and may contain undigested food particles, blood (hematemesis), or bilious material mixed with gastric juices. The causes of nausea and vomiting are many; they may result from (1) visceral afferent stimulation (ie, dysmotility, peritoneal irritation, infections, hepatobiliary or pancreatic disorders, mechanical obstruction); (2) CNS disorders (ie, vestibular disorders, increased intracranial pressure, infections, psychogenic disorder); or (3) irritation of the chemoreceptor trigger zone from radiation therapy, systemic disorders, and antitumor chemotherapy medications.

Change in Bowel Habits and Stool Characteristics

Changes in bowel habits may signal colonic dysfunction or disease. Diarrhea, an abnormal increase in the frequency and liquidity of the stool or in daily stool weight or volume, commonly occurs when the contents move so rapidly through the intestine and colon that there is inadequate time for the GI secretions and oral contents to be absorbed. This physiologic function is typically associated with abdominal pain or cramping and nausea or vomiting. Constipation, a decrease in the frequency of stool, or stools that are hard, dry, and of smaller volume than normal, may be associated with anal discomfort and rectal bleeding. See Chapter 38 for further discussion of diarrhea and constipation.

The characteristics of the stool can vary greatly. Stool is normally light to dark brown; however, specific disease processes and ingestion of certain foods and medications may change the appearance of stool (Table 34-4). Blood in the stool can present in various ways and must be investigated. If blood is shed in sufficient quantities into the upper GI tract, it produces a tarry-black color (melena), whereas blood entering the lower portion of the GI tract or passing rapidly through it will appear bright or dark red. Lower rectal or anal bleeding is suspected if there is streaking of blood on the surface of the stool or if blood is noted on toilet tissue.

Table 34-4 FOODS AND MEDICATIONS THAT ALTER STOOL COLOR

Altering Substance	Color
Meat protein	Dark brown
Spinach	Green
Carrots and beets	Red
Cocoa	Dark red or brown
Senna	Yellow
Bismuth, iron, licorice, and charcoal	Black
Barium	Milky white

Other common abnormalities in stool characteristics described by the patient may include:

- Bulky, greasy, foamy stools that are foul in odor and may or may not float
- Light-gray or clay-colored stool, caused by a decrease or absence of conjugated bilirubin
- Stool with mucous threads or pus that may be visible on gross inspection of the stool
- Small, dry, rock-hard masses occasionally streaked with blood
- Loose, watery stool that may or may not be streaked with blood

Past Health, Family, and Social History

The nurse asks about the patient’s normal brushing and flossing routine; frequency of dental visits; awareness of any lesions or irritated areas in the mouth, tongue, or throat; recent history of sore throat or bloody sputum; discomfort caused by certain foods; daily food intake; use of alcohol and tobacco, including smokeless chewing tobacco; and the need to wear dentures or a partial plate. For information about denture care, see Chart 34-1.

Past and current medication use and any previous diagnostic studies, treatments, or surgery are noted. Current nutritional status is assessed via history; laboratory tests (complete metabolic panel including liver function studies, triglycerides, iron studies, and complete blood count [CBC]) are obtained. History of tobacco and alcohol use includes details about type, amount, length of use, and the date of discontinuation, if any. The nurse and patient discuss changes in appetite or eating patterns and any unexplained weight gain or loss over the past year. It is also important to include questions about psychosocial, spiritual, or cultural factors that may be affecting the patient.

Physical Assessment

The physical examination includes assessment of the mouth, abdomen, and rectum and requires a good source of light, full exposure of the abdomen, warm hands with short fingernails, and a comfortable, relaxed patient with an empty bladder.

Oral Cavity Inspection and Palpation

Dentures should be removed to allow good visualization of the entire oral cavity.

CHART
34-1

HEALTH PROMOTION Denture Care

- Brush dentures twice a day.
- Remove dentures at night and soak them in water or a denture product. (Never put dentures in hot water, because they may warp.)
- Rinse mouth with warm salt water in the morning, after meals, and at bedtime.
- Clean well under partial dentures, where food particles tend to get caught.
- Consume nonsticky foods that have been cut into small pieces; chew slowly.
- See dentist regularly to assess and adjust fit.

Lips

The examination begins with inspection of the lips for moisture, hydration, color, texture, symmetry, and the presence of ulcerations or fissures. The lips should be moist, pink, smooth, and symmetric. The patient is instructed to open the mouth wide; a tongue blade is then inserted to expose the buccal mucosa for an assessment of color and lesions. Stensen’s duct of each parotid gland is visible as a small red dot in the buccal mucosa next to the upper molars.

Gums

The gums are inspected for inflammation, bleeding, retraction, and discoloration. The odor of the breath is also noted. The hard palate is examined for color and shape.

Tongue

The dorsum (back) of the tongue is inspected for texture, color, and lesions. A thin white coat and large, vallate papillae in a “V” formation on the distal portion of the dorsum of the tongue are normal findings. The patient is instructed to protrude the tongue and move it laterally. This provides the examiner with an opportunity to estimate the tongue’s size as well as its symmetry and strength (to assess the integrity of the 12th cranial nerve [hypoglossal]).

Further inspection of the ventral surface of the tongue and the floor of the mouth is accomplished by asking the patient to touch the roof of the mouth with the tip of the tongue. Any lesions of the mucosa or any abnormalities involving the frenulum or superficial veins on the undersurface of the tongue are assessed for location, size, color, and pain. This is a common area for oral cancer, which presents as a white or red plaque, an indurated ulcer, or a warty growth.

A tongue blade is used to depress the tongue for adequate visualization of the pharynx. It is pressed firmly beyond the midpoint of the tongue; proper placement avoids a gagging response. The patient is told to tip the head back, open the mouth wide, take a deep breath, and say “ah.” Often this flattens the posterior tongue and briefly allows a full view of the tonsils, uvula, and posterior pharynx. These structures are inspected for color, symmetry, and evidence of exudate, ulceration, or enlargement. Normally, the uvula and soft palate rise symmetrically with a deep inspiration or “ah”; this indicates an intact vagus nerve (10th cranial nerve).

A complete assessment of the oral cavity is essential because many disorders, such as cancer, diabetes, and immunosuppressive conditions resulting from medication therapy or acquired immunodeficiency syndrome (AIDS), may be manifested by changes in the oral cavity, including stomatitis.

Abdominal Inspection, Auscultation, Palpation, and Percussion

The patient lies supine with knees flexed slightly for inspection, auscultation, palpation, and percussion of the abdomen. For the purposes of examination and documentation, the abdomen can be divided into either four quadrants or nine regions (Fig. 34-4).

Consistent use of one of these mapping methods results in a thorough evaluation of the abdomen and appropriate documentation. The four-quadrant method involves the use of an imaginary line drawn vertically from the sternum to the pubis through the umbilicus and a horizontal line drawn across the abdomen through the umbilicus. Inspection is performed first, noting skin changes, nodules, lesions, scarring, discolorations, inflammation, bruising, or striae. Lesions are of particular importance, because GI diseases often produce skin changes. The contour and symmetry of the abdomen are noted and any localized bulging, distention, or peristaltic waves are identified. Expected contours of the anterior abdominal wall can be described as flat, rounded, or scaphoid.

Auscultation always precedes percussion and palpation because they may alter sounds. It is used to determine the character, location, and frequency of bowel sounds and to identify vascular sounds. Bowel sounds are assessed in all four quadrants using the diaphragm of the stethoscope for high-pitched and gurgling sounds. The frequency and character of the sounds are usually heard as clicks and gurgles that occur irregularly and range from 5 to 35 per minute. The terms *normal* (sounds heard about every 5 to 20 seconds), *hypoactive* (one or two sounds in 2 minutes), *hyperactive* (five to six sounds heard in less than 30 seconds), or *absent* (no sounds in 3 to 5 minutes) are frequently used in documentation, but these assessments are highly subjective. Using the bell of the stethoscope, any bruits in the aortic, renal, iliac, and femoral arteries are noted. Friction rubs are high-pitched and can be heard over the liver and spleen

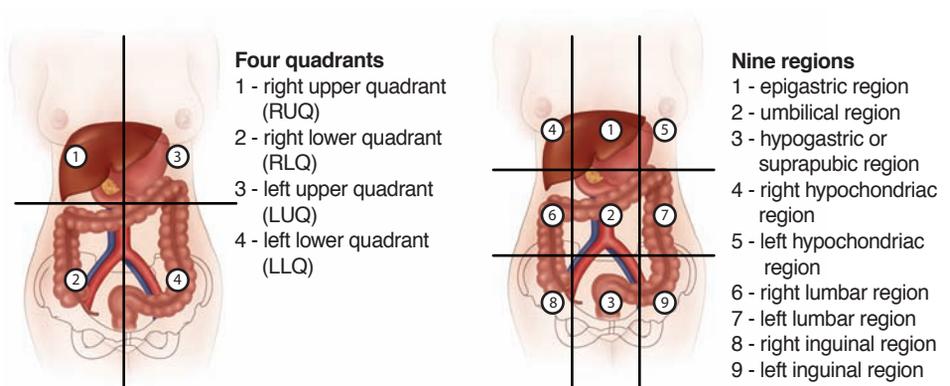

Figure 34-4 Division of the abdomen into four quadrants or nine regions.

during respiration. Borborygmi or “stomach growling” is heard as a loud prolonged gurgle.

Percussion is used to assess the size and density of the abdominal organs and to detect the presence of air-filled, fluid-filled, or solid masses. Percussion is used either independently or concurrently with palpation because it can validate palpation findings. Use of light palpation is appropriate for identifying areas of tenderness or muscular resistance, and deep palpation is used to identify masses. All quadrants are percussed for overall tympani and dullness. Tympani is the sound that results from the presence of air in the stomach and small intestines; dullness is heard over organs and solid masses. Testing for rebound tenderness is not performed by many examiners because it can cause severe pain; light percussion is used instead to produce a mild localized response when peritoneal irritation is present.

Rectal Inspection and Palpation

The final part of the examination is evaluation of the terminal portions of the GI tract, rectum, perianal region, and anus. The anal canal is approximately 2.5 to 4 cm (1 to 1.6 inches) in length and opens into the perineum. Concentric rings of muscle, the internal and external sphincters, normally keep the anal canal securely closed. Gloves, water-soluble lubrication, a penlight, and drapes are necessary tools for the evaluation. Although the rectal examination is generally uncomfortable and often embarrassing for the patient, it is a mandatory part of every thorough examination. For women, the rectal examination may be part of the gynecologic examination. Positions for the rectal examination include knee-chest, left lateral with hips and knees flexed, or standing with hips flexed and upper body supported by the examination table. Most patients are comfortable on the right side with knees brought up to the chest. External examination includes inspection for lumps, rashes, inflammation, excoriation, tears, scars, pilonidal dimpling, and tufts of hair at the pilonidal area. The discovery of tenderness, inflammation, or both should alert the examiner to the possibility of a pilonidal cyst, perianal abscess, or anorectal fistula or fissure. The patient's buttocks are carefully spread and visually inspected until the patient has relaxed the external sphincter control. The patient is asked to bear down, thus allowing the ready appearance of fistulas, fissures, rectal prolapse, polyps, and internal hemorrhoids. Internal examination is performed with a lubricated index finger inserted into the anal canal while the patient bears down. The tone of the sphincter is noted, as are any nodules or irregularities of the anal ring. Because this is an uncomfortable part of the examination for most patients, the patient is encouraged to focus on deep breathing and visualization of a pleasant setting during the brief examination.

Diagnostic Evaluation

GI diagnostic studies can confirm, rule out, stage, or diagnose disease. The diagnosis and treatment of cancer brings psychological distress to patients and their families and can cause anxiety, depression, and adjustment disorders (Steginga, Campbell, Ferguson, et al., 2008; Pirl, Muriel, Hwang,

et al., 2007). After the diagnosis, time should be allotted for discussion with the patient, in addition to offering resource materials for information.

Many modalities are available for diagnostic assessment of the GI tract. The majority of these tests and procedures are performed on an outpatient basis in special settings designed for this purpose (eg, endoscopy suite or GI laboratory). In the past, patients who required such tests frequently were elderly; however, within the past 10 years, in part due to heightened media exposure and early diagnosis of colorectal cancer, the median age of patients evaluated for colorectal cancer has decreased significantly. Preparation for many of these studies includes clear liquid diet, fasting, ingestion of a liquid bowel preparation, the use of laxatives or enemas, and ingestion or injection of a contrast agent or a radiopaque dye. These measures are poorly tolerated by some patients and are especially problematic in the elderly population or patients with comorbidities because bowel preparations can significantly alter the internal fluid and electrolyte balance. If further assessment or treatment is needed after any outpatient procedure, the patient may be admitted to the hospital.

Specific nursing interventions for each test are provided later in this chapter. General nursing interventions for the patient who is undergoing a GI diagnostic evaluation include:

- Establishing the nursing diagnosis
- Providing needed information about the test and the activities required of the patient
- Providing instructions about postprocedure care and activity restrictions
- Providing health information and procedural teaching to patients and significant others
- Helping the patient cope with discomfort and alleviating anxiety
- Informing the primary care provider of known medical conditions or abnormal laboratory values that may affect the procedure
- Assessing for adequate hydration before, during, and immediately after the procedure, and providing education about maintenance of hydration

Serum Laboratory Studies

Initial diagnostic tests begin with serum laboratory studies, including but not limited to CBC, complete metabolic panel, prothrombin time/partial thromboplastin time, triglycerides, liver function tests, amylase, and lipase. Studies such as carcinoembryonic antigen (CEA) and cancer antigen (CA) 19-9 that have sensitivity for colorectal cancer, and alpha-fetoprotein that has sensitivity for liver cancer may be performed. CEA is a protein that is normally not detected in the blood of a healthy person; therefore, when detected, it indicates that cancer is present, but not what type of cancer is present. Practitioners can use CEA results to determine the stage and extent of the disease and the prognosis for those with cancer, especially GI and, in particular, colorectal cancer (Porth & Matfin, 2009; Wang, Lin, Wu, et al., 2007). CA 19-9 is also a protein that exists on the surface of certain cells and is shed by tumor cells, making it useful as a tumor marker to follow the course of the cancer. CA 19-9 levels are elevated in most patients

with advanced pancreatic cancer, but they may also be elevated in other conditions such as colorectal, lung, and gallbladder cancers; gallstones; pancreatitis; cystic fibrosis; and liver disease.

Stool Tests

Basic examination of the stool includes inspecting the specimen for consistency, color, and occult (not visible) blood. Additional studies, including fecal urobilinogen, fecal fat, nitrogen, *Clostridium difficile*, fecal leukocytes, calculation of stool osmolar gap, parasites, pathogens, food residues, and other substances, require laboratory evaluation.

Stool samples are usually collected on a random basis unless a quantitative study (eg, fecal fat, urobilinogen) is to be performed. Random specimens should be sent promptly to the laboratory for analysis; however, the quantitative 24- to 72-hour collections must be kept refrigerated until transported to the laboratory. Some stool collections require the patient to follow a specific diet or refrain from taking certain medications before the collection. Thorough and accurate patient education regarding a specific stool study prior to collection greatly increases the accuracy of study results.

Fecal occult blood testing (FOBT) is one of the most commonly performed stool tests. It can be useful in initial screening for several disorders, although it is used most frequently in early cancer detection programs. FOBT can be performed at the bedside, in the laboratory, or at home. Probably the most widely used in-office or at-home occult blood test is the Hemoccult II. It is inexpensive, is noninvasive, and carries minimal risk to the patient. However, it should not be performed when there is hemorrhoidal bleeding. In addition, red meats, aspirin, nonsteroidal anti-inflammatory drugs, turnips, and horseradish should be avoided for 72 hours prior to the study, because they may cause a false-positive result. Also, ingestion of vitamin C from supplements or foods can cause a false-negative result. Therefore, a careful assessment of the patient's diet and medication regimen is essential to avoid incorrect interpretation of results. A small amount of the specimen is applied to the guaiac-impregnated paper slide. If the test is performed at home, the patient mails the slide to the physician in an envelope provided for that purpose. Other occult blood tests that may yield more specific and more sensitive readings include Hematest II SENSE and HemoQuant.

Fecal immunologic tests use monoclonal or polyclonal antibodies to detect the globin protein in human hemoglobin. There is no reaction with nonhuman hemoglobin or with foods that contain peroxidase activity; these tests are therefore more specific than guaiac tests (Mandel, 2008). Hemoporphyrin assays detect the broadest range of blood derivatives, but a strict dietary protocol is essential. Quantitative fecal immunochemical tests may be more accurate than guaiac testing and useful for patients who refuse invasive testing (Deenadayalu & Rex, 2007).

The stool DNA test is a relatively new test to detect certain DNA known to be related to colon cancer. More research is needed to determine how often the test needs to be performed. The stool DNA test does not require any dietary or medication restrictions and can detect neoplasia anywhere in the colon. The stool sample can be collected at home (Schroy, Lal, Glick, et al., 2007).

Breath Tests

The hydrogen breath test was developed to evaluate carbohydrate absorption, in addition to aiding in the diagnosis of bacterial overgrowth in the intestine and short bowel syndrome. This test determines the amount of hydrogen expelled in the breath after it has been produced in the colon (on contact of galactose with fermenting bacteria) and absorbed into the blood.

Urea breath tests detect the presence of *Helicobacter pylori*, the bacteria that can live in the mucosal lining of the stomach and cause peptic ulcer disease. After the patient ingests a capsule of carbon-labeled urea, a breath sample is obtained 10 to 20 minutes later. Because *H. pylori* metabolizes urea rapidly, the labeled carbon is absorbed quickly; it can then be measured as carbon dioxide in the expired breath to determine whether *H. pylori* is present. The patient is instructed to avoid antibiotics or loperamide (Pepto Bismol) for 1 month before the test; sucralfate (Carafate) and omeprazole (Prilosec) for 1 week before the test; and cimetidine (Tagamet), famotidine (Pepcid), and ranitidine (Zantac) for 24 hours before the test. *H. pylori* also can be detected by assessing serum antibody levels.

Abdominal Ultrasonography

Ultrasonography is a noninvasive diagnostic technique in which high-frequency sound waves are passed into internal body structures and the ultrasonic echoes are recorded on an oscilloscope as they strike tissues of different densities. It is particularly useful in the detection of an enlarged gallbladder or pancreas, the presence of gallstones, an enlarged ovary, an ectopic pregnancy, or appendicitis. Most recently this technique has proven useful in diagnosing acute colonic diverticulitis.

Advantages of abdominal ultrasonography include an absence of ionizing radiation, no noticeable side effects, relatively low cost, and almost immediate results. It cannot be used to examine structures that lie behind bony tissue because bone prevents sound waves from traveling into deeper structures. Gas and fluid in the abdomen or air in the lungs also prevents transmission of ultrasound. An ultrasound produces no ill effects. However, some patients, typically pregnant women, have concerns regarding the energy emitted by the probe.

Endoscopic ultrasonography (EUS) is a specialized enteroscopic procedure that aids in the diagnosis of GI disorders by providing direct imaging of a target area. A small high-frequency ultrasonic transducer is mounted at the tip of the fiberoptic scope, which displays an image that enables tumor staging and visualization of marginal structures. The resulting images have higher-quality resolution and definition than regular ultrasound imaging. EUS may be used to evaluate submucosal lesions, specifically their location and depth of penetration. In addition, EUS may aid in the evaluation of Barrett's esophagus, portal hypertension, chronic pancreatitis, suspected pancreatic neoplasm, biliary tract disease, and changes in the bowel wall due to ulcerative colitis. EUS is a safe and accurate test to use to select patients suspected of having biliary obstructive disease for therapeutic endoscopic retrograde cholangiopancreatography (ERCP) (Lee, Chan, Leung, et al., 2008). Intestinal gas,

bone, and thick layers of adipose tissue, which hamper conventional ultrasonography, are not problems when EUS is used.

Nursing Interventions

The patient is instructed to fast for 8 to 12 hours before the test to decrease the amount of gas in the bowel. If gallbladder studies are being performed, the patient should eat a fat-free meal the evening before the test. If barium studies are to be performed, they should be scheduled after ultrasonography; otherwise, the barium could interfere with the transmission of the sound waves.

DNA Testing

Researchers have refined methods for genetics risk assessment, preclinical diagnosis, and prenatal diagnosis to identify people who are at risk for certain GI disorders (eg, gastric cancer, lactose deficiency, inflammatory bowel disease, colon cancer) (Chart 34-2). In some cases, DNA testing allows clinicians to prevent (or minimize) disease, by intervening before its onset, and to improve therapy (Chan-Smutko, Patel, Shannon, et al., 2008). People who are identified as at risk for certain GI disorders may choose to have genetic counseling to learn about the disease and options for preventing and treating the disease and to receive support in coping with the situation.

Imaging Studies

Numerous minimally invasive and noninvasive imaging studies, including x-ray and contrast studies, computed tomography (CT), three-dimensional CT, magnetic resonance imaging (MRI), positron emission tomography (PET), scintigraphy (radionuclide imaging), and virtual colonoscopy, are available today.

Upper Gastrointestinal Tract Study

An upper GI fluoroscopy delineates the entire GI tract after the introduction of a contrast agent. A radiopaque liquid (eg, barium sulfate) is commonly used; however, thin barium, Hypaque, and at times water are used due to their low associated risks. The GI series enables the examiner to detect or exclude anatomic or functional disorders of the upper GI organs or sphincters. It also aids in the diagnosis of ulcers, varices, tumors, regional enteritis, and malabsorption syndromes. The procedure may be extended to examine the duodenum and small bowel (small bowel follow-through). As the barium descends into the stomach, the position, patency, and caliber of the esophagus are visualized, enabling the examiner to detect or exclude any anatomic or functional derangement of that organ. Fluoroscopic examination next extends to the stomach as its lumen fills with barium, allowing observation of stomach motility, thickness of the gastric wall, the mucosal pattern,

CHART
34-2

GENETICS IN NURSING PRACTICE

Digestive and Gastrointestinal Disorders

Several digestive and gastrointestinal disorders are associated with genetic abnormalities. Some examples are:

- Cleft lip and/or palate
- Familial adenomatous polyposis
- Hereditary nonpolyposis colorectal cancer (HNPCC)
- Hirschsprung disease (aganglionic megacolon)
- Inflammatory bowel disease (eg, Crohn's disease)
- Pyloric stenosis

Nursing Assessments

Family History Assessment

- Careful family history assessment for other family members with a similar condition (eg, cleft lip/palate, pyloric stenosis)
- Assess for other family members in several generations with early-onset colorectal cancer
- Inquire about other family members with inflammatory bowel disease
- Assess family history for other cancers (eg, endometrial, ovarian, renal)

Patient Assessment

Assess for presence of other clinical conditions:

- With clefting—congenital heart defect, other birth defects suggestive of a genetic syndrome
- With familial adenomatous polyposis—congenital hypertrophy of retinal pigment epithelium (CHRPE)

Management Issues Specific to Genetics

- Inquire whether any affected family member has had DNA mutation testing

- If indicated, refer for further genetic counseling and evaluation so that family members can discuss inheritance, risk to other family members, availability of genetic testing, and gene-based interventions
- Offer appropriate genetic information and resources
- Assess patients' understanding of genetic information
- Provide support to families with newly diagnosed genetic digestive disorders
- Participate in management and coordination of care for patients with genetic conditions and for those who are predisposed to develop or pass on a genetic condition

Genetics Resources

American Cancer Society—offers general information about cancer and support resources for families, www.cancer.org

Gene Clinics—a listing of common genetic disorders with up-to-date clinical summaries and genetic counseling and testing information, www.geneclinics.org

Genetic Alliance—a directory of support groups for patients and families with genetic conditions, www.geneticalliance.org

National Cancer Institute—current information about cancer research, treatment, resources for health providers, individuals, and families, www.nci.nih.gov

National Organization of Rare Disorders—a directory of support groups and information for patients and families with rare genetic disorders, www.rarediseases.org

Online Mendelian Inheritance in Man (OMIM)—a complete listing of inherited genetic conditions, www.ncbi.nlm.nih.gov/omim/stats/html

patency of the pyloric valve, and the anatomy of the duodenum. Multiple x-ray films are obtained during the procedure, and additional images may be taken at intervals for up to 24 hours to evaluate the rate of gastric emptying. Small bowel x-rays taken while the barium is passing through that area allow for observation of the motility of the small bowel. Obstructions, ileitis, and diverticula can also be detected.

Variations of the upper GI study include double-contrast studies and enteroclysis. The double-contrast method of examining the upper GI tract involves administration of a thick barium suspension to outline the stomach and esophageal wall, after which tablets that release carbon dioxide in the presence of water are administered. This technique has the advantage of showing the esophagus and stomach in finer detail, permitting signs of early superficial neoplasms to be noted.

Enteroclysis is a very detailed, double-contrast study of the entire small intestine that involves the continuous infusion, through a duodenal tube, of 500 to 1000 mL of a thin barium sulfate suspension; after this, methylcellulose is infused through the tube. The barium and methylcellulose fill the intestinal loops and are observed continuously by fluoroscopy and viewed at frequent intervals as they progress through the jejunum and the ileum. This process (even with normal motility) can take up to 6 hours and can be quite uncomfortable for the patient. The procedure aids in the diagnosis of partial small bowel obstructions or diverticula. The value of these x-ray screening studies has diminished as better technology has emerged (Mandel, 2008).

Nursing Interventions

Education regarding dietary changes prior to the study should include a clear liquid diet, with nothing by mouth (NPO) from midnight the night before the study; however, each physician may prefer a specific bowel preparation for specific studies. The nurse advises against smoking, chewing gum, and using mints because they can stimulate gastric motility. Typically, oral medications are withheld on the morning of the study and resumed that evening, but each patient's medication regimen should be evaluated on an individual basis. When a patient with insulin-dependent diabetes is NPO, his or her insulin requirements will need to be adjusted accordingly.

Follow-up care is provided after the upper GI procedure to ensure that the patient has eliminated most of the ingested barium. Fluids may be increased to facilitate evacuation of stool and barium.

Lower Gastrointestinal Tract Study

Visualization of the lower GI tract is obtained after rectal installation of barium. The barium enema can be used to detect the presence of polyps, tumors, or other lesions of the large intestine and demonstrate any anatomic abnormalities or malfunctioning of the bowel. After proper preparation and evacuation of the entire colon, each portion of the colon may be readily observed. The procedure usually takes about 15 to 30 minutes, during which time x-ray images are obtained.

Other means for visualizing the colon include double-contrast studies and a water-soluble contrast study. These tests are still occasionally used because they are relatively

inexpensive and simple (Rollandi, Biscaldi & DeCicco, 2007). A double-contrast or air-contrast barium enema involves the instillation of a thicker barium solution, followed by the instillation of air. The patient may feel some cramping or discomfort during this process. This test provides a contrast between the air-filled lumen and the barium-coated mucosa, allowing easier detection of smaller lesions.

If active inflammatory disease, fistulas, or perforation of the colon is suspected, a water-soluble iodinated contrast agent (eg, Gastrografin) can be used. The procedure is the same as for a barium enema, but the patient must first be assessed for allergy to iodine or contrast agent. The contrast agent is eliminated readily after the procedure, so there is no need for postprocedure laxatives. Some diarrhea may occur in a few patients until the contrast agent has been totally eliminated.

Nursing Interventions

Preparation of the patient includes emptying and cleansing the lower bowel. This often necessitates a low-residue diet 1 to 2 days before the test (the preparation required by different x-ray departments may vary); a clear liquid diet and a laxative the evening before; NPO after midnight; and cleansing enemas until returns are clear the following morning. The nurse makes sure that barium enemas are scheduled before any upper GI studies. If the patient has active inflammatory disease of the colon, enemas are contraindicated. Barium enemas also are contraindicated in patients with signs of perforation or obstruction; instead, a water-soluble contrast study may be performed. Active GI bleeding may prohibit the use of laxatives and enemas.

Postprocedural patient education includes information about increasing fluid intake; evaluating bowel movements for evacuation of barium; and noting increased number of bowel movements, because barium, due to its high osmolarity, may draw fluid into the bowel, thus increasing the intraluminal contents and resulting in greater output.

Computed Tomography

CT provides cross-sectional images of abdominal organs and structures. Multiple x-ray images are taken from numerous angles, digitized in a computer, reconstructed, and then viewed on a computer monitor. As the sensitivity and specificity of CT have increased in recent years, so has its use. CT is a valuable tool for detecting and localizing many inflammatory conditions in the colon, such as appendicitis, diverticulitis, regional enteritis, and ulcerative colitis, as well as evaluating the abdomen for diseases of the liver, spleen, kidney, pancreas, and pelvic organs, and structural abnormalities of the abdominal wall. Because the adequacy of detail in the test depends on the presence of fat, this diagnostic tool is not useful for very thin, cachectic patients. The procedure is completely painless, but radiation doses are considerable. Continuous-motion (helical or spiral), three-dimensional CT that provides very detailed pictures of the GI organs and vasculature is also available.

Nursing Interventions

CT may be performed with or without oral or intravenous (IV) contrast, but the enhancement of the study is greater

with use of a contrast agent. Any allergies to contrast agents, iodine, or shellfish; the patient's current serum creatinine level; and urine human chorionic gonadotropin must be determined before administration of a contrast agent. Patients allergic to the contrast agent may be premedicated with IV prednisone 24 hours, 12 hours, and 1 hour before the scan.

In addition, renal protective measures include the administration of IV sodium bicarbonate 1 hour before and 6 hours after IV contrast and oral acetylcysteine (Mucomyst) before or after the study. Both sodium bicarbonate and Mucomyst are free radical scavengers that sequester the contrast byproducts that are destructive to renal cells (Ozcan, Guneri, Akdeniz, et al., 2007).

Magnetic Resonance Imaging

MRI is used in gastroenterology to supplement ultrasonography and CT. This noninvasive technique uses magnetic fields and radio waves to produce images of the area being studied. The use of oral contrast agents to enhance the image has increased the application of this technique for the diagnosis of GI diseases. It is useful in evaluating abdominal soft tissues as well as blood vessels, abscesses, fistulas, neoplasms, and other sources of bleeding.

The physiologic artifacts of heartbeat, respiration, and peristalsis may create a less-than-clear image; however, newer, fast-imaging MRI techniques help eliminate these physiologic motion artifacts. MRIs are not totally safe for all people. Any ferromagnetic objects (metals that contain iron) can be attracted to the magnet and cause injury. Items that can be problematic or dangerous include jewelry, pacemakers, dental implants, paperclips, pens, keys, IV poles, clips on patient gowns, and oxygen tanks. MRI is contraindicated for patients with permanent pacemakers, artificial heart valves and defibrillators, implanted insulin pumps, or implanted transcutaneous electrical nerve stimulation devices, because the magnetic field could cause malfunction. MRI is also contraindicated for patients with internal metal devices (eg, aneurysm clips), intraocular metallic fragments, or cochlear implants. Foil-backed skin patches (eg, NicoDerm, nitroglycerine [Transderm-Nitro], scopolamine [Transderm-Scop], clonidine [Catapres-TTS]) should be removed before an MRI because of the risk of burns; however, the patient's physician should be consulted before the patch is removed to determine whether an alternate form of the medication should be provided.

Nursing Interventions

Prestudy patient education includes NPO status 6 to 8 hours before the study and removal of all jewelry and other metals. The patient and family are informed that the study may take 60 to 90 minutes; during this time, the technician will instruct the patient to take deep breaths at specific intervals. The close-fitting scanners used in many MRI facilities may induce feelings of claustrophobia, and the machine will make a knocking sound during the procedure. Patients may choose to wear a headset and listen to music or to wear a blindfold during the procedure. Open MRIs that are less close-fitting eliminate the claustrophobia that many patients experience.

Positron Emission Tomography

PET scans produce images of the body by detecting the radiation emitted from radioactive substances. The radioactive substances are injected into the body by IV and are usually tagged with a radioactive atom, such as carbon-11, fluorine-18, oxygen-15, or nitrogen-13. The atoms decay quickly, do not harm the body, have lower radiation levels than a typical x-ray or CT scan, and are eliminated in the urine or feces. The scanner essentially "captures" where the radioactive substances are in the body, transmits information to a scanner, and produces a scan with "hot spots" for evaluation by the radiologist or oncologist.

Scintigraphy

Scintigraphy (radionuclide testing) relies on the use of radioactive isotopes (ie, technetium, iodine, and indium) to reveal displaced anatomic structures, changes in organ size, and the presence of neoplasms or other focal lesions, such as cysts or abscesses. Scintigraphic scanning is also used to measure the uptake of tagged red blood cells and leukocytes. Tagging of red blood cells and leukocytes by injection of a radionuclide is performed to define areas of inflammation, abscess, blood loss, or neoplasm. A sample of blood is removed, mixed with a radioactive substance, and reinjected into the patient. Abnormal concentrations of blood cells are then detected at 24- and 48-hour intervals. Tagged red cell studies are useful in determining the source of internal bleeding when all other studies have returned a negative result.

Gastrointestinal Motility Studies

Radionuclide testing also is used to assess gastric emptying and colonic transit time. During gastric emptying studies, the liquid and solid components of a meal (typically scrambled eggs) are tagged with radionuclide markers. After ingestion of the meal, the patient is positioned under a scintiscanner, which measures the rate of passage of the radioactive substance from the stomach. This is useful in diagnosing disorders of gastric motility, diabetic gastroparesis, and dumping syndrome.

Colonic transit studies are used to evaluate colonic motility and obstructive defecation syndromes. The patient is administered a capsule containing 20 radionuclide markers and instructed to follow a regular diet and normal daily activities. Abdominal x-rays are taken every 24 hours until all markers are passed. This process usually takes 4 to 5 days, but in the presence of severe constipation it may take as long as 10 days. Patients with chronic diarrhea may be evaluated at 8-hour intervals. The amount of time that it takes for the radioactive material to move through the colon indicates colonic motility.

Endoscopic Procedures

Endoscopic procedures used in GI tract assessment include fibroscopy/esophagogastroduodenoscopy (EGD), small bowel enteroscopy, colonoscopy, sigmoidoscopy, proctoscopy, anoscopy, and endoscopy through an ostomy.

Upper Gastrointestinal Fibroscopy/ Esophagogastroduodenoscopy

Fibroscopy of the upper GI tract allows direct visualization of the esophageal, gastric, and duodenal mucosa through a

Figure 34-5 Patient undergoing gastroscopy.

lighted endoscope (gastroscope) (Fig. 34-5). EGD is valuable when esophageal, gastric, or duodenal disorders or inflammatory, neoplastic, or infectious processes are suspected. This procedure also can be used to evaluate esophageal and gastric motility and to collect secretions and tissue specimens for further analysis.

In EGD, the gastroenterologist views the GI tract through a viewing lens and can obtain images through the scope to document findings. Electronic video endoscopes also are available that attach directly to a video processor, converting the electronic signals into pictures on a television screen. This allows larger and continuous viewing capabilities, as well as the simultaneous recording of the procedure.

PillCam ESO, a pill-sized instrument equipped with two cameras, is available. Each camera takes seven photographs per second and transmits them wirelessly to a nearby storage device (Eliakim, Sharma & Yassin, 2005). This technique is gaining popularity with patients and clinicians alike as a comfortable, convenient alternative to endoscopy. Two major drawbacks to this method of endoscopy are that it evaluates only the esophagus and that the instrument may become lodged in a previously anastomosed section of bowel and require further endoscopic or surgical intervention for removal.

ERCP uses the endoscope in combination with x-rays to view the ductal structures of the biliary tract (Tse, Barkum, Romagnuolo, et al., 2006). The side-viewing flexible scopes are used to visualize the common bile duct and the pancreatic and hepatic ducts through the ampulla of Vater in the duodenum. ERCP is helpful in evaluating jaundice, pancreatitis, pancreatic tumors, common bile duct stones, and biliary tract disease. ERCP is described further in Chapter 40.

Upper GI fibroscopy also can be a therapeutic procedure when combined with other procedures. Therapeutic endoscopy can be used to remove common bile duct stones, dilate strictures, and treat gastric bleeding and esophageal varices. Laser-compatible scopes can be used to provide laser therapy for upper GI neoplasms. Sclerosing solutions can be injected through the scope in an attempt to control upper GI bleeding.

After the patient is sedated, the endoscope is lubricated with a water-soluble lubricant and passed smoothly and slowly along the back of the mouth and down into the esophagus. The gastroenterologist views the gastric wall and the sphincters, and then advances the endoscope into the duodenum for further examination. Biopsy forceps to obtain tissue specimens or cytology brushes to obtain cells for microscopic study can be passed through the scope. The procedure usually takes about 30 minutes.

The patient may experience nausea, gagging, or choking. Use of topical anesthetic agents and moderate sedation makes it important to monitor and maintain the patient's oral airway during and after the procedure. Finger or ear oximeters are used to monitor oxygen saturation, and supplemental oxygen may be administered if needed. Precautions must be taken to protect the scope, because the fiberoptic bundles can be broken if the scope is bent at an acute angle. The patient wears a mouth guard to keep from biting the scope.

Nursing Interventions

The patient should be NPO for 8 hours prior to the examination. Before the introduction of the endoscope, the patient is given a local anesthetic gargle or spray. Midazolam (Versed), a sedative that provides moderate sedation and relieves anxiety during the procedure, may be administered. Atropine may be administered to reduce secretions, and glucagon may be administered to relax smooth muscle. The patient is positioned in the left lateral position to facilitate clearance of pulmonary secretions and provide smooth entry of the scope.

After gastroscopy, assessment includes level of consciousness, vital signs, oxygen saturation, pain level, and monitoring for signs of perforation (ie, pain, bleeding, unusual difficulty swallowing, and rapidly elevated temperature). After the patient's gag reflex has returned, lozenges, saline gargle, and oral analgesic agents may be offered to relieve minor throat discomfort. Patients who were sedated for the procedure must remain in bed until fully alert. After moderate sedation, the patient must be transported home with a family member or friend if the procedure was performed on an outpatient basis. Someone should stay with the patient until the morning after the procedure. Because of sedation, many patients will not remember postprocedure instructions. For this reason, discharge and follow-up instructions are provided to the person accompanying the patient home, as well as to the patient. In addition, many endoscopy suites have a program in which a nurse telephones the patient the morning after the procedure to find out if the patient has any concerns or questions related to the procedure.

Fiberoptic Colonoscopy

Historically, direct visualization of the bowel was the only means to evaluate the colon, but virtual colonoscopy (also known as CT colonography) has brought a more patient-friendly approach to this study. Virtual colonoscopy provides a computer-simulated endoluminal perspective of the air-filled distended colon using conventional spiral or helical CT scanning (Fletcher, Booya & Johnson, 2005; Burling, Moore, Marshall, et al., 2008).

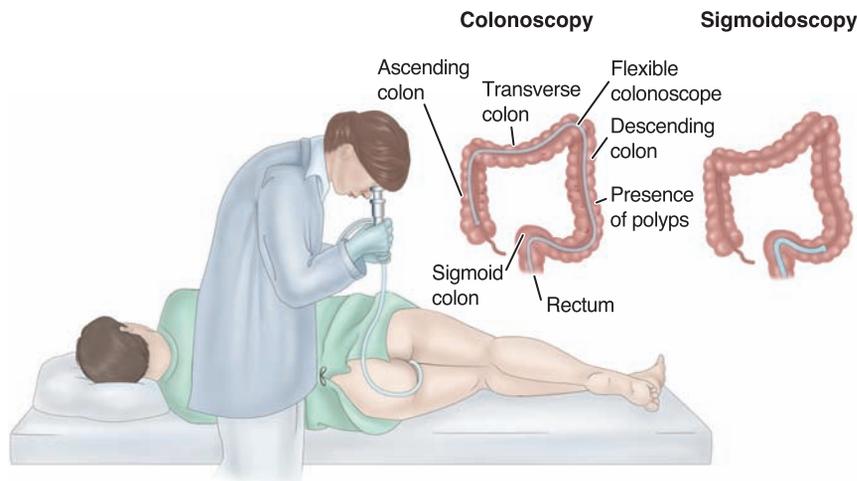

Figure 34-6 Colonoscopy and flexible fiberoptic sigmoidoscopy. For the colonoscopy, the flexible scope is passed through the rectum and sigmoid colon into the descending, transverse, and ascending colon. For the flexible fiberoptic sigmoidoscopy, the flexible scope is advanced past the proximal sigmoid and then into the descending colon.

Direct visual inspection of the large intestine (anus, rectum, sigmoid, transcending and ascending colon) is possible by means of a flexible fiberoptic colonoscope (Fig. 34-6). These scopes have the same capabilities as those used for EGD but are larger in diameter and longer. Still and video recordings can be used to document the procedure and findings.

This procedure is used commonly as a diagnostic aid and screening device. It is most frequently used for cancer screening (Chart 34-3) and for surveillance in patients with previous colon cancer or polyps. In addition, tissue biopsies can be obtained as needed, and polyps can be removed and evaluated. Other uses of colonoscopy include the evaluation of patients with diarrhea of unknown cause, occult bleeding, or anemia; further study of abnormalities detected on barium enema; and diagnosis, clarification, and determination of the extent of inflammatory or other bowel disease.

Therapeutically, the procedure can be used to remove all visible polyps with a special snare and cautery through the colonoscope. Many colon cancers begin with adenomatous polyps of the colon; therefore, one goal of colonoscopic polypectomy is early detection and prevention of colorectal cancer. This procedure also can be used to treat areas of bleeding or stricture. Use of bipolar and unipolar coagulators, use of heater probes, and injections of sclerosing agents or vasoconstrictors are all possible during this procedure. Laser-compatible scopes provide laser therapy for bleeding lesions or colonic neoplasms. Bowel decompression (removal of intestinal contents to prevent gas and fluid from distending the coils of the intestine) can also be completed during the procedure.

Colonoscopy is performed while the patient is lying on the left side with the legs drawn up toward the chest. The

CHART 34.3

HEALTH PROMOTION

American Cancer Society Guidelines for Early Detection of Colon and Rectal Cancer

Beginning at age 50, both men and women *at average risk* for developing colorectal cancer should use one of the screening tests below. The tests that are designed to find both early cancer and polyps are preferred if these tests are available to you and you are willing to have one of these more invasive tests. Talk to your doctor about what test is best for you.

Tests That Find Polyps and Cancer

- Flexible sigmoidoscopy every 5 years*
- Colonoscopy every 10 years
- Double-contrast barium enema every 5 years*
- Computed tomography (CT) colonography (virtual colonoscopy) every 5 years*

Tests That Mainly Find Cancer

- Fecal occult blood test (FOBT) every year***
- Fecal immunochemical test (FIT) every year***

- Stool DNA test (sDNA), interval uncertain*

People should talk to their doctor about starting colorectal cancer screening earlier and/or being screened more often if they have any of the following colorectal cancer risk factors:

- A personal history of colorectal cancer or adenomatous polyps
- A personal history of chronic inflammatory bowel disease (Crohn's disease or ulcerative colitis)
- A strong family history of colorectal cancer or polyps (cancer or polyps in a first-degree relative [parent, sibling, or child] younger than 60 or in two or more first-degree relatives of any age)
- A known family history of hereditary colorectal cancer syndrome such as familial adenomatous polyposis (FAP) or hereditary nonpolyposis colon cancer (HNPCC)

*Colonoscopy should be done if test results are positive.

**For FOBT or FIT used as a screening test, the take-home multiple sample method should be used. An FOBT or FIT done during a digital rectal exam in the doctor's office is not adequate for screening.

patient's position may be changed during the test to facilitate advancement of the scope. Biopsy forceps or a cytology brush may be passed through the scope to obtain specimens for histology and cytology examinations. Complications during and after the procedure can include cardiac dysrhythmias and respiratory depression resulting from the medications administered; vasovagal reactions; and circulatory overload or hypotension resulting from overhydration or underhydration during bowel preparation. The patient's cardiac and respiratory function and oxygen saturation are monitored continuously, with supplemental oxygen used as necessary. Typically the procedure takes about 1 hour, and postprocedure discomfort results from instillation of air to expand the colon and insertion and movement of the scope during the procedure.

Nursing Interventions

The success of the procedure depends on how well the colon is prepared and on adequate sedation (Selehi, Leung & Wong, 2008). Adequate colon cleansing provides optimal visualization and decreases the time needed for the procedure. Cleansing of the colon can be accomplished in various ways. The physician may prescribe a laxative for 2 nights before the examination and a Fleet's or saline enema until the return is clear the morning of the test. However, more commonly, polyethylene glycol electrolyte lavage solutions (Go-LYTELY, CoLyte, and Nu-Lytely) are used as intestinal lavages for effective cleansing of the bowel. The patient maintains a clear liquid diet starting at noon the day before the procedure. Then the patient ingests the lavage solution orally at intervals over 3 to 4 hours. If necessary, the nurse can give the solution through a feeding tube if the patient cannot swallow. Patients with a colostomy can receive this same bowel preparation. The use of lavage solutions is contraindicated in patients with intestinal obstruction or inflammatory bowel disease.

A sodium phosphate tablet (Osmoprep, Visicol) can be used for colon cleansing prior to colonoscopy. Dosing consists of 32 tablets: 20 tablets (4 tablets every 15 minutes with 8 ounces of any clear liquid (water, any clear carbonated beverage, or juice) on the evening prior to the examination, and 12 tablets (taken in the same manner) on the morning of the examination (Johanson, Popp, Cohen, et al., 2007).

With the use of lavage solutions, bowel cleansing is fast (rectal effluent is clear in about 4 hours) and is tolerated fairly well by most patients. Side effects of the electrolyte solutions include nausea, bloating, cramps or abdominal fullness, fluid and electrolyte imbalance, and hypothermia (patients are often told to drink the preparation as cold as possible to make it more palatable). The side effects are especially problematic for elderly patients, and sometimes they have difficulty ingesting the required volume of solution. Monitoring elderly patients after a bowel prep is especially important because their physiologic ability to compensate for fluid loss is diminished. Many elderly people take multiple medications each day; therefore, the nurse's knowledge of their daily medication regimen can prompt assessment for and prevention of potential problems and early detection of physiologic changes.

Additionally, the nurse advises the patient with diabetes to consult with his or her physician about medication ad-

justment to prevent hyperglycemia or hypoglycemia resulting from the dietary modifications required in preparing for the test. The nurse also instructs all patients, especially the elderly, to maintain adequate fluid, electrolyte, and caloric intake while undergoing bowel cleansing.

Special precautions must be taken for some patients. Implantable defibrillators and pacemakers are at high risk of malfunction if electrosurgical procedures (ie, polypectomy) are performed in conjunction with colonoscopy. A cardiologist should be consulted before the test is performed, and the defibrillator should be turned off. These patients require careful cardiac monitoring during the procedure.

Colonoscopy cannot be performed if there is a suspected or documented colon perforation, acute severe diverticulitis, or fulminant colitis. Patients with prosthetic heart valves or a history of endocarditis require prophylactic antibiotics before the procedure.

Informed consent is obtained by the practitioner before the patient is sedated. Before the examination, an opioid analgesic or sedative agent (eg, midazolam [versed]) is administered to provide moderate sedation and relieve anxiety during the procedure. Glucagon may be administered, if needed, to relax the colonic musculature and to reduce spasm during the test. Elderly or debilitated patients may require a reduced dosage of the analgesic or sedative agent to decrease the risks of oversedation and cardiopulmonary complications.

During the procedure, the patient is monitored for changes in oxygen saturation, vital signs, color and temperature of the skin, level of consciousness, abdominal distention, vagal response, and pain intensity. After the procedure, patients are maintained on bed rest until fully alert. Some patients have abdominal cramps caused by increased peristalsis stimulated by the air insufflated into the bowel during the procedure.

Immediately after the test, the patient is monitored for signs and symptoms of bowel perforation (eg, rectal bleeding, abdominal pain or distention, fever, focal peritoneal signs). Because of the amnesic effects of midazolam, it is important to provide written instructions, because the patient may be unable to recall verbal information. If the procedure is performed on an outpatient basis, someone must transport the patient home. After a therapeutic procedure, the nurse instructs the patient to report any bleeding to the physician.

Anoscopy, Proctoscopy, and Sigmoidoscopy

Endoscopic examination of the anus, rectum, and sigmoid and descending colon is used to evaluate chronic diarrhea, fecal incontinence, ischemic colitis, and lower GI hemorrhage and to observe for ulceration, fissures, abscesses, tumors, polyps, or other pathologic processes.

Flexible scopes have largely replaced the rigid scopes used in the past for routine examinations. The flexible fiberoptic sigmoidoscope (see Fig. 34-6) permits the colon to be examined up to 40 to 50 cm (16 to 20 inches) from the anus, much more than the 25 cm (10 inches) that can be visualized with the rigid sigmoidoscope. It has many of the same capabilities as the scopes used for the upper GI study, including the use of still or video images to document findings.

For flexible scope procedures, the patient assumes a comfortable position on the left side with the right leg bent and placed anteriorly. It is important to keep the patient informed throughout the examination and to explain the sensations associated with it. Biopsies and polypectomies can be performed during this procedure. Biopsy is performed with small biting forceps introduced through the endoscope; one or more small pieces of tissue may be removed. If polyps are present, they may be removed with a wire snare, which is used to grasp the pedicle, or stalk. An electrocoagulating current is then used to sever the polyp and prevent bleeding. It is extremely important that all excised tissue be placed immediately in moist gauze or in an appropriate receptacle, labeled correctly, and delivered without delay to the pathology laboratory for examination.

Nursing Interventions

These examinations require only limited bowel preparation, including a warm tap water or Fleet's enema until returns are clear. Dietary restrictions usually are not necessary, and sedation usually is not required. During the procedure, the nurse monitors vital signs, skin color and temperature, pain tolerance, and vagal response. After the procedure, the nurse monitors the patient for rectal bleeding and signs of intestinal perforation (ie, fever, rectal drainage, abdominal distention, and pain). On completion of the examination, the patient can resume his or her regular activities and diet.

Small Bowel Enteroscopy

There are several methods available for visualization of the small intestine, including capsule endoscopy and double-balloon endoscopy. Capsule endoscopy allows the noninvasive visualization of the mucosa throughout the entire small intestine. It is particularly useful in the evaluation of obscure gastrointestinal bleeding. The technique consists of the patient swallowing a capsule that has embedded in it a wireless miniature camera, a light source, and an image transmission system. The capsule is the size of a large vitamin pill (26 mm long, 11 mm wide, and 3.7 g in weight). It is propelled through the intestine by peristalsis. Images are transmitted from the end of the capsule to a recording device worn on a belt. Typically the capsule passes from the rectum in 1 or 2 days. This diagnostic procedure is limited by its inability to allow for obtaining tissue samples for histology and for providing endoscopic therapy (Cellier, 2008).

Double-balloon enteroscopy (DBE), also known as push-and-pull enteroscopy, has made it possible to visualize the mucosa of the entire small bowel as well as carry out diagnostic and therapeutic interventions (Pohl, May, Nachbar, et al., 2007). This endoscope is composed of two balloons, one that is attached to the distal end of the scope and the other that is attached to the transparent overtube that slides over the endoscope. The endoscope is advanced using a push-and-pull technique that involves alternately inflating and deflating the balloons, causes telescoping of the small intestine onto the overtube. As a result of this telescoping, the endoscope can visualize much more of the small intestine than the length of the scope itself. The procedure takes between 1 and 3 hours and requires moderate sedation (Cellier, 2008).

Endoscopy Through Ostomy

Endoscopy through an ostomy stoma is useful for visualizing a segment of the small or large intestine and may be indicated to evaluate the anastomosis for recurrent disease, or to visualize and treat bleeding in a segment of the bowel. Nursing interventions are similar to those for other endoscopic procedures.

Manometry and Electrophysiologic Studies

Manometry and electrophysiologic studies are methods for evaluating patients with GI motility disorders. The manometry test measures changes in intraluminal pressures and the coordination of muscle activity in the GI tract with the pressures transmitted to a computer analyzer.

Esophageal manometry is used to detect motility disorders of the esophagus and the upper and lower esophageal sphincter. Also known as esophageal motility studies, these studies are very helpful in the diagnosis of **achalasia**, diffuse esophageal spasm, scleroderma, and other esophageal motor disorders. The patient must refrain from eating or drinking for 8 to 12 hours before the test. Medications that could have a direct effect on motility (eg, calcium channel blockers, anticholinergic agents, sedatives) are withheld for 24 to 48 hours. A pressure-sensitive catheter is inserted through the nose and is connected to a transducer and a video recorder. The patient then swallows small amounts of water while the resultant pressure changes are recorded. Evaluation of a patient for gastroesophageal reflux disease (GERD) typically includes esophageal manometry.

Gastroduodenal, small intestine, and colonic manometry procedures are used to evaluate delayed gastric emptying and gastric and intestinal motility disorders such as irritable bowel syndrome or atonic colon. This is often an ambulatory outpatient procedure lasting 24 to 72 hours. Anorectal manometry measures the resting tone of the internal anal sphincter and the contractibility of the external anal sphincter. It is helpful in evaluating patients with chronic constipation or fecal incontinence and is useful in biofeedback for the treatment of fecal incontinence. It can be performed in conjunction with rectal sensory functioning tests. Phospho-Soda or a saline cleansing enema is administered 1 hour before the test, and positioning for the test is either the prone or the lateral position.

Rectal sensory function studies are used to evaluate rectal sensory function and neuropathy. A catheter and balloon are passed into the rectum, with increasing balloon inflation until the patient feels distention. Then the tone and pressure of the rectum and anal sphincter are measured. The results are especially helpful in the evaluation of patients with chronic constipation, diarrhea, or incontinence.

Electrogastrography, an electrophysiologic study, also may be performed to assess gastric motility disturbances and can be useful in detecting motor or nerve dysfunction in the stomach. Electrodes are placed over the abdomen, and gastric electrical activity is recorded for up to 24 hours. Patients may exhibit rapid, slow, or irregular waveform activity.

Defecography measures anorectal function and is performed with very thick barium paste instilled into the rectum. Fluoroscopy is used to assess the function of the rectum

and anal sphincter while the patient attempts to expel the barium. The test requires no preparation.

Gastric Analysis, Gastric Acid Stimulation Test, and pH Monitoring

Analysis of the gastric juice yields information about the secretory activity of the gastric mucosa and the presence or degree of gastric retention in patients thought to have pyloric or duodenal obstruction. It is also useful for diagnosing Zollinger-Ellison syndrome, or atrophic gastritis.

The patient is NPO for 8 to 12 hours before the procedure. Any medications that affect gastric secretions are withheld for 24 to 48 hours before the test. Smoking is not allowed on the morning of the test because it increases gastric secretions. A small nasogastric tube with a catheter tip marked at various points is inserted through the nose. When the tube is at a point slightly less than 50 cm (21 inches), it should be within the stomach, lying along the greater curvature. Once in place, the tube is secured to the patient's cheek and the patient is placed in a semireclining position. The entire stomach contents are aspirated by gentle suction into a syringe, and gastric samples are collected every 15 minutes for the next hour.

Important diagnostic information to be gained from gastric analysis includes the ability of the mucosa to secrete HCl. This ability is altered in various disease states, including:

- Pernicious anemia—patients with this disease secrete no acid under basal conditions or after stimulation.
- Severe chronic atrophic gastritis or gastric cancer—patients with these diseases secrete little or no acid.
- Peptic ulcer—patients with this disease secrete some acid.
- Duodenal ulcers—patients with this disease usually secrete an excess amount of acid.

The gastric acid stimulation test usually is performed in conjunction with gastric analysis. Histamine or pentagastrin is administered subcutaneously to stimulate gastric secretions. It is important to inform the patient that this injection may produce a flushed feeling. The nurse monitors the patient's blood pressure and pulse frequently to detect hypotension. Gastric specimens are collected after the injection every 15 minutes for 1 hour and are labeled to indicate the time of specimen collection after histamine injection. The volume and pH of the specimen are measured; in certain instances, cytologic study by the Papanicolaou technique may be used to determine the presence or absence of malignant cells.

Esophageal reflux of gastric acid may be diagnosed by ambulatory pH monitoring (Smout, 2008). The patient is NPO for 6 hours before the test, and all medications affecting gastric secretions are withheld for 24 to 36 hours before the test. A probe that measures pH is inserted through the nose and into position about 5 inches above the lower esophageal sphincter. It is connected to an external recording device and is worn for 24 hours while the patient continues normal daily activities. The end result is a computer analysis and graphic display of the results. This test allows for the direct correlation between chest pain and reflux episodes (Malhotra, Freston & Aziz, 2008).

The Bravo pH monitoring system offers the advantage of pH monitoring of the esophagus without the transnasal catheter. The clinician, by means of endoscopy, attaches a

capsule (approximately the size of a gel cap) to the patient's esophageal wall. Data related to pH are transmitted from the capsule to a pager-sized receiver that the patient wears. Data are collected for up to 48 hours and then downloaded and analyzed. The capsule spontaneously detaches from the esophagus in 7 to 10 days and then is passed through the patient's digestive system. The accuracy of this method of pH testing is greater than methods in which a catheter is used because the patient can eat normally and continue normal activities during the testing. The system reliably distinguishes reflux conditions from functional conditions if the study is performed with the patient off medications (Pardolino & Kwiatek, 2008).

Laparoscopy (Peritoneoscopy)

With the tremendous advances in minimally invasive surgery, diagnostic laparoscopy is efficient, cost-effective, and useful in the diagnosis of GI disease. After a pneumoperitoneum (injecting carbon dioxide into the peritoneal cavity to separate the intestines from the pelvic organs) is created, a small incision is made lateral to the umbilicus, allowing for the insertion of the fiberoptic laparoscope. This permits direct visualization of the organs and structures within the abdomen, permitting visualization and identification of any growths, anomalies, and inflammatory processes. In addition, biopsy samples can be taken from the structures and organs as necessary. This procedure can be used to evaluate peritoneal disease, chronic abdominal pain, abdominal masses, and gallbladder and liver disease. However, laparoscopy has not become an important diagnostic modality in patients with acute abdominal pain, because less invasive tools (eg, CT and MRI) are readily available. Laparoscopy usually requires general anesthesia and sometimes requires that the stomach and bowel be decompressed. Gas (usually carbon dioxide) is insufflated into the peritoneal cavity to create a working space for visualization. One of the benefits of this procedure is that after visualization of a problem, excision (eg, removal of the gallbladder) can then be performed at the same time, if appropriate.

CRITICAL THINKING EXERCISES

1 You are caring for a 60-year-old man with a history of diabetes, pancreatitis, alcohol abuse, and abdominal pain associated with meals. He states that he sometimes has nausea and vomiting after eating dinner. Identify questions that should be asked when taking the patient's history. What assessment parameters would be addressed? What diagnostic tests would you expect to be ordered?

EBP 2 You are working in a medical internist's office. A 56-year-old female patient comes into the office for a routine examination. She states that she did not get her recommended colonoscopy examination because no one in her family has colon cancer and she did not understand the instructions. What education would you provide for this patient? What is the evidence base that supports the education? Discuss the strength of the evidence for the education. Identify the criteria used to evaluate the strength of the evidence.

chapter 35

Management of Patients With Oral and Esophageal Disorders

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

- 1 Describe the nursing management of patients with conditions of the oral cavity.
- 2 Describe the relationship of dental hygiene and dental problems to nutrition.
- 3 Describe the nursing management of patients with abnormalities of the lips, gums, teeth, mouth, and salivary glands.
- 4 Describe the nursing management of patients with cancer of the oral cavity.
- 5 Identify the physical and psychosocial long-term needs of patients with oral cancer.
- 6 Use the nursing process as a framework for care of patients undergoing neck dissection.
- 7 Use the nursing process as a framework for care of patients with various conditions of the esophagus.
- 8 Describe the various conditions of the esophagus and their clinical manifestations and management.

GLOSSARY

- achalasia:** absent or ineffective peristalsis (wavelike contraction) of the distal esophagus accompanied by failure of the esophageal sphincter to relax in response to swallowing
- dysphagia:** difficulty swallowing
- dysplasia:** abnormal change in cells
- esophagogastroduodenoscopy (EGD):** passage of a fiberoptic tube through the mouth and throat into the digestive tract for visualization of the esophagus, stomach, and small intestine; biopsies can be performed
- gastroesophageal reflux:** back-flow of gastric or duodenal contents into the esophagus
- hernia:** protrusion of an organ or part of an organ through the wall of the cavity that normally contains it
- lithotripsy:** use of shock waves to break up or disintegrate stones
- odynophagia:** pain on swallowing
- parotitis:** inflammation of the parotid gland
- periapical abscess:** abscessed tooth
- pyrosis:** heartburn
- sialadenitis:** inflammation of the salivary glands
- stomatitis:** inflammation of the oral mucosa
- temporomandibular disorders:** a group of conditions that cause pain or dysfunction of the temporomandibular joint (TMJ) and surrounding structures
- vagotomy syndrome:** dumping syndrome; gastrointestinal symptoms, such as diarrhea and abdominal cramping, resulting from rapid gastric emptying
- xerostomia:** dry mouth

Because digestion normally begins in the mouth, adequate nutrition is related to good dental health and the general condition of the mouth. Any discomfort or adverse condition in the oral cavity can affect a person's nutritional status. Changes in the oral cavity can influence the type and amount of food ingested as well as the degree to which food particles are properly mixed with salivary enzymes. Disease of the mouth or tongue can interfere with speech and thus affect communication and self-image. Esophageal problems related to swallowing can also adversely affect food and fluid intake, thereby jeopardizing general health and well-being. Given the close relationship between adequate nutritional intake and the structures of the upper gastrointestinal tract (lips, mouth, teeth, pharynx, esophagus), health teaching can help prevent disorders associated with these structures (Fig. 35-1).

DISORDERS OF THE ORAL CAVITY

Oral health is a very important component of a person's physical and psychological sense of well-being. Severe periodontal disease affects approximately 14% of adults 45 to 64 years of age and 23% of adults 65 to 74 years of age (U.S. Department of Health and Human Services, 2000). Table 35-1 reviews common abnormalities of the oral cavity, their possible causes, and nursing management. Figure 35-2 illustrates structures of the oral cavity.

Dental Plaque and Caries

Tooth decay is an erosive process that begins with the action of bacteria on fermentable carbohydrates in the mouth, which produces acids that dissolve tooth enamel. Tooth enamel is the hardest substance in the human body, but dental erosion occurs for several reasons. Contributing factors include nutrition, soft drink consumption, and genetic predisposition. In addition, the extent of damage to the teeth may be related to the following:

- The presence of dental plaque. Dental plaque is a gluey, gelatin-like substance that adheres to the teeth.

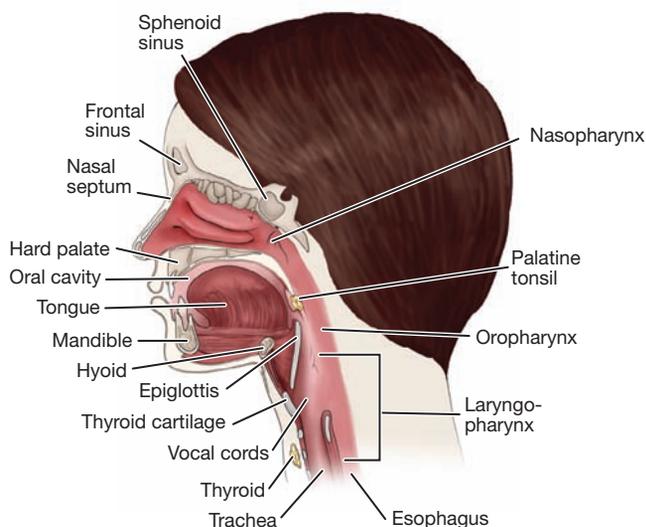

Figure 35-1 Anatomy of the head and neck.

The initial action that causes damage to a tooth occurs under dental plaque.

- The length of time acids are in contact with the teeth.
- The strength of acids and the ability of the saliva to neutralize them.
- The susceptibility of the teeth to decay.

Dental decay begins with a small hole, usually in a fissure (a break in the tooth's enamel) or in an area that is hard to clean. Left unchecked, the decay extends into the dentin. Because dentin is not as hard as enamel, decay progresses more rapidly and in time reaches the pulp of the tooth.

Dentists can determine the extent of damage and the type of treatment needed using x-ray studies. Treatment for dental caries includes fillings, dental implants, or extraction, if necessary. In general, dental decay can occur in anyone. Contributing factors can be as simple as not brushing teeth on a regular basis to an improper diet. Older adults are subject to decay from drug-induced or age-related oral dryness (Chart 35-1).

Prevention

Measures used to prevent and control dental caries include practicing effective mouth care, reducing the intake of starches and sugars (refined carbohydrates), applying fluoride to the teeth or drinking fluoridated water, refraining from smoking, controlling diabetes, and using pit and fissure sealants. Regular dental visits are another method of preventive dental maintenance.

Mouth Care

Healthy teeth must be conscientiously and effectively cleaned on a daily basis. Brushing and flossing are particularly effective in mechanically breaking up the bacterial plaque that collects around teeth.

Normal mastication (chewing) and the normal flow of saliva also aid greatly in keeping the teeth clean. Because many ill patients do not eat adequate amounts of food, they produce less saliva, which in turn reduces this natural tooth-cleaning process. The nurse may need to assume the responsibility for brushing the patient's teeth. Merely wiping the patient's mouth and teeth with a swab is ineffective. The most effective method is mechanical cleansing (brushing). If brushing is impossible, it is better to wipe the teeth with a gauze pad, then have the patient swish an antiseptic mouthwash several times before expectorating into an emesis basin. A soft-bristled toothbrush is more effective than a sponge or foam stick. To prevent drying, the lips may be coated with a water-soluble gel.

Diet

Dental caries may be prevented by decreasing the amount of sugar and starch in the diet. Patients who snack should be encouraged to choose less cariogenic alternatives, such as fruits, vegetables, nuts, cheeses, or plain yogurt. In addition, frequent brushing, especially after meals, is necessary. Flossing should be performed daily.

Fluoridation

Fluoridation of public water supplies has been found to decrease dental caries. Some areas of the country have natural

Table 35-1 DISORDERS OF THE LIPS, MOUTH, AND GUMS

Condition	Signs and Symptoms	Possible Causes and Sequelae	Nursing Considerations
Abnormalities of the Lips			
Actinic cheilitis	Irritation of lips associated with scaling, crusty, fissure; white overgrowth of horny layer of epidermis (hyperkeratosis) Considered a premalignant squamous cell skin cancer	Exposure to sun; more common in fair-skinned people and in those whose occupations involve sun exposure, such as farmers May lead to squamous cell cancer	Teach patient importance of protecting lips from the sun by using protective ointment such as sun block Instruct patient to have a periodic checkup by physician
Herpes simplex 1 (cold sore or fever blister)	Symptoms may be delayed up to 20 days after exposure; singular or clustered painful vesicles that may rupture	An opportunistic infection; frequently seen in immunosuppressed patients; very contagious May recur with menstruation, fever, or sun exposure	Use acyclovir (Zovirax) ointment or systemic medications as prescribed Administer analgesics as prescribed Instruct patient to avoid irritating foods
Chancre	Reddened circumscribed lesion that ulcerates and becomes crusted	Primary lesion of syphilis; very contagious	Comfort measures: cold soaks to lip, mouth care Administer antibiotics as prescribed Instruct patient regarding contagion
Contact dermatitis	Red area or rash; itching	Allergic reaction to lipstick, cosmetic ointments, or toothpaste	Instruct patient to avoid possible causes Administer corticosteroids as prescribed
Abnormalities of the Mouth			
Leukoplakia	White patches; may be hyperkeratotic; usually in buccal mucosa; usually painless	Fewer than 2% are malignant, but may progress to cancer Common among tobacco users	Instruct patient to see a physician if leukoplakia persists longer than 2 weeks Eliminate risk factors, such as tobacco
Hairy leukoplakia	White patches with rough hair-like projections; typically found on lateral border of the tongue	Possibly viral; smoking and use of tobacco Often seen in people who are HIV positive	Instruct patient to see a physician if condition persists longer than 2 weeks
Lichen planus	White papules at the intersection of a network of interlacing lesions; usually ulcerated and painful	Recurrences are common May lead to a malignant process Unknown cause	Apply topical corticosteroids such as fluocinolone acetonide oral base gel Avoid foods that irritate Administer corticosteroids systemically or intralesionally as prescribed Instruct the patient of need for follow-up if condition is chronic
Candidiasis (moniliasis/thrush)	Cheesy white plaque that looks like milk curds; when rubbed off, it leaves an erythematous and often bleeding base	<i>Candida albicans</i> fungus; predisposing factors include diabetes, antibiotic therapy, and immunosuppression	Antifungal medications such as nystatin (Mycostatin), amphotericin B, clotrimazole, or ketoconazole may be prescribed; these may be taken in pill form or as a suspension; when used as a suspension, instruct the patient to swish vigorously for at least 1 minute and then swallow
Aphthous stomatitis (canker sore)	Shallow ulcer with a white or yellow center and red border; seen on the inner side of the lip and cheek or on the tongue; it begins with a burning or tingling sensation and slight swelling; painful; usually lasts 7–10 days and heals without a scar	Associated with emotional or mental stress, fatigue, hormonal factors, minor trauma (such as biting), allergies, acidic foods and juices, and dietary deficiencies Associated with HIV infection May recur	Instruct the patient in comfort measures, such as saline rinses, and a soft or bland diet Antibiotics or corticosteroids may be prescribed
Nicotine stomatitis (smoker's patch)	Two stages—begins as a red stomatitis; over time the tongue and mouth become covered with a creamy, thick, white mucous membrane, which may slough, leaving a beefy red base	Chronic irritation by tobacco	Cessation of tobacco use; if condition exists for longer than 2 weeks a physician should be consulted and a biopsy may be needed
Krythoplakia	Red patch on the oral mucous membrane	Nonspecific inflammation; more frequently seen in the elderly	
Kaposi's sarcoma	Appears first on the oral mucosa as a red, purple, or blue lesion; may be singular or multiple; may be flat or raised	HIV infection	Instruct patient regarding side effects of planned treatment

Continued on following page

Table 35-1 DISORDERS OF THE LIPS, MOUTH, AND GUMS (Continued)			
Condition	Signs and Symptoms	Possible Causes and Sequelae	Nursing Considerations
Stomatitis	Mild redness (erythema) and edema; if severe, painful ulcerations, bleeding, and secondary infection	Chemotherapy; radiation therapy; severe drug allergy; myelosuppression (bone marrow depression)	Prophylactic mouth care, including brushing, flossing, and rinsing, for any patient receiving chemotherapy or radiation therapy Teach patient proper oral hygiene, including the use of a soft-bristled toothbrush and nonabrasive toothpaste; for painful ulcers, oral swabs with sponge-like applicators can be used in place of a toothbrush; avoid alcohol-based mouth rinses and hot or spicy foods Apply topical anti-inflammatory, antibiotic, and anesthetic agents as prescribed
Abnormalities of the Gums			
Gingivitis	Painful, inflamed, swollen gums; usually the gums bleed in response to light contact	Poor oral hygiene: food debris, bacterial plaque, and calculus (tartar) accumulate; the gums may also swell in response to normal processes such as puberty and pregnancy	Teach patient proper oral hygiene; toothbrushing, flossing, rinsing, dental appointments at least every 6 months
Necrotizing gingivitis (trench mouth)	Gray-white pseudomembranous ulcerations affecting the edges of the gums, mucosa of the mouth, tonsils, and pharynx; foul breath; painful, bleeding gums; swallowing and talking are painful	Poor oral hygiene; bacterial infection, inadequate rest, overwork, emotional stress, smoking, and poor nutrition may contribute to development	Teach patient proper oral hygiene; see Chart 35-2 Irrigate with 2% to 3% hydrogen peroxide or normal saline solution Avoid irritants such as smoking and spicy foods
Herpetic gingivostomatitis	Burning sensation with the appearance of small vesicles 24–48 hours later; vesicles may rupture, forming sore, shallow ulcers covered with a gray membrane	Herpes simplex virus; occurs most frequently in people who are immunosuppressed; may occur in other infectious processes such as streptococcal pneumonia, meningococcal meningitis, and malaria	Apply topical anesthetics as prescribed; may need opioids if pain is severe Saline or 2% to 3% hydrogen peroxide irrigations Antiviral agents such as acyclovir may be prescribed
Periodontitis	Little discomfort at onset; may have bleeding, infection, gum recession, and loosening of teeth; later in the disease tooth loss may occur	May result from untreated gingivitis Poor or inadequate dental hygiene and inadequate diet contribute to development	Instruct patient in proper oral hygiene Instruct patient to consult a dentist

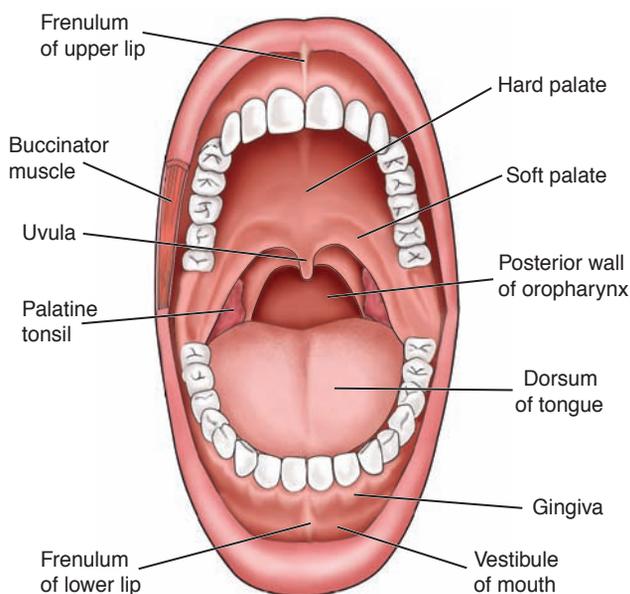

Figure 35-2 Structures of the mouth, including the tongue and palate.

fluoridation; other communities have added fluoride to public water supplies. Fluoridation may also be achieved by having a dentist apply a concentrated gel or solution to the teeth; adding fluoride to home water supplies; using fluoridated toothpaste or mouth rinse; or using sodium fluoride tablets, drops, or lozenges.

Pit and Fissure Sealants

The occlusal surfaces of the teeth have pits and fissures, areas that are prone to caries. Some dentists apply a special coating to fill and seal these areas from potential exposure to cariogenic processes. These sealants can last 5 to 10 years, depending on how dry the tooth surface is prior to application.

Dentoalveolar Abscess or Periapical Abscess

Periapical abscess, more commonly referred to as an abscessed tooth, involves a collection of pus in the apical dental periosteum (fibrous membrane supporting the tooth structure) and the tissue surrounding the apex of the tooth

CHART
35-1GERONTOLOGIC CONSIDERATIONS
Oral Conditions in the Older Adult

Many medications taken by the elderly cause dry mouth, which is uncomfortable, impairs communication, and increases the risk of oral infection. These medications include the following:

- Diuretics
- Antihypertensive medications
- Anti-inflammatory agents
- Antidepressant medications

Poor dentition can exacerbate problems of aging, such as:

- Decreased food intake
- Loss of appetite
- Social isolation
- Increased susceptibility to systemic infection (from periodontal disease)
- Trauma to the oral cavity secondary to thinner, less vascular oral mucous membranes

(where it is suspended in the jaw bone). The abscess may be acute or chronic. Acute periapical abscess is usually secondary to a suppurative pulpitis (a pus-producing inflammation of the dental pulp) that arises from an infection extending from dental caries. The infection of the dental pulp extends through the apical foramen of the tooth to form an abscess around the apex.

Chronic dentoalveolar abscess is a slowly progressive infectious process. In contrast to the acute form, a fully formed abscess may occur without the patient's knowledge. The infection eventually leads to a "blind dental abscess," which is actually a periapical granuloma. It may enlarge to as much as 1 cm in diameter. It is often discovered on x-ray films and is treated by extraction or root canal therapy, often with apicectomy (excision of the apex of the tooth root).

Clinical Manifestations

The abscess produces a dull, gnawing, continuous pain, often with a surrounding cellulitis and edema of the adjacent facial structures, and mobility of the involved tooth. The gum opposite the apex of the tooth is usually swollen on the cheek side. Swelling and cellulitis of the facial structures may make it difficult for the patient to open the mouth. There may also be a systemic reaction, fever, and malaise.

Medical Management

In the early stages of an infection, a dentist or oral surgeon may perform a needle aspiration or drill an opening into the pulp chamber to relieve pressure and pain and to provide drainage. Usually, the infection will have progressed to a periapical abscess. Drainage is provided by an incision through the gingiva down to the jawbone. Purulent material escapes under pressure. This procedure may be performed in the dentist's office, an outpatient surgery center, or a same-day surgery department. After the inflammatory reaction has subsided, the tooth may be extracted or root canal therapy performed. Antibiotics and opioids may be prescribed.

Nursing Management

The nurse assesses the patient for bleeding after treatment and instructs the patient to use a warm saline or warm water mouth rinse to keep the area clean. The patient is also instructed to take antibiotics and analgesics as prescribed, to advance from a liquid diet to a soft diet as tolerated, and to keep follow-up appointments.

Malocclusion

Malocclusion is a misalignment of the teeth of the upper and lower dental arcs when the jaws are closed. Malocclusion can be inherited or acquired (from thumb-sucking, trauma, or some medical conditions). Malocclusion makes the teeth difficult to clean and can lead to decay, gum disease, and excess wear on supporting bone and gum tissues. About 50% of the population has some form of malocclusion. Correction of malocclusion requires an orthodontist and a patient who is motivated and cooperative. Most treatments begin when the patient has shed the last primary tooth and the last permanent tooth has erupted, usually at about 12 or 13 years of age, but treatment may occur in adulthood. Preventive orthodontics may be started in children as early as 5 years of age if malocclusion is diagnosed early. The need for teeth straightening in adolescents is reduced if preventive orthodontics is started with the primary teeth.

Medical Management

People with malocclusion have an obviously misaligned bite or crooked, crowded, widely spaced, or protruding teeth. To realign the teeth, the orthodontist gradually forces the teeth into a new location by using wires or plastic bands (braces). These devices may be unattractive, but this psychological burden must be overcome if good results are to be achieved. In the final phase of treatment, a retaining device is worn for several hours each day to support the tissues as they adjust to the new alignment of the teeth.

Nursing Management

The patient must practice meticulous oral hygiene, and the nurse encourages the patient to continue this important part of the treatment. An adolescent or adult undergoing orthodontic correction who is admitted to the hospital for some other problem may have to be reminded to continue wearing the retainer (if it does not interfere with the condition requiring hospitalization).

DISORDERS OF THE JAW

Abnormal conditions affecting the mandible (jaw) and of the temporomandibular joint (which connects the mandible to the temporal bone at the side of the head in front of the ear) include congenital malformation, fracture, chronic

dislocation, cancer, and syndromes characterized by pain and limited motion. Temporomandibular disorders and jaw surgery (a treatment common in many structural abnormalities or cancer of the jaw) are presented in this section.

Temporomandibular Disorders

Temporomandibular disorders are categorized as follows (National Institute of Dental and Craniofacial Research [NICDR], 2006):

- Myofascial pain: a discomfort in the muscles controlling jaw function and in neck and shoulder muscles
- Internal derangement of the joint: a dislocated jaw, a displaced disk, or an injured condyle
- Degenerative joint disease: rheumatoid arthritis or osteoarthritis in the jaw joint

Diagnosis and treatment of temporomandibular disorders remain somewhat ambiguous, but the condition is thought to affect about 10 million people in the United States. Misalignment of the joints in the jaw and other problems associated with the ligaments and muscles of mastication are thought to result in tissue damage and muscle tenderness. Suggested causes include arthritis of the jaw, head injury, trauma or injury to the jaw or joint, stress, and malocclusion (although research does not support malocclusion as a cause).

Clinical Manifestations

Patients have jaw pain ranging from a dull ache to throbbing, debilitating pain that can radiate to the ears, teeth, neck muscles, and facial sinuses. They often have restricted jaw motion and locking of the jaw. There also may be a sudden change in the way the upper and lower teeth fit together. The patient may hear clicking, popping, and grating sounds when the mouth is opened, and chewing and swallowing may be difficult. Symptoms such as headaches, earaches, dizziness, and hearing problems may sometimes be related to temporomandibular disorders (Buescher, 2007; NICDR, 2006).

Assessment and Diagnostic Findings

Diagnosis is based on the patient's report of pain, limitations in range of motion, dysphagia, difficulty chewing, difficulty with speech, or hearing difficulties. Magnetic resonance imaging and x-ray studies are generally only used for severe or chronic symptoms.

Medical Management

Signs and symptoms improve over time for the majority of patients with temporomandibular joint disorders, with or without treatment. Some practitioners think the role of stress in these disorders is overrated, but patient education in stress management may be helpful (to reduce grinding and clenching of teeth). Patients may also benefit from range-of-motion exercises. Pain management measures may include nonsteroidal anti-inflammatory drugs (NSAIDs), with the possible addition of opioids, muscle relaxants, or mild antidepressants. Occasionally, intraoral orthotics (a plastic guard worn over the upper and lower teeth) may be worn to reposition the condyle head in the joint space to a more normal position, which in turn relieves the stress and pressure on the tissues of the joint. This allows the tissues to

heal. Conservative and reversible treatment is recommended. If irreversible surgical options are recommended, patients are encouraged to seek a second opinion.

Jaw Disorders Requiring Surgical Management

Correction of mandibular structural abnormalities may require surgery involving repositioning or reconstruction of the jaw. Simple fractures of the mandible without displacement, resulting from a blow on the chin, and planned surgical interventions, as in the correction of long or short jaw syndrome, may require treatment by these means. Jaw reconstruction may be necessary in the aftermath of trauma from a severe injury or cancer, both of which can cause tissue and bone loss.

Mandibular fractures are usually closed fractures. Rigid plate fixation (insertion of metal plates and screws into the bone to approximate and stabilize the bone) is the current treatment of choice in many cases of mandibular fracture and in some mandibular reconstructive surgery procedures. Bone grafting may be performed to replace structural defects using bones from the patient's own ilium, ribs, or cranial sites. Rib tissue may also be harvested from cadaver donors.

Nursing Management

The patient who has had rigid fixation should be instructed not to chew food in the first 1 to 4 weeks after surgery. A liquid diet is recommended, and dietary counseling should be obtained to ensure optimal caloric and protein intake.

Promoting Home and Community-Based Care

The patient needs specific guidelines for mouth care and feeding. Any irritated areas in the mouth should be reported to the physician. The importance of keeping scheduled appointments to assess the stability of the fixation appliance is emphasized.

Consultation with a dietitian may be indicated so that the patient and family can learn about foods that are high in essential nutrients and ways in which these foods can be prepared so that they can be consumed through a straw or spoon while remaining palatable. Nutritional supplements may be recommended.

DISORDERS OF THE SALIVARY GLANDS

The salivary glands consist of the parotid glands, one on each side of the face below the ear; the submandibular and sublingual glands, both in the floor of the mouth; and the buccal gland, beneath the lips. About 1200 mL of saliva are produced daily and swallowed. The glands' primary functions are lubrication, protection against harmful bacteria, and digestion.

Parotitis

Parotitis (inflammation of the parotid gland) is the most common inflammatory condition of the salivary glands, although inflammation can occur in the other salivary glands as well. Mumps (epidemic parotitis), a communicable

disease caused by viral infection and most commonly affecting children, is an inflammation of a salivary gland, usually the parotid.

Elderly, acutely ill, or debilitated people with decreased salivary flow from general dehydration or medications are at high risk for parotitis. The infecting organisms travel from the mouth through the salivary duct. The organism is usually *Staphylococcus aureus* (except in mumps). The onset of this complication is sudden, with an exacerbation of both fever and the symptoms of the primary condition. The gland swells and becomes tense and tender. The patient feels pain in the ear, and swollen glands interfere with swallowing. The swelling increases rapidly, and the overlying skin soon becomes red and shiny.

Medical management includes maintaining adequate nutritional and fluid intake, good oral hygiene, and discontinuing medications (eg, tranquilizers, diuretics) that can diminish salivation. Antibiotic therapy is necessary, and analgesics may be prescribed to control pain. If antibiotic therapy is not effective, the gland may need to be drained by a surgical procedure known as parotidectomy. This procedure may be necessary to treat chronic parotitis. The patient is advised to have any necessary dental work performed prior to surgery.

Sialadenitis

Sialadenitis (inflammation of the salivary glands) may be caused by dehydration, radiation therapy, stress, malnutrition, salivary gland calculi (stones), or improper oral hygiene. The inflammation is associated with infection by *S. aureus*, *Streptococcus viridans*, or *pneumococci*. In hospitalized or institutionalized patients, the infecting organism may be methicillin-resistant *S. aureus* (MRSA). Symptoms include pain, swelling, and purulent discharge. Antibiotics are used to treat infections. Massage, hydration, warm compresses, and corticosteroids frequently cure the problem. Chronic sialadenitis with uncontrolled pain is treated by surgical drainage of the gland or excision of the gland and its duct.

Salivary Calculus (Sialolithiasis)

Sialolithiasis, or salivary calculi (stones), usually occurs in the submandibular gland. Salivary gland ultrasonography or sialography (x-ray studies filmed after the injection of a radiopaque substance into the duct) may be required to demonstrate obstruction of the duct by stenosis. Salivary calculi are formed mainly from calcium phosphate. If located within the gland, the calculi are irregular and vary in diameter from 3 to 30 mm. Calculi in the duct are small and oval.

Calculi within the salivary gland itself cause no symptoms unless infection arises; however, a calculus that obstructs the gland's duct causes sudden, local, and often colicky pain, which is abruptly relieved by a gush of saliva. This characteristic symptom is often disclosed in the patient's health history. On physical assessment, the gland is swollen and quite tender, the stone itself can be palpable, and its shadow may be seen on x-ray films.

The calculus can be extracted fairly easily from the duct in the mouth. Sometimes, enlargement of the ductal orifice permits the stone to pass spontaneously. Occasionally **lithotripsy**, a procedure that uses shock waves to disintegrate the stone, may be used instead of surgical extraction for parotid stones and smaller submandibular stones. Lithotripsy requires no anesthesia, sedation, or analgesia. Side effects can include local hemorrhage and swelling. Surgery may be necessary to remove the gland if symptoms and calculi recur repeatedly.

Neoplasms

Although they are uncommon, neoplasms (tumors or growths) of almost any type may develop in the salivary gland. Tumors occur more often in the parotid gland. The incidence of salivary gland tumors is similar in men and women. Risk factors include prior exposure to radiation to the head and neck. Diagnosis is based on the health history and physical examination and the results of fine-needle aspiration biopsy.

Management of salivary gland tumors may involve partial excision of the gland, along with the tumor and a wide margin of surrounding tissue. Dissection is carefully performed to preserve the seventh cranial nerve (facial nerve), although it may not be possible to do so if the tumor is extensive. If the tumor is malignant, radiation therapy may follow surgery. Radiation therapy alone may be a treatment choice for tumors that are thought to be localized or if there is risk of facial nerve damage from surgical intervention. Chemotherapy is usually used for palliative purposes. Local recurrences are common, and the recurrence rate can be as high as 25% (Chahin & Kaufman, 2005). Recurrent tumors usually are more aggressive than initial tumors. Tumors of the salivary gland lead to an increased incidence of second primary cancers, which may be due to inadequate excision of the original tumor.

CANCER OF THE ORAL CAVITY AND PHARYNX

Cancers of the oral cavity and pharynx, which can occur in any part of the mouth or throat, are curable if discovered early. Risk factors for cancer of the oral cavity and pharynx include cigarette, cigar, and pipe smoking; use of smokeless tobacco; and excessive use of alcohol. Oral cancers are often associated with the combined use of alcohol and tobacco; these substances have a synergistic carcinogenic effect. Patient education directed toward avoiding high-risk behaviors is critical to prevent oral cancers.

The incidence of cancers of the oral cavity and pharynx is greatest in men older than 50 years of age. In general, it is almost twice as high in men as it is in women. Cancers of the oral cavity and pharynx occur more often in African Americans than in Caucasians.

Approximately 35,000 new cases of oral cavity and oropharyngeal cancer occur annually in the United States. For the past 20 to 40 years, the number of new cases and death rate has been decreasing. Eighty-four percent of patients with

cancer of the oral cavity and oropharynx survive at least 1 year after diagnosis. Regardless of the stage of cancer at diagnosis, the 5-year relative survival rate is 59%, and the 10-year survival rate is 48% (American Cancer Society, 2008).

Pathophysiology

Malignancies of the oral cavity are usually squamous cell cancers. Any area of the oropharynx can be a site of malignant growths, but the lips, the lateral aspects of the tongue, and the floor of the mouth are most commonly affected.

Clinical Manifestations

Many oral cancers produce few or no symptoms in the early stages. Later, the most frequent symptom is a painless sore or mass that does not heal. It may bleed easily and it may present as a red or white patch that persists (American Cancer Society, 2009). A typical lesion in oral cancer is a painless indurated (hardened) ulcer with raised edges. As the cancer progresses, the patient may complain of tenderness; difficulty in chewing, swallowing, or speaking; coughing of blood-tinged sputum; or enlarged cervical lymph nodes.

Assessment and Diagnostic Findings

Diagnostic evaluation consists of an oral examination as well as an assessment of the cervical lymph nodes to detect possible metastases. Biopsies are performed on suspicious lesions (those that have not healed in 2 weeks). In people who use snuff or smoke cigars or pipes, high-risk areas include the buccal mucosa and gingiva. In those who smoke cigarettes and drink alcohol, high-risk areas include the floor of the mouth, the ventrolateral tongue, and the soft palate complex (soft palate, anterior and posterior tonsillar area, uvula, and the area behind the molar and tongue junction).

Medical Management

Management varies with the nature of the lesion, the preference of the physician, and patient choice. Surgical resection and radiation therapy are standard treatment. Addition of chemotherapy may be useful for advanced disease (American Cancer Society, 2009).

In cancer of the lip, small lesions are usually excised liberally. Radiation therapy may be more appropriate for larger lesions involving more than one third of the lip because of superior cosmetic results. The choice depends on the extent of the lesion and what is necessary to cure the patient while preserving the best appearance. Tumors larger than 4 cm often recur.

In cancer of the tongue, treatment with radiation therapy and chemotherapy may preserve organ function and maintain quality of life. A combination of radioactive interstitial implants (surgical implantation of a radioactive source into the tissue adjacent to or at the tumor site) and external beam radiation may be used. Surgical procedures include hemiglossectomy (surgical removal of half of the tongue) and total glossectomy (removal of the tongue).

Often, cancer of the oral cavity has metastasized through the extensive lymphatic channel in the neck region, requiring a neck dissection and reconstructive surgery of the oral

cavity. One common reconstructive technique involves use of a radial forearm free flap (a thin layer of skin from the forearm along with the radial artery).

Nursing Management

The nurse assesses the patient's nutritional status preoperatively, and a dietary consultation may be necessary. The patient may require enteral (through the gastrointestinal tract) or parenteral (intravenous [IV]) feedings before and after surgery to maintain adequate nutrition. Continual assessment and reevaluation are necessary. If a radial graft is to be performed, an Allen test on the donor arm must be performed to ensure that the ulnar artery is patent and can provide blood flow to the hand after removal of the radial artery. The Allen test is performed by asking the patient to make a fist and then manually compressing the ulnar artery. The patient is then asked to open the hand into a relaxed, slightly flexed position. The palm is pale. Pressure on the ulnar artery is released. If the ulnar artery is patent, the palm flushes within about 3 to 5 seconds.

Verbal communication may be impaired by radical surgery for oral cancer. It is therefore vital to assess the patient's ability to communicate in writing before surgery. Pen and paper are provided postoperatively to patients who can use them to communicate. A communication board with commonly used words or pictures is obtained preoperatively and given after surgery to patients who cannot write so that they may point to needed items. A speech therapist is also consulted postoperatively.

Postoperatively, the nurse assesses for a patent airway. The patient may be unable to manage oral secretions, making suctioning necessary. If grafting was part of the surgery, suctioning must be performed with care to prevent damage to the graft. The graft is assessed postoperatively for viability. Although color should be assessed (white may indicate arterial occlusion, and blue mottling may indicate venous congestion), it can be difficult to assess the graft by looking into the mouth. A Doppler ultrasound device may be used to locate the radial pulse at the graft site and to assess graft perfusion.

Nursing Management of the Patient With Conditions of the Oral Cavity

Promoting Mouth Care

The nurse instructs the patient in the importance and techniques of preventive mouth care. If a patient cannot tolerate brushing or flossing, an irrigating solution of 1 tsp of baking soda to 8 oz of warm water, half-strength hydrogen peroxide, or normal saline solution is recommended. The nurse reinforces the need to perform oral care and provides such care to patients who cannot provide it for themselves.

If a bacterial or fungal infection is present, the nurse administers the prescribed medications and instructs the patient how to administer the medications at home. The nurse monitors the patient's physical and psychological response to treatment.

Xerostomia, dryness of the mouth, is a frequent sequela of oral cancer, particularly when the salivary glands have

been exposed to radiation or major surgery. It is also seen in patients who are receiving psychopharmacologic agents, patients with human immunodeficiency virus (HIV) infection, and patients who cannot close the mouth and as a result become mouth-breathers. To minimize this problem, the patient is advised to avoid dry, bulky, and irritating foods and fluids, as well as alcohol and tobacco. The patient is also encouraged to increase intake of fluids (when not contraindicated) and to use a humidifier while sleeping. The use of synthetic saliva, a moisturizing antibacterial gel such as Oral Balance, or a saliva production stimulant such as Salagen may be helpful.

Stomatitis, or mucositis, which involves inflammation and breakdown of the oral mucosa, is often a side effect of chemotherapy or radiation therapy. Prophylactic mouth care is started when the patient begins receiving treatment; however, mucositis may become so severe that a break in treatment is necessary. If a patient receiving radiation therapy has poor dentition, extraction of the teeth before radiation treatment in the oral cavity is often initiated to prevent infection. Many radiation therapy centers recommend the use of fluoride treatments for patients receiving radiation to the head and neck. (See Chapter 16 for more information about stomatitis.)

Ensuring Adequate Food and Fluid Intake

The patient's weight, age, and level of activity are recorded to determine whether nutritional intake is adequate. A daily calorie count may be necessary to determine the exact quantity of food and fluid ingested. The frequency and pattern of eating are recorded to determine whether any psychosocial or physiologic factors are affecting ingestion. Based on the disorder and the patient's preferences, the nurse recommends changes in the consistency of foods and the frequency of eating. Consultation with a dietitian may be helpful. The goal is to help the patient attain and maintain desirable body weight and level of energy, as well as to promote the healing of tissue.

Supporting a Positive Self-Image

A patient who has a disfiguring oral condition or has undergone disfiguring surgery may experience an alteration in self-image. The patient is encouraged to verbalize the perceived change in body appearance and to realistically discuss actual changes or losses. The nurse offers support while the patient verbalizes fears and negative feelings (withdrawal, depression, anger). The nurse listens attentively and determines the patient's needs and individualizes the plan of care. The patient's strengths and achievements are reinforced.

The nurse should determine the patient's anxieties concerning relationships with others. Referral to support groups, a psychiatric liaison nurse, a social worker, or a spiritual advisor may be useful in helping the patient to cope with anxieties and fears. The patient's progress toward development of positive self-esteem is documented. The nurse should be alert to signs of grieving and should document emotional changes. By providing acceptance and support, the nurse encourages the patient to verbalize feelings.

Minimizing Pain and Discomfort

Oral lesions can be painful. Strategies to reduce pain and discomfort include avoiding foods that are spicy, hot, or hard (eg, pretzels, nuts). A soft or liquid diet may be preferred. The patient is instructed about mouth care. Using a soft tooth brush may prevent secondary trauma. It may be necessary to provide the patient with an analgesic such as viscous lidocaine (Xylocaine Viscous 2%) or opioids, as prescribed. Topical medications such as sucralfate (Carafate) and aluminum-magnesium liquid antacids may provide relief. The nurse can reduce the patient's fear of pain by providing information about pain control methods.

Preventing Infection

Leukopenia (a decrease in white blood cells) may result from radiation, chemotherapy, acquired immunodeficiency syndrome (AIDS), and some medications used to treat HIV infection. Leukopenia reduces defense mechanisms, increasing the risk of infections. Malnutrition, which is also common among these patients, may further decrease resistance to infection. If the patient has diabetes, the risk of infection is further increased.

Laboratory results should be evaluated frequently and the patient's temperature checked every 4 to 8 hours for an elevation that may indicate infection. Visitors who might transmit microorganisms are prohibited if the patient's immunologic system is depressed. Sensitive skin tissues are protected from trauma to maintain skin integrity and prevent infection. Aseptic technique is necessary when changing dressings. Desquamation (shedding of the epidermis) is a reaction to radiation therapy that causes dryness and itching and can lead to a break in skin integrity and subsequent infection.

Signs of wound infection (redness, swelling, drainage, tenderness) are reported to the physician. Antibiotics may be prescribed prophylactically.

Promoting Home and Community-Based Care

Teaching Patients Self-Care

The patient who is recovering from treatment of an oral condition is instructed about mouth care, nutrition, prevention of infection, and signs and symptoms of complications (Chart 35-2). Methods of preparing nutritious foods that are seasoned according to the patient's preference and at the preferred temperature are explained to the patient and family. For some patients, it may be more convenient (but also more expensive) to use commercial baby foods than to prepare liquid and soft diets. The patient who cannot take foods orally may receive enteral or parenteral nutrition; the administration of these feedings is explained and demonstrated to the patient and the caregiver.

For patients with oral cancer, instructions are provided in the use and care of any dentures. The importance of keeping dressings clean and the need for conscientious oral hygiene are emphasized.

Continuing Care

The need for ongoing care in the home depends on the patient's condition. The patient, the family members, and others responsible for home care (eg, nurse, speech therapist,

CHART
35-2

HOME CARE CHECKLIST

The Patient With an Oral Condition

At the completion of the home care instruction, the patient or caregiver will be able to:	PATIENT	CAREGIVER
• Demonstrate use of suction equipment if indicated.	✓	✓
• State rationale for humidification.	✓	✓
• Identify foods necessary to meet caloric needs and dietary needs (ie, change in consistency, seasoning limitations, supplements).	✓	✓
• Demonstrate effective oral hygiene.	✓	✓
• Demonstrate care of incision.	✓	✓
• State when next medical/dental follow-up appointment will be scheduled.	✓	✓

nutritionist, psychologist) work together to prepare an individual plan of care.

If suctioning of the mouth or tracheostomy tube is required, the necessary equipment is obtained and the patient and caregivers are taught how to use it. Considerations include the control of odors and humidification of the home to keep secretions moist. The patient and caregivers are taught how to assess for obstruction, hemorrhage, and infection and what actions to take if they occur. The home care nurse may provide physical care, monitor for changes in the patient's physical status (eg, skin integrity, nutritional status, respiratory function), and assess the adequacy of pain control measures. The nurse also assesses the patient's and family's ability to manage incisions, drains, and feeding tubes and the use of recommended strategies for communication. The ability of the patient and family to accept physical, psychological, and role changes is assessed and addressed.

Follow-up visits to the physician are important to monitor the patient's condition and to determine the need for modifications in treatment and general care. Because patients and their family members, as well as health care providers, tend to focus on the most obvious needs and issues, the nurse reminds the patient and family about the importance of continuing health promotion and screening practices and refers them to appropriate practitioners. The nurse also reinforces instructions in an effort to promote the patient's self-care and comfort.

NECK DISSECTION

Malignancies of the head and neck include those of the oral cavity, oropharynx, hypopharynx, nasopharynx, nasal cavity, paranasal sinus, and larynx. (Laryngeal cancer is presented in Chapter 22.) These cancers account for fewer than 5% of all cancers. Depending on the location and stage, treatment may consist of radiation therapy, chemotherapy, surgery, or a combination of these modalities. Deaths from malignancies of the head and neck are primarily attributable to local-regional metastasis to the cervical lymph nodes in the neck. This often occurs by way of the lymphatics before the primary lesion has been treated. This local-regional metastasis is not amenable to surgical

resection and responds poorly to chemotherapy and radiation therapy.

A radical neck dissection involves removal of all cervical lymph nodes (Fig. 35-3) from the mandible to the clavicle and removal of the sternocleidomastoid muscle, internal jugular vein, and spinal accessory muscle on one side of the neck. The associated complications include shoulder drop and poor cosmesis (visible neck depression). Modified radical neck dissection, which preserves one or more of the nonlymphatic structures, is used more often. A selective neck dissection (in comparison to a radical dissection) preserves one or more of the lymph node groups, the internal jugular vein, the sternocleidomastoid muscle, and the spinal accessory nerve (Fig. 35-4).

Reconstructive techniques may be performed with a variety of grafts. A cutaneous flap (skin and subcutaneous tissue), such as the deltopectoral flap, may be used. A myocutaneous flap (subcutaneous tissue, muscle, and skin) is a more frequently used graft; the pectoralis major muscle is usually used. For large grafts, a microvascular free flap may be used. This involves the transfer of muscle, skin, or bone

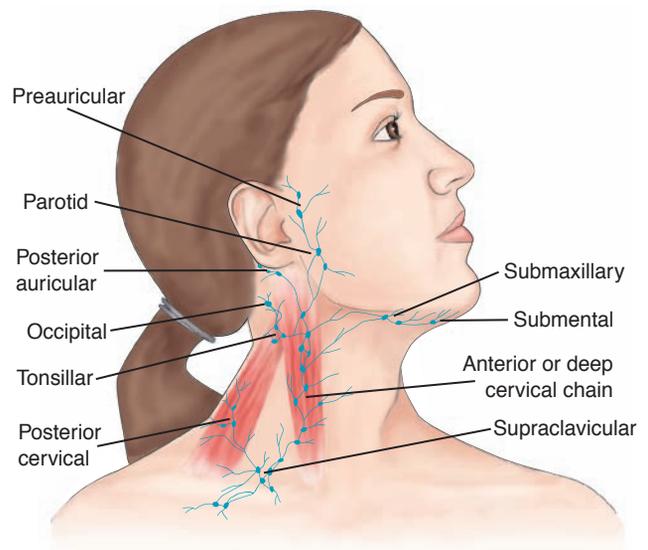

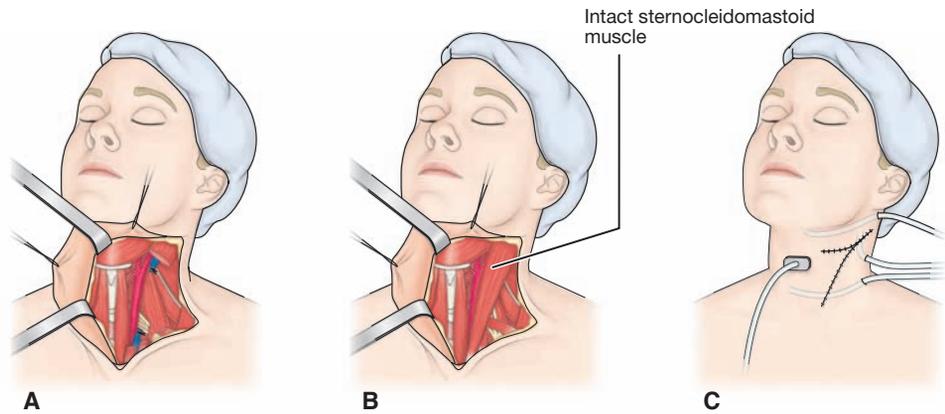

Figure 35-3 Lymphatic drainage of the head and neck.

Figure 35-4 **A**, A classic radical neck dissection in which the sternocleidomastoid and smaller muscles are removed. All tissue is removed, from the ramus of the jaw to the clavicle. The jugular vein has also been removed. **B**, The selective neck dissection is similar but preserves the sternocleidomastoid muscle, internal jugular vein, and spinal accessory nerve. **C**, The wound is closed, and portable suction drainage tubes are in place.

with an artery and vein to the area of reconstruction, using microinstrumentation. Areas used for a free flap include the scapula, the radial area of the forearm, or the fibula. The fibula, which provides a larger bone area, may be used if mandibular reconstruction is involved.

NURSING PROCESS

THE PATIENT UNDERGOING A NECK DISSECTION

Assessment

Preoperatively, the patient's physical and psychological preparation for major surgery is assessed, along with his or her knowledge of the preoperative and postoperative procedures. Postoperatively, the patient is assessed for complications such as altered respiratory status, wound infection, and hemorrhage. As healing occurs, neck range of motion is assessed to determine whether there has been a decrease in range of motion due to nerve or muscle damage.

Diagnosis

Nursing Diagnoses

Based on all the assessment data, major nursing diagnoses may include the following:

- Deficient knowledge about preoperative and postoperative procedures
- Ineffective airway clearance related to obstruction by mucus, hemorrhage, or edema
- Acute pain related to surgical incision
- Risk for infection related to surgical intervention secondary to decreased nutritional status, or immunosuppression from chemotherapy or radiation therapy
- Impaired tissue integrity secondary to surgery and grafting
- Imbalanced nutrition, less than body requirements, related to disease process or treatment
- Situational low self-esteem related to diagnosis or prognosis
- Impaired verbal communication secondary to surgical resection
- Impaired physical mobility secondary to nerve injury

Collaborative Problems/Potential Complications

Potential postoperative complications that may develop include the following:

- Hemorrhage
- Chyle fistula
- Nerve injury

Planning and Goals

The major goals for the patient include participation in the treatment plan, maintenance of respiratory status, attainment of comfort, absence of infection, viability of the graft, maintenance of adequate intake of food and fluids, effective coping strategies, effective communication, maintenance of shoulder and neck motion, and absence of complications.

Nursing Interventions

Providing Preoperative Patient Education

Before surgery, the patient should be informed about the nature and extent of the surgery and what the postoperative period will be like. The patient is encouraged to ask questions and to express concerns about the upcoming surgery and the expected results. During this exchange, the nurse has an opportunity to assess the patient's coping abilities, answer questions, and develop a plan for offering assistance. A sense of mutual understanding and rapport make the postoperative experience less traumatic for the patient. The patient's expressions of concern, anxieties, and fears guide the nurse in providing support postoperatively.

Providing General Postoperative Care

The general postoperative nursing interventions are similar to those presented in Chapter 20 and are directed toward the identified nursing diagnoses and goals.

Maintaining the Airway

After the endotracheal tube or airway has been removed and the effects of the anesthesia have worn off, the patient may be placed in the Fowler's position to facilitate breathing and promote comfort. This position also increases lymphatic and venous drainage, facilitates swallowing, decreases venous pressure on the skin flaps, and prevents regurgitation and aspiration of stomach contents. Signs of

respiratory distress, such as dyspnea, cyanosis, changes in mental status, and changes in vital signs, are assessed because they may suggest edema, hemorrhage, inadequate oxygenation, or inadequate drainage.

NURSING ALERT

In the immediate postoperative period, the nurse assesses for stridor (coarse, high-pitched sound on inspiration) by listening frequently over the trachea with a stethoscope. This finding must be reported immediately because it indicates obstruction of the airway.

Pneumonia may occur in the postoperative phase if pulmonary secretions are not removed. To aid in the removal of secretions, coughing and deep breathing are encouraged. With the nurse supporting the neck, the patient should assume a sitting position so that excessive secretions can be coughed up and expectorated. If this is ineffective, the patient's respiratory tract may have to be suctioned. Care is taken to protect the suture lines during suctioning. If a tracheostomy tube is in place, suctioning is performed through the tube. The patient may also be instructed on use of Yankauer suction (tonsil tip suction) to remove oral secretions. Humidified air or oxygen is provided through the tracheostomy to keep secretions thin. Temperature should not be taken orally.

Relieving Pain

Pain and the patient's fear of pain are assessed and managed. Patients with head and neck cancer often report less pain than patients with other types of cancer; however, the nurse needs to be aware that each person's pain experience is individual. Pain management is monitored on a continual basis by the nursing staff and adjusted on an individual basis. Patient-controlled analgesia may be prescribed for postoperative pain management, thereby reducing the wait time for pain relief.

Providing Wound Care

Wound drainage tubes are usually inserted during surgery to prevent the collection of fluid subcutaneously. The drainage tubes are connected to a portable suction device (eg, Jackson-Pratt), and the container is emptied periodically. Between 80 and 120 mL of serosanguineous secretions may drain over the first 24 hours. Excessive drainage may be indicative of a chyle fistula or hemorrhage (see later discussion). Dressings are reinforced as needed and are observed for evidence of hemorrhage and constriction, which impairs respiration and perfusion of the graft. A graft, if present, is assessed for color and temperature and for the presence of a pulse, if applicable, to determine viability. The graft should be pale pink and warm to the touch. The surgical incisions are also assessed for signs of infection (purulent, malodorous drainage), which are reported immediately. Prophylactic antibiotics may be prescribed in the early postoperative period. Aseptic technique is used when cleansing skin around the drains; dressings are changed as prescribed by the surgeon, usually on the second through the fifth postoperative days.

Maintaining Adequate Nutrition

Nutritional status is assessed preoperatively; early intervention to correct nutritional imbalances may decrease the risk of postoperative complications. Frequently, nutrition is less than optimal because of inadequate intake, and the patient often requires enteral or parenteral supplements preoperatively and postoperatively to attain and maintain a positive nitrogen balance. Supplements (eg, Ensure, Sustacal, Boost) that are nutritionally dense may help reestablish a positive nitrogen balance. They may be taken enterally by mouth, by nasogastric feeding tube, or by gastrostomy feeding tube.

The patient who can chew may take food by mouth; the patient's chewing ability determines whether some diet modification (eg, soft, puréed, or liquid foods) is necessary. Food preferences should also be discussed with the patient. Oral care before eating may enhance the patient's appetite, and oral care after eating is important to prevent infection and dental caries. Most patients can maintain and gain weight.

Supporting Coping Measures

Preoperatively, information about the planned surgery is given to the patient and family. Any questions are answered as accurately as possible. It is important for the health care provider to pay attention to nonverbal behavior that may indicate something different from what the patient is able to articulate. Postoperatively, psychological nursing interventions are aimed at supporting the patient who has had a change in body image or who has major concerns related to the prognosis. The patient may have difficulty communicating and may be concerned about his or her ability to breathe and swallow normally. The nurse supports the patient's family in encouraging and reassuring the patient that adjusting to the results of this surgery will take time.

The person who has had extensive neck surgery often is sensitive about his or her appearance. This can occur when the operative area is covered by bulky dressings, when the incision line is visible, or later after healing has occurred and the appearance of the neck and possibly the lower face has been significantly altered. If the nurse accepts the patient's appearance and expresses a positive, optimistic attitude, the patient is more likely to be encouraged. The patient also needs an opportunity to express fears and concerns regarding the success of the surgery and the prognosis. The American Cancer Society (ACS) may be a resource to provide a volunteer who meets with the patient either preoperatively or postoperatively and shares his or her own experience about the diagnosis, treatment, and recovery. The "Look Good, Feel Better" programs of the ACS also are a source of information about clothing and cosmetics that can be used to deemphasize physical defects.

People with cancer of the head and neck frequently have used alcohol or tobacco before surgery; postoperatively, they are encouraged to abstain from these substances. Alternative methods of coping need to be explored. A referral to Alcoholics Anonymous, a smoking cessation program, and family counseling may be appropriate.

Promoting Effective Communication

Communication begins preoperatively, when the patient and family determine which method of communication will be the best postoperatively. Useful communication methods

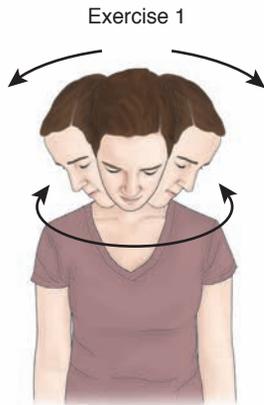

for the patient who has undergone a laryngectomy include Magic Slates, writing materials, pictorial guides, computer aids, and hand signals. During the postoperative period, the call bell must be readily accessible to the patient at all times.

The nurse obtains a consultation with a speech or language therapist. Alternative speech techniques, such as an electrolarynx (a mechanical device held against the neck) or esophageal speech, may be taught by a speech or language therapist. The most widely used technique for creating laryngeal speech is tracheoesophageal puncture. A surgically created fistula extends from the superior wall of the

tracheal stoma into the proximal esophageal wall. A voice prosthesis is then inserted into the fistula to assist with speech (see Chapter 22).

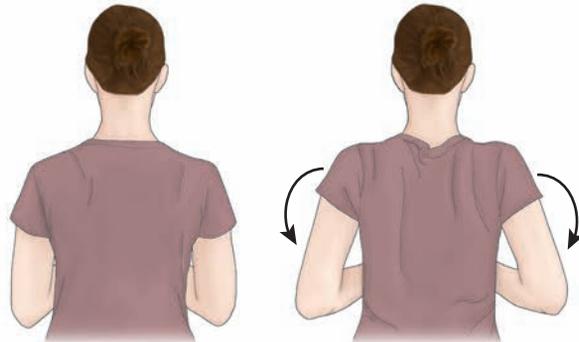

Maintaining Physical Mobility

Excision of muscles and nerves results in weakness at the shoulder that can cause shoulder drop, a forward curvature of the shoulder. Many problems can be avoided with a conscientious exercise program. These exercises are usually started after the drains have been removed and the neck incision is sufficiently healed. The purpose of the exercises depicted in Figure 35-5 is to promote maximal shoulder function and

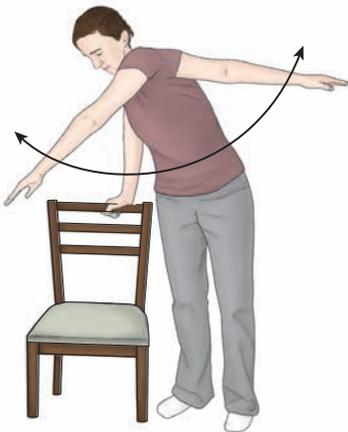

Gently turn head to each side and look as far as possible. Gently tip right ear toward right shoulder as far as possible. Repeat on left side. Move chin to chest and then lift head up and back.

Exercise 2

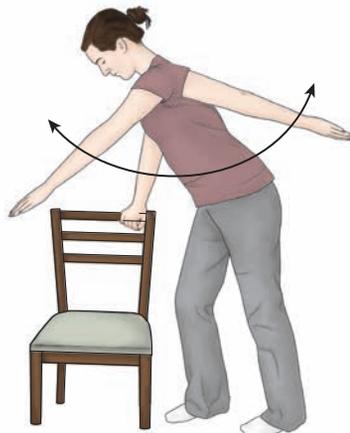

Place hands in front with elbows at right angles away from body. Rotate shoulders back, bringing elbows to side. Then relax whole body.

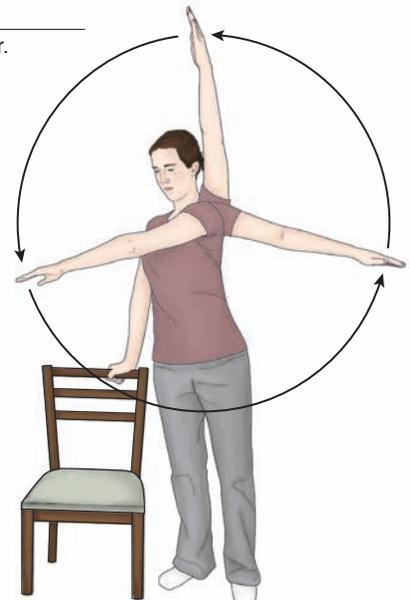

Exercise 3: Using the hand on the unaffected side, lean or hold onto a low table or chair.

Bend body slightly at waist and swing shoulder and arm from left to right.

Swing shoulder and arm from front to back

Swing shoulder and arm in a wide circle, gradually bringing arm above head.

Figure 35-5 Three rehabilitation exercises after head and neck surgery. The objective is to regain maximum shoulder function and neck motion after neck surgery. From *Exercise for radical neck surgery patients*. Head and Neck Service, Department of Surgery, Memorial Hospital, New York, NY.

neck motion after surgery. Physical therapists and occupational therapists can assist patients in performing these exercises.

Monitoring and Managing Potential Complications

HEMORRHAGE. Hemorrhage may occur from carotid artery rupture as a result of necrosis of the graft or damage to the artery itself from tumor or infection. The following measures are indicated:

- Vital signs are assessed frequently (every 1 to 2 hours or every 15 minutes if the patient is critical). Once the patient is stabilized, assessment is increased to every 4 hours. Tachycardia, tachypnea, and hypotension may indicate hemorrhage and impending hypovolemic shock.
- The patient is instructed to avoid the Valsalva maneuver to prevent stress on the graft and carotid artery.
- Signs of impending rupture, such as high epigastric pain or discomfort, are reported.
- Dressings and wound drainage are observed for excessive bleeding.
- If hemorrhage occurs, assistance is summoned immediately.
- Hemorrhage requires the continuous application of pressure to the bleeding site or major associated vessel.
- Although some clinicians advocate placing the patient in the modified Trendelenburg position to maintain blood pressure, others recommend that the head of the patient's bed be elevated to maintain airway patency and prevent aspiration.
- A controlled, calm manner allays the patient's anxiety.
- The surgeon is notified immediately, because a vascular or ligature tear requires surgical intervention.

CHYLE FISTULA. A chyle fistula (milklike drainage from the thoracic duct into the thoracic cavity) may develop as a result of damage to the thoracic duct during surgery. The diagnosis is made if there is excess drainage that has a 3% fat content and a specific gravity of 1.012 or greater. Treat-

ment of a small leak (500 mL or less) includes application of a pressure dressing and a diet of medium-chain fatty acids or parenteral nutrition. Surgical intervention to repair the damaged duct is necessary for larger leaks.

NERVE INJURY. Nerve injury can occur if the cervical plexus or spinal accessory nerves are severed during surgery. Because lower facial paralysis may occur as a result of injury to the facial nerve, this complication is observed for and reported. Likewise, if the superior laryngeal nerve is damaged, the patient may have difficulty swallowing liquids and food because of the partial lack of sensation of the glottis. Speech therapy may be indicated to assist with the problems related to nerve injury.

Promoting Home and Community-Based Care

TEACHING PATIENTS SELF-CARE. The patient and caregiver require instructions about management of the wound, the dressing, and any drains that remain in place. Patients who require oral suctioning or who have a tracheostomy may be very anxious about their care at home; the transition to home can be eased if the caregiver is given several opportunities to demonstrate the ability to meet the patient's needs (Chart 35-3). The patient and caregiver are also instructed about possible complications such as bleeding and respiratory distress and when to notify the health care provider of signs and symptoms of these complications.

If the patient cannot take food by mouth, detailed instructions and demonstration of enteral or parenteral feedings will be required. Education in techniques of effective oral hygiene is also important.

CONTINUING CARE. A referral for home care nursing may be necessary in the early period after discharge. The nurse assesses healing, ensures that feedings are being administered properly, and monitors for any complications. The nurse also assesses the patient's adjustment to changes in physical appearance and status and ability to communicate and eat normally. Physical and speech therapy also are likely to be continued at home.

The patient is given information regarding local support groups such as "I Can Cope" or "New Voice Club," if

CHART
35-3

HOME CARE CHECKLIST Recovering From Neck Surgery

At the completion of the home care instruction, the patient or caregiver will be able to:	PATIENT	CAREGIVER
• Demonstrate use of suction equipment.	✓	✓
• State rationale for humidification.	✓	✓
• State dietary modifications needed to meet caloric needs.	✓	✓
• Demonstrate enteral or parenteral feeding techniques.	✓	✓
• Demonstrate care of incision and drains.	✓	✓
• Identify signs and symptoms (eg, bleeding, respiratory distress, drainage) to be reported to health care provider.	✓	✓
• State when next checkup is needed.	✓	✓
• Demonstrate exercises.	✓	
• Identify available support groups.	✓	✓

indicated. The local chapter of the ACS may be contacted for information and equipment needed for the patient.

Evaluation

Expected Patient Outcomes

Expected patient outcomes may include:

1. Discusses expected course of treatment
2. Demonstrates good respiratory exchange
 - a. Lungs are clear to auscultation
 - b. Breathes easily with no shortness of breath
 - c. Demonstrates ability to use suction effectively
3. Remains free of infection
 - a. Maintains normal laboratory values
 - b. Is afebrile
4. Graft is pink and warm to touch
5. Maintains adequate intake of foods and fluids
 - a. Accepts altered route of feeding
 - b. Is well hydrated
 - c. Maintains or gains weight
6. Demonstrates ability to cope
 - a. Discusses emotional responses to the diagnosis
 - b. Attends support group meetings
7. Verbalizes comfort
8. Attains maximal mobility
 - a. Adheres to physical therapy exercises
 - b. Attains maximal range of motion
9. Exhibits no complications
 - a. Vital signs stable
 - b. No excessive bleeding or discharge
 - c. Able to move muscles of lower face

DISORDERS OF THE ESOPHAGUS

The esophagus is a mucus-lined, muscular tube that carries food from the mouth to the stomach. It begins at the base of the pharynx and ends about 4 cm below the diaphragm. Its ability to transport food and fluid is facilitated by two sphincters. The upper esophageal sphincter, also called the hypopharyngeal sphincter, is located at the junction of the pharynx and the esophagus. The lower esophageal sphincter, also called the gastroesophageal sphincter or cardiac sphincter, is located at the junction of the esophagus and the stomach. An incompetent lower esophageal sphincter allows reflux (backward flow) of gastric contents. There is no serosal layer of the esophagus; therefore, if surgery is necessary, it is more difficult to perform suturing or anastomosis.

Disorders of the esophagus include motility disorders (achalasia, diffuse spasm), hiatal hernias, diverticula, perforation, foreign bodies, chemical burns, gastroesophageal reflux disease (GERD), Barrett's esophagus, benign tumors, and carcinoma. **Dysphagia** (difficulty swallowing), the most common symptom of esophageal disease, may vary from an uncomfortable feeling that a bolus of food is caught in the upper esophagus to acute pain on swallowing (**odynophagia**). Obstruction of food (solid and soft) and even liquids may occur anywhere along the esophagus. Often the patient can indicate that the problem is located in the upper, middle, or lower third of the esophagus.

Achalasia

Achalasia is absent or ineffective peristalsis of the distal esophagus, accompanied by failure of the esophageal sphincter to relax in response to swallowing. Narrowing of the esophagus just above the stomach results in a gradually increasing dilation of the esophagus in the upper chest. Achalasia may progress slowly and occurs most often in people 40 years of age or older.

Clinical Manifestations

The primary symptom is difficulty in swallowing both liquids and solids. The patient has a sensation of food sticking in the lower portion of the esophagus. As the condition progresses, food is commonly regurgitated either spontaneously or intentionally by the patient to relieve the discomfort produced by prolonged distention of the esophagus by food that will not pass into the stomach. The patient may also report chest pain and heartburn (**pyrosis**) that may or may not be associated with eating. Secondary pulmonary complications may result from aspiration of gastric contents.

Assessment and Diagnostic Findings

X-ray studies show esophageal dilation above the narrowing at the gastroesophageal junction. Barium swallow, computed tomography (CT) of the chest, and endoscopy may be used for diagnosis; however, manometry, a process in which the esophageal pressure is measured by a radiologist or gastroenterologist, confirms the diagnosis.

Management

The patient is instructed to eat slowly and to drink fluids with meals. As a temporary measure, calcium channel blockers and nitrates have been used to decrease esophageal pressure and improve swallowing. Injection of botulinum toxin (Botox) into quadrants of the esophagus via endoscopy has been helpful because it inhibits the contraction of smooth muscle. Periodic injections are required to maintain remission.

Achalasia may be treated conservatively by pneumatic dilation to stretch the narrowed area of the esophagus (Fig. 35-6). Pneumatic dilation has a high success rate. Although perforation is a potential complication, its incidence is low. The procedure can be painful; therefore, moderate sedation in the form of an analgesic or tranquilizer, or both, is administered for the treatment. The patient is monitored for perforation. Abdominal tenderness and fever may indicate perforation (see later discussion).

Achalasia may be treated surgically by esophagomyotomy. The procedure is usually performed laparoscopically, either with a complete lower esophageal sphincter myotomy and an antireflux procedure or without an antireflux procedure. The esophageal muscle fibers are separated to relieve the lower esophageal stricture.

Diffuse Esophageal Spasm

Diffuse spasm is a motor disorder of the esophagus. The cause is unknown, but stress may be a factor. It is more common in women and usually manifests in middle age.

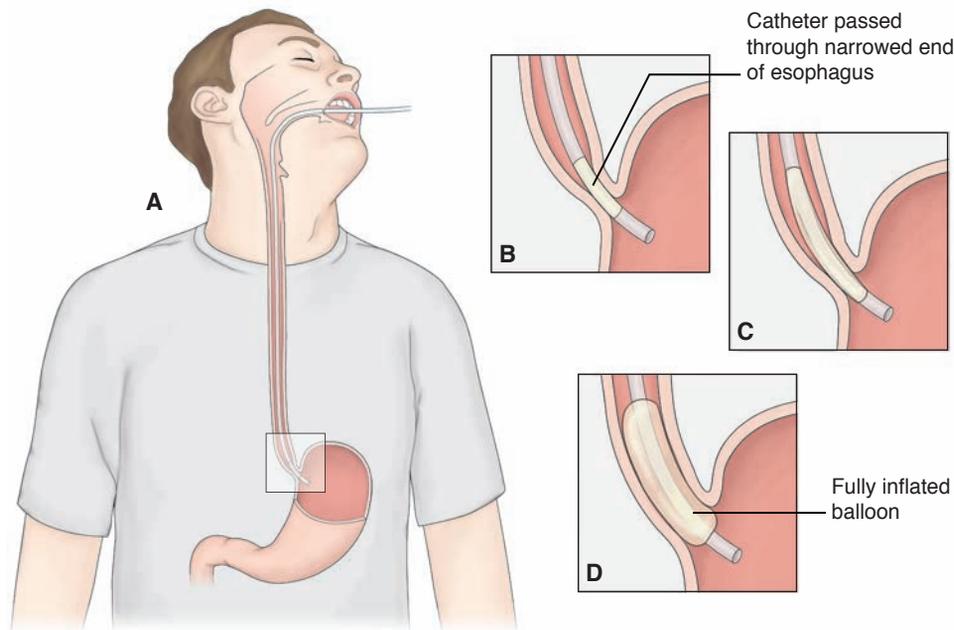

Figure 35-6 Treatment of achalasia by pneumatic dilation. **A–C**, The dilator is passed, guided by a previously inserted guide wire. **D**, When the balloon is in proper position, it is distended by pressure sufficient to dilate the narrowed area of the esophagus.

Clinical Manifestations

Diffuse spasm is characterized by difficulty (dysphagia) or pain (odynophagia) on swallowing and by chest pain similar to that of coronary artery spasm.

Assessment and Diagnostic Findings

Esophageal manometry, which measures the motility of the esophagus and the pressure within the esophagus, indicates that simultaneous contractions of the esophagus occur irregularly. Diagnostic x-ray studies after ingestion of barium show separate areas of spasm.

Management

Conservative therapy includes administration of sedatives and long-acting nitrates to relieve pain. Calcium channel blockers (eg, nifedipine [Procardia], verapamil [Calan]) have also been used to manage diffuse spasm. Small, frequent feedings and a soft diet are usually recommended to decrease the esophageal pressure and irritation that lead to spasm. Dilation performed by bougienage (use of progressively sized flexible dilators), pneumatic dilation, or esophagomyotomy may be necessary if the pain becomes intolerable.

If none of the conservative approaches is successful in managing symptoms, surgery may be considered. An esophageal Heller myotomy (a surgical procedure in which the cardiac sphincter is cut, allowing food and liquids to pass into the stomach) by a minimally invasive approach is considered first and has shown positive results (Rosemurgy, Villadolid, Thometz, et al., 2005). If an open surgical approach is required, then a transhiatal esophagectomy is performed (see Cancer of the Esophagus).

Hiatal Hernia

In the condition known as hiatus (or hiatal) **hernia**, the opening in the diaphragm through which the esophagus passes becomes enlarged, and part of the upper stomach

tends to move up into the lower portion of the thorax. Hiatal hernia occurs more often in women than in men. There are two types of hiatal hernias: sliding and paraesophageal. Sliding, or type I, hiatal hernia occurs when the upper stomach and the gastroesophageal junction are displaced upward and slide in and out of the thorax (Fig. 35-7A). About 90% of patients with esophageal hiatal hernia have a sliding hernia. A paraesophageal hernia occurs when all or part of the stomach pushes through the diaphragm beside the esophagus (see Fig. 35-7B). Paraesophageal hernias are further classified as types II, III, or IV, depending on the extent of herniation, with type IV having the greatest herniation.

Clinical Manifestations

The patient with a sliding hernia may have heartburn, regurgitation, and dysphagia, but at least 50% of patients are asymptomatic. Sliding hiatal hernia is often implicated in reflux. The patient with a paraesophageal hernia usually feels a sense of fullness or chest pain after eating, or there may be no symptoms. Reflux usually does not occur, because the gastroesophageal sphincter is intact. Hemorrhage, obstruction, and strangulation can occur with any type of hernia.

Assessment and Diagnostic Findings

Diagnosis is confirmed by x-ray studies, barium swallow, and fluoroscopy.

Management

Management for a hiatal hernia includes frequent, small feedings that can pass easily through the esophagus. The patient is advised not to recline for 1 hour after eating, to prevent reflux or movement of the hernia, and to elevate the head of the bed on 4- to 8-inch (10- to 20-cm) blocks to prevent the hernia from sliding upward. Surgery is indicated in about 15% of patients. Medical and surgical management of a paraesophageal hernia is similar to that for gastroesophageal

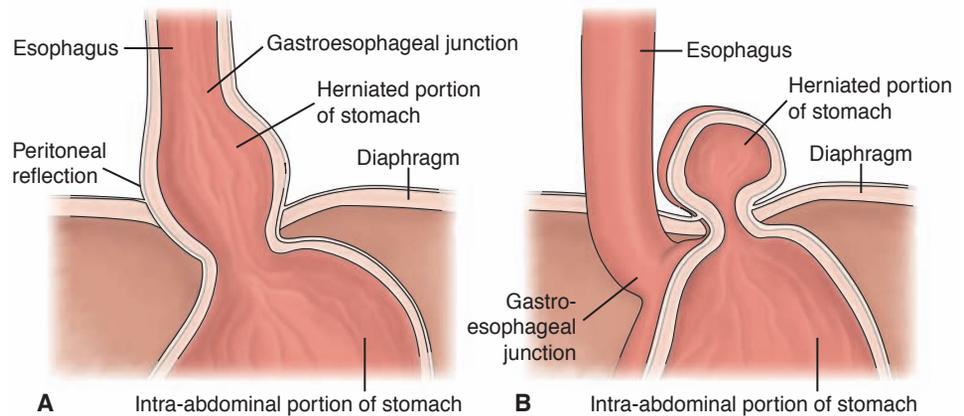

Figure 35-7 **A**, Sliding esophageal hernia. The upper stomach and gastroesophageal junction have moved upward and slide in and out of the thorax. **B**, Paraesophageal hernia. All or part of the stomach pushes through the diaphragm next to the gastroesophageal junction.

reflux; however, people with paraesophageal hernias may require emergency surgery to correct torsion (twisting) of the stomach or other body organ that leads to restriction of blood flow to that area.

Diverticulum

A diverticulum is an outpouching of mucosa and submucosa that protrudes through a weak portion of the musculature. Diverticula may occur in one of the three areas of the esophagus—the pharyngoesophageal or upper area of the esophagus, the midesophageal area, or the epiphrenic or lower area of the esophagus—or they may occur along the border of the esophagus intramurally.

The most common type of diverticulum, which is found three times more frequently in men than in women, is Zenker's diverticulum (also known as pharyngoesophageal pulsion diverticulum or a pharyngeal pouch). It occurs posteriorly through the cricopharyngeal muscle in the midline of the neck. It is usually seen in people older than 60 years of age. Other types of diverticula include midesophageal, epiphrenic, and intramural diverticula.

Midesophageal diverticula are uncommon. Symptoms are less acute, and usually the condition does not require surgery. Epiphrenic diverticula are usually larger diverticula in the lower esophagus just above the diaphragm. They may be related to the improper functioning of the lower esophageal sphincter or to motor disorders of the esophagus. Intramural diverticulosis is the occurrence of numerous small diverticula associated with a stricture in the upper esophagus.

Clinical Manifestations

Symptoms experienced by the patient with a pharyngoesophageal pulsion diverticulum include difficulty swallowing, fullness in the neck, belching, regurgitation of undigested food, and gurgling noises after eating. The diverticulum, or pouch, becomes filled with food or liquid. When the patient assumes a recumbent position, undigested food is regurgitated, and coughing may be caused by irritation of the trachea. Halitosis and a sour taste in the mouth are also common because of the decomposition of food retained in the diverticulum.

Symptoms produced by midesophageal diverticula are less acute. One third of patients with epiphrenic diverticula are asymptomatic, and the remaining two thirds report dysphagia and chest pain. Dysphagia is the most common symptom of patients with intramural diverticulosis.

Assessment and Diagnostic Findings

A barium swallow may determine the exact nature and location of a diverticulum. Manometric studies are often performed for patients with epiphrenic diverticula to rule out a motor disorder. Esophagoscopy usually is contraindicated because of the danger of perforation of the diverticulum, with resulting mediastinitis (inflammation of the organs and tissues that separate the lungs). Blind insertion of a nasogastric tube should be avoided.

Management

Because pharyngoesophageal pulsion diverticulum is progressive, the only means of cure is surgical removal of the diverticulum. During surgery, care is taken to avoid trauma to the common carotid artery and internal jugular veins. The sac is dissected free and amputated flush with the esophageal wall. In addition to a diverticulectomy, a myotomy of the cricopharyngeal muscle is often performed to relieve spasticity of the musculature, which otherwise seems to contribute to a continuation of the previous symptoms. A nasogastric tube may be inserted at the time of surgery. Postoperatively, the surgical incision must be observed for evidence of leakage from the esophagus and a developing fistula. Food and fluids are withheld until x-ray studies show no leakage at the surgical site. The diet begins with liquids and is progressed as tolerated.

Surgery is indicated for epiphrenic and midesophageal diverticula only if the symptoms are troublesome and becoming worse. Treatment consists of a diverticulectomy and long myotomy. Intramural diverticula usually regress after the esophageal stricture is dilated.

Perforation

The esophagus is a common site of injury. Perforation may result from stab or bullet wounds of the neck or chest, trauma from a motor vehicle crash, caustic injury from a

chemical burn, or inadvertent puncture by a surgical instrument during examination or dilation such as endoscopy.

Clinical Manifestations

The patient has persistent pain followed by dysphagia. Infection, fever, leukocytosis, and severe hypotension may be noted. In some instances, signs of pneumothorax are observed.

Assessment and Diagnostic Findings

X-ray studies and fluoroscopy by either a barium swallow or esophagram are used to identify the site of the injury.

Management

Because of the high risk of infection, broad-spectrum antibiotic therapy is initiated. If the perforation is small enough and without symptoms, surgical intervention may not be necessary. The patient is immediately made nothing by mouth status. Nutritional needs are met by parenteral or enteral nutrition. The type of nutritional support depends on the location of the injury. Enteral or parenteral nutrition is provided for at least 1 month to give the esophagus a chance to heal. A repeat barium swallow study is performed after 1 month, and the involved area is reevaluated. If there is no evidence of perforation, foods are reintroduced, beginning with liquids and then slowly progressing to solids as tolerated.

Surgery is performed if the esophageal perforation is large or if mediastinitis or infection of the thoracic cavity is a threat. In a cervical esophagostomy, the upper portion of the esophagus is attached to an opening made in the neck; this “spit” fistula allows for the drainage of saliva. The lower portion of the esophagus remaining within the chest is closed. After 6 months, during which the patient is allowed to heal and recover from possible infection, surgery is again performed to reconnect the two parts of the esophagus.

Postoperative nutritional status is a primary concern. The patient is not allowed any oral nourishment for 6 months. Enteral or parenteral support is maintained. Water to moisten the patient’s mouth is allowed for comfort measures only. The postoperative nursing management is similar to that for patients who have had thoracic or abdominal surgery.

Foreign Bodies

Many swallowed foreign bodies pass through the gastrointestinal tract without the need for medical intervention. However, some swallowed foreign bodies (eg, dentures, fish bones, pins, small batteries, items containing mercury or lead) may injure the esophagus or obstruct its lumen and must be removed. Pain and dysphagia may be present, and dyspnea may occur as a result of pressure on the trachea. The foreign body may be identified by x-ray. Perforation may have occurred (see earlier discussion).

Glucagon, because of its relaxing effect on the esophageal muscle, may be injected intramuscularly. An endoscope (with a covered hood or overtube) may be used to remove the impacted food or object from the esophagus. A mixture consisting of sodium bicarbonate and tartaric acid

may be prescribed to increase intraluminal pressure by the formation of a gas. Caution must be used with this treatment because of the risk of perforation.

Chemical Burns

Chemical burns of the esophagus occur most often when a patient, either intentionally or unintentionally, swallows a strong acid or base (eg, lye). This patient is emotionally distraught as well as in acute physical pain. Chemical burns of the esophagus may also be caused by undissolved medications in the esophagus. This occurs more frequently in the elderly than it does among the general adult population. A chemical burn may also occur after swallowing of a battery, which may release a caustic alkaline. An acute chemical burn of the esophagus may be accompanied by severe burns of the lips, mouth, and pharynx, with pain on swallowing. There may be difficulty in breathing due to either edema of the throat or a collection of mucus in the pharynx.

The patient, who may be profoundly toxic, febrile, and in shock, is treated immediately for shock, pain, and respiratory distress. Esophagoscopy and barium swallow are performed as soon as possible to determine the extent and severity of damage. The patient is given nothing by mouth, and IV fluids are administered. A nasogastric tube may be inserted by the physician. Vomiting and gastric lavage are avoided to prevent further exposure of the esophagus to the caustic agent. The use of corticosteroids to reduce inflammation and minimize subsequent scarring and stricture formation is of questionable value. Antibiotics are prescribed if there is documented infection (Nervi, 2008).

After the acute phase has subsided, the patient may need nutritional support via enteral or parenteral feedings. The patient may require further treatment to prevent or manage strictures of the esophagus. Dilation by bougienage may be sufficient but may need to be repeated periodically. (In bougienage, cylindrical rubber tubes of different sizes, called bougies, are advanced into the esophagus via the oral cavity. Progressively larger bougies are used to dilate the esophagus. The procedure usually is performed in the endoscopy suite or clinic by the gastroenterologist.) Some strictures require rigid dilators, such as Savory dilators. These dilators are used in the same fashion as bougies but may be more successful for opening difficult strictures. For strictures that do not respond to either method of dilation, surgical management may be necessary. Reconstruction may be accomplished by esophagectomy and colon interposition to replace the portion of esophagus removed. This surgery is quite complex and should be considered only when other options have failed.

Gastroesophageal Reflux Disease

Some degree of **gastroesophageal reflux** (backflow of gastric or duodenal contents into the esophagus) is normal in both adults and children. Excessive reflux may occur because of an incompetent lower esophageal sphincter, pyloric stenosis, or a motility disorder. The incidence of GERD seems to increase with aging.

Clinical Manifestations

Symptoms may include pyrosis (burning sensation in the esophagus), dyspepsia (indigestion), regurgitation, dysphagia or odynophagia (pain on swallowing), hypersalivation, and esophagitis. The symptoms may mimic those of a heart attack. The patient's history aids in obtaining an accurate diagnosis.

Assessment and Diagnostic Findings

Diagnostic testing may include an endoscopy or barium swallow to evaluate damage to the esophageal mucosa. Ambulatory 12- to 36-hour esophageal pH monitoring is used to evaluate the degree of acid reflux. Bilirubin monitoring (Bilitec) is used to measure bile reflux patterns. Exposure to bile can cause mucosal damage.

Management

Management begins with teaching the patient to avoid situations that decrease lower esophageal sphincter pressure or cause esophageal irritation. The patient is instructed to eat a low-fat diet; to avoid caffeine, tobacco, beer, milk, foods containing peppermint or spearmint, and carbonated beverages; to avoid eating or drinking 2 hours before bedtime; to maintain normal body weight; to avoid tight-fitting clothes; to elevate the head of the bed on 6- to 8-inch (15- to 20-cm) blocks; and to elevate the upper body on pillows. If reflux persists, antacids or H₂ receptor antagonists, such as famotidine (Pepcid), nizatidine (Axid), or ranitidine (Zantac), may be prescribed. Proton pump inhibitors (medications that decrease the release of gastric acid, such as lansoprazole [Prevacid], rabeprazole [AcipHex], esomeprazole [Nexium], omeprazole [Prilosec], and pantoprazole [Protonix]) may be used; however, these products may increase intragastric bacterial growth and the risk of infection. In addition, the patient may receive prokinetic agents, which accelerate gastric emptying. These agents include bethanechol (Urecholine), domperidone (Motilium), and metoclopramide (Reglan). Because metoclopramide can have extrapyramidal side effects that are increased in certain neuromuscular disorders, such as Parkinson's disease, it should be used only if no other option exists, and the patient should be monitored closely.

If medical management is unsuccessful, surgical intervention may be necessary. Surgical management involves a Nissen fundoplication (wrapping of a portion of the gastric fundus around the sphincter area of the esophagus). A Nissen fundoplication can be performed by the open method or by laparoscopy.

Barrett's Esophagus

Barrett's esophagus is a condition in which the lining of the esophageal mucosa is altered. It typically occurs in association with GERD; indeed, longstanding untreated GERD may lead to Barrett's esophagus. Reflux eventually causes changes in the cells lining the lower esophagus. The cells that are laid to cover the exposed area are no longer squamous in origin. These precancerous cells initiate the healing process and can be a precursor to esophageal cancer.

Clinical Manifestations

The patient complains of symptoms of GERD, notably frequent heartburn. The patient may also complain of symptoms related to peptic ulcers or esophageal stricture, or both.

Assessment and Diagnostic Findings

An esophagogastroduodenoscopy (EGD) is performed. This usually reveals an esophageal lining that is red rather than pink. Biopsies are performed, and high-grade dysplasia (HGD) is evidenced by the squamous mucosa of the esophagus replaced by columnar epithelium that resembles that of the stomach or intestines. HGD has been found to be associated with a 30% risk of development of cancer (Wang & Sampliner, 2008).

Management

Monitoring varies depending on the extent of cell changes. Follow-up endoscopy is performed within 6 months if there are minor cell changes. Treatment is individualized for each patient. The options include intensive surveillance with biopsies, endoscopic ablation therapy (eg, photodynamic therapy), and esophagectomy, each of which has been found to result in similar outcomes (Wang & Sampliner, 2008).

Benign Tumors of the Esophagus

Benign tumors can arise anywhere along the esophagus. The most common lesion is a leiomyoma (tumor of the smooth muscle), which can occlude the lumen of the esophagus. Most benign tumors are asymptomatic and are distinguished from cancerous lesions by a biopsy. Small lesions are excised during esophagoscopy; lesions that occur within the wall of the esophagus may require treatment via a thoracotomy.

NURSING PROCESS

THE PATIENT WITH A NONCANCEROUS CONDITION OF THE ESOPHAGUS

Assessment

Emergency conditions of the esophagus (perforation, chemical burns) usually occur in the home or away from medical help and require emergency medical care. The patient is treated for shock and respiratory distress and transported as quickly as possible to a health care facility. Foreign bodies in the esophagus do not pose an immediate threat to life unless pressure is exerted on the trachea, resulting in dyspnea or interfering with respiration, or unless there is leakage of caustic alkali from a battery or exposure to another corrosive agent. Educating the public to prevent inadvertent swallowing of foreign bodies or corrosive agents is a major health goal.

For nonemergency symptoms, a complete health history may reveal the nature of the esophageal disorder. The nurse asks about the patient's appetite. Has it remained the same, increased, or decreased? Is there any discomfort

with swallowing? If so, does it occur only with certain foods? Is it associated with pain? Does a change in position affect the discomfort? The patient is asked to describe the pain. Does anything aggravate it? Are there any other symptoms that occur regularly, such as regurgitation, nocturnal regurgitation, eructation (belching), heartburn, substernal pressure, a sensation that food is sticking in the throat, a feeling of fullness after eating a small amount of food, nausea, vomiting, or weight loss? Are the symptoms aggravated by emotional upset? If the patient reports any of these symptoms, the nurse asks about when they occur, their relationship to eating, and factors that relieve or aggravate them (eg, position change, belching, antacids, vomiting).

This history also includes questions about past or present causative factors, such as infections and chemical, mechanical, or physical irritants; alcohol and tobacco use; and the amount of daily food intake. The nurse determines whether the patient appears emaciated and auscultates the patient's chest to assess for pulmonary complications.

Nursing Diagnosis

Based on the assessment data, the nursing diagnoses may include the following:

- Imbalanced nutrition, less than body requirements, related to difficulty swallowing
- Risk for aspiration related to difficulty swallowing or to tube feeding
- Acute pain related to difficulty swallowing, ingestion of an abrasive agent, tumor, or frequent episodes of gastric reflux
- Deficient knowledge about the esophageal disorder, diagnostic studies, medical management, surgical intervention, and rehabilitation

Planning and Goals

The major goals for the patient may include attainment of adequate nutritional intake, avoidance of respiratory compromise from aspiration, relief of pain, and increased knowledge level.

Nursing Interventions

Encouraging Adequate Nutritional Intake

The patient is encouraged to eat slowly and to chew all food thoroughly so that it can pass easily into the stomach. Small, frequent feedings of nonirritating foods are recommended to promote digestion and to prevent tissue irritation. Sometimes liquid swallowed with food helps the food pass through the esophagus, but usually liquids should be consumed between meals. Food should be prepared in an appealing manner to help stimulate the appetite. Irritants such as tobacco and alcohol should be avoided. A baseline weight is obtained, and daily weights are recorded. The patient's intake of nutrients is assessed.

Decreasing Risk of Aspiration

The patient who has difficulty swallowing or difficulty handling secretions should be kept in at least a semi-Fowler's position to decrease the risk of aspiration. The patient is instructed in the use of oral suction to decrease the risk of aspiration further.

Relieving Pain

Small, frequent feedings (six to eight per day) are recommended because large quantities of food overload the stomach and promote gastric reflux. The patient is advised to avoid any activities that increase pain and to remain upright for 1 to 4 hours after each meal to prevent reflux. The head of the bed should be placed on 4- to 8-inch (10- to 20-cm) blocks. Eating before bedtime is discouraged.

The patient is advised that excessive use of over-the-counter antacids can cause rebound acidity. Antacid use should be directed by the primary care provider, who can recommend the daily, safe dose needed to neutralize gastric juices and prevent esophageal irritation. H₂ antagonists are administered as prescribed to decrease gastric acid irritation.

Providing Patient Education

The patient is prepared physically and psychologically for diagnostic tests, treatments, and possible surgery. The principal nursing interventions include reassuring the patient and explaining the procedures and their purposes. Some disorders of the esophagus evolve over time, whereas others are the result of trauma (eg, chemical burns, perforation). In instances of trauma, the emotional and physical preparation for treatment is more difficult because of the short time available and the circumstances of the injury. Treatment interventions must be evaluated continually, and the patient is given sufficient information to participate in care and diagnostic tests. If endoscopic diagnostic methods are used, the patient is instructed regarding the moderate sedation that will be used during the procedure. If outpatient procedures are performed with the use of moderate sedation, someone must be available to drive the patient home after the procedure. If surgery is required, immediate and long-term evaluation is similar to that for a patient undergoing thoracic surgery.

Promoting Home and Community-Based Care

TEACHING PATIENTS SELF-CARE. The self-care required of the patient depends on the nature of the disorder and on the surgery or treatment measures used (eg, diet, positioning, medications). If an ongoing condition exists, the nurse helps the patient plan for needed physical and psychological adjustments and for follow-up care (Chart 35-4).

Special equipment, such as suction or enteral or parenteral feeding devices, may be required. The patient may need assistance in planning meals, using medications as prescribed, and resuming activities. Education about nutritional requirements and how to measure the adequacy of nutrition is important. Elderly and debilitated patients in particular often need assistance and education about ways they can adjust to their limitations and resume activities that are important to them.

CONTINUING CARE. Patients with chronic esophageal conditions require an individualized approach to their management at home. Foods may need to be prepared in a special way (blenderized foods, soft foods), and the patient may need to eat more frequently (eg, six to eight small servings per day). The medication schedule is adjusted to the patient's daily activities as much as possible. Analgesic medications and antacids can usually be taken as needed every 3 to 4 hours.

Postoperative home health care focuses on nutritional support, management of pain, and respiratory function.

CHART
35-4  **HOME CARE CHECKLIST**
The Patient With an Esophageal Condition

At the completion of the home care instruction, the patient or caregiver will be able to:	PATIENT	CAREGIVER
• Demonstrate use of suction equipment.	✓	✓
• State dietary modifications needed to meet caloric needs.	✓	✓
• Demonstrate enteral or parenteral feeding techniques.	✓	✓
• Demonstrate care of incision if indicated.	✓	✓
• Identify signs and symptoms (eg, difficulty swallowing, pain, respiratory distress) to be reported to health care provider.	✓	✓
• State when next checkup is needed.	✓	✓
• Identify available support groups.	✓	✓

Some patients are discharged from the hospital with enteral feeding by means of a gastrostomy or jejunostomy tube or parenteral nutrition. The patient and caregiver need specific instructions regarding management of the equipment and treatments. Home care visits by a nurse may be necessary to assess the patient and the caregiver's ability to provide the necessary care. (See Chapter 36 for more information about parenteral nutrition and management of the patient with a gastrostomy.) For some patients, a multidisciplinary team that includes a dietitian, a social worker, and family members is helpful. Hospice care and consideration of end-of-life issues are appropriate for some patients.

Evaluation

Expected Patient Outcomes

Expected patient outcomes may include:

1. Achieves an adequate nutritional intake
 - a. Eats small, frequent meals
 - b. Drinks small sips of water with small servings of food
 - c. Avoids irritants (alcohol, tobacco, very hot beverages)
 - d. Maintains desired weight
2. Does not aspirate or develop pneumonia
 - a. Maintains upright position during feeding
 - b. Uses oral suction equipment effectively
3. Is free of pain or able to control pain within a tolerable level
 - a. Avoids large meals and irritating foods
 - b. Takes medications as prescribed and with adequate fluids (at least 4 ounces), and remains upright for at least 10 minutes after taking medications
 - c. Maintains an upright position after meals for 1 to 4 hours
 - d. Reports that there is less eructation and chest pain
4. Increases knowledge level of esophageal condition, treatment, and prognosis
 - a. States cause of condition
 - b. Discusses rationale for medical or surgical management and diet or medication regimen
 - c. Describes treatment program
 - d. Practices preventive measures so injuries are avoided

Cancer of the Esophagus

In the United States, carcinoma of the esophagus occurs more than three times as often in men as in women. It is seen more frequently in African Americans than in Caucasians and usually occurs in the fifth or sixth decade of life. Cancer of the esophagus has a much higher incidence (10 to 100 times higher) in other parts of the world, including China and northern Iran (American Cancer Society, 2009).

Pathophysiology

Esophageal cancer can be of two cell types: adenocarcinoma and squamous cell carcinoma. The rate of adenocarcinoma is rapidly increasing in the United States as well as in other Western countries. It is found primarily in the distal esophagus and gastroesophageal junction (American Cancer Society, 2009).

Risk factors for esophageal cancer include chronic esophageal irritation. In the United States, cancer of the esophagus has been associated with ingestion of alcohol and the use of tobacco. There is an apparent association between GERD and adenocarcinoma of the esophagus. People with Barrett's esophagus (which is caused by chronic irritation of the mucous membranes due to reflux of gastric and duodenal contents) have a higher incidence of esophageal cancer (American Cancer Society, 2009). Risk factors for squamous cell carcinoma of the esophagus include chronic ingestion of hot liquids or foods, nutritional deficiencies, poor oral hygiene, exposure to nitrosamines in the environment or food, cigarette smoking or chronic alcohol exposure (especially in Western cultures), and some esophageal medical conditions such as caustic injury.

Tumor cells of adenocarcinoma and of squamous cell carcinoma may spread beneath the esophageal mucosa or directly into, through, and beyond the muscle layers into the lymphatics. In the latter stages, obstruction of the esophagus is noted, with possible perforation into the mediastinum and erosion into the great vessels.

Clinical Manifestations

Many patients have an advanced ulcerated lesion of the esophagus before symptoms are manifested. Symptoms include dysphagia, initially with solid foods and eventually

with liquids; a sensation of a mass in the throat; painful swallowing; substernal pain or fullness; and, later, regurgitation of undigested food with foul breath and hiccups. The patient first becomes aware of intermittent and increasing difficulty in swallowing. As the tumor grows and the obstruction becomes nearly complete, even liquids cannot pass into the stomach. Regurgitation of food and saliva occurs, hemorrhage may take place, and progressive loss of weight and strength occurs from inadequate nutrition. Later symptoms include substernal pain, persistent hiccup, respiratory difficulty, and foul breath.

The delay between the onset of early symptoms and the patient seeking medical advice is often 12 to 18 months. Any person having swallowing difficulties should be encouraged to consult a physician immediately.

Assessment and Diagnostic Findings

Currently, diagnosis is confirmed most often by EGD with biopsy and brushings. The biopsy can be used to determine the presence of disease and cell differentiation. At presentation, most patients have moderately differentiated tumors.

Several imaging techniques may provide useful diagnostic information. CT of the chest and abdomen is beneficial for detecting any metastatic disease, especially of the lungs, liver, and kidney. Positron emission tomography (PET) may help detect metastasis with more sensitivity than CT. Endoscopic ultrasound is used to determine whether the cancer has spread to the lymph nodes and other mediastinal structures; it can also determine the size and invasiveness of the tumor. Exploratory laparoscopy is the best method for finding positive lymph nodes in patients with distal lesions.

Future diagnostic techniques that may serve as predictors for dysplastic progression in patients with Barrett's esophagus involve molecular markers. The usefulness of molecular markers in treating esophageal cancer is being researched. Research also includes the development of medications that target the pathways of various molecular markers (D'Amico, 2006).

Medical Management

If esophageal cancer is detected at an early stage, treatment goals may be directed toward cure; however, it is often detected in late stages, making relief of symptoms the only reasonable goal of therapy. Treatment may include surgery, radiation, chemotherapy, or a combination of these modalities, depending on the type of cancer cell, the extent of the disease, and the patient's condition. A standard treatment plan for a person who is newly diagnosed with esophageal cancer includes the following: preoperative combination chemotherapy and radiation therapy for 4 to 6 weeks; followed by a period of no medical intervention for 4 weeks; and, lastly, surgical resection of the esophagus.

Standard surgical management includes a total resection of the esophagus (esophagectomy) with removal of the tumor plus a wide tumor-free margin of the esophagus and the lymph nodes in the area. The surgical approach may be through the thorax or the abdomen, depending on the location of the tumor. When tumors occur in the cervical or upper thoracic area, esophageal continuity may be maintained by a free jejunal graft transfer, in which the tumor is removed and the area is replaced with a portion of the jejunum (Fig. 35-8). A segment of the colon may be used,

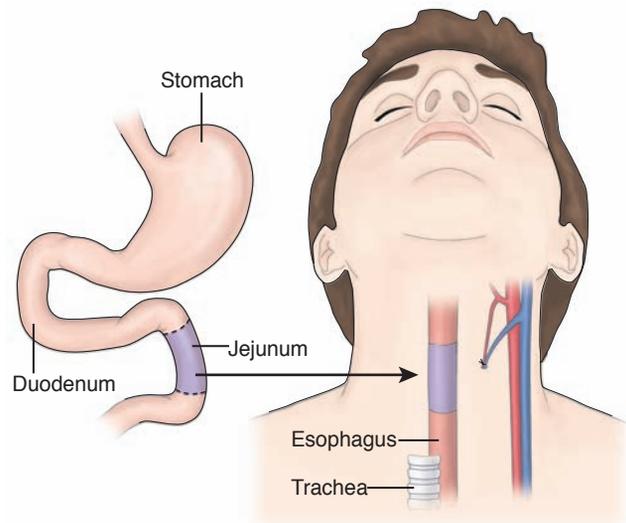

Figure 35-8 Esophageal reconstruction with free jejunal transfer. A portion of the jejunum is grafted between the esophagus and pharynx to replace the abnormal portion of the esophagus. The vascular structures are also anastomosed.

or the stomach can be elevated into the chest and the proximal section of the esophagus anastomosed to the stomach.

Tumors of the lower thoracic esophagus are more amenable to surgery than are tumors located higher in the esophagus. Gastrointestinal tract integrity is maintained by anastomosing the lower esophagus to the stomach (Fig. 35-9).

Surgical resection of the esophagus has a relatively high mortality rate because of infection, pulmonary complications, or leakage through the anastomosis. Postoperatively, the patient has a nasogastric tube in place that should not be manipulated. The patient is given nothing by mouth until x-ray studies confirm that the anastomosis is free from an esophageal leak, there is no obstruction, and there is no evidence of pulmonary aspiration.

Palliative treatment may be necessary to keep the esophagus open, to assist with nutrition, and to control saliva. Palliation may be accomplished with dilation of the esophagus, laser therapy, placement of an endoprosthesis (stent) via EGD, radiation, or chemotherapy.

Nursing Management

Intervention is directed toward improving the patient's nutritional and physical status in preparation for surgery, radiation therapy, or chemotherapy. A program to promote weight gain based on a high-calorie and high-protein diet, in liquid or soft form, is provided if adequate food can be taken by mouth. If this is not possible, parenteral or enteral nutrition is initiated. Nutritional status is monitored throughout treatment. The patient is informed about the nature of the postoperative equipment that will be used, including that required for closed chest drainage, nasogastric suction, parenteral fluid therapy, and gastric intubation.

Immediate postoperative care is similar to that provided for patients undergoing thoracic surgery. It is not uncommon for patients to be placed in an intensive care unit or step-down unit. After recovering from the effects of anesthesia, the patient is placed in a low Fowler's position, and later in a

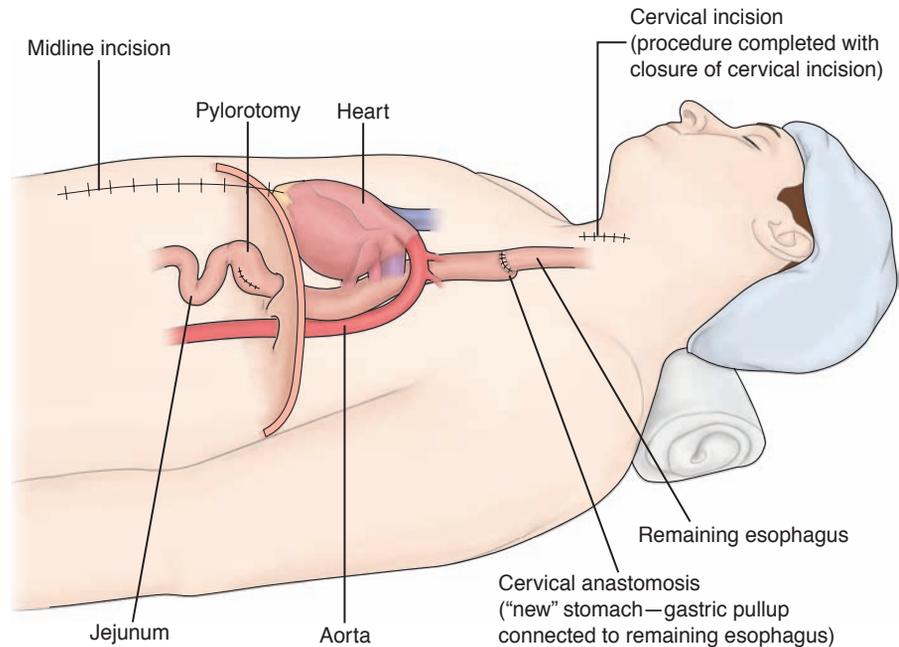

Figure 35-9 Transhiatal esophagectomy: surgical removal of tumor of the lower esophagus with anastomosis of the remaining esophagus to the stomach. (Redrawn with permission from *Operative Techniques in Thoracic and Cardiovascular Surgery*, 4(3), 263 © 1999 Elsevier Inc.)

Fowler's position, to help prevent reflux of gastric secretions. The patient is observed carefully for regurgitation and dyspnea. A common postoperative complication is aspiration pneumonia. Therefore, the patient is placed on a vigorous pulmonary plan of care that includes incentive spirometry, sitting up in a chair, and, if necessary, nebulizer treatments. Chest physiotherapy is avoided due to the risk of aspiration. The patient's temperature is monitored to detect any elevation that may indicate aspiration or seepage of fluid through the operative site into the mediastinum, which would indicate an esophageal leak. Drainage from the cervical neck wound, usually saliva, is evidence of an early esophageal leak. Typically, no treatment other than nothing by mouth and parenteral or enteral support is warranted.

Cardiac complications include atrial fibrillation, which occurs due to irritation of the vagus nerve at the time of surgery. Typical medical management includes digitalization or use of beta-blockers, depending on the patient's response. Rarely, cardioversion may be used.

During surgery, a nasogastric tube is inserted and taped in place. It is connected to low intermittent suction. The nasogastric tube is not manipulated; if displacement occurs, it is not replaced, because damage to the anastomosis may occur. The nasogastric tube is removed 5 to 7 days after surgery; before the patient is allowed to eat, a barium swallow is performed to assess for any anastomotic leak.

Once feeding begins, the nurse encourages the patient to swallow small sips of water. Eventually, the diet is advanced as tolerated to a soft, mechanical diet. When the patient can increase his or her food and fluid intake to an adequate amount, parenteral fluids are discontinued. After each meal, the patient remains upright for at least 2 hours to allow the food to move through the gastrointestinal tract. It is a challenge to encourage the patient to eat because the appetite is usually poor. Family involvement and home-cooked favorite foods may help the patient to eat. Antacids may help patients with gastric distress. Metoclopramide is useful in promoting gastric motility.

If chemotherapy and radiation are part of the therapy, the patient's appetite will be further depressed, and esophagitis may occur, causing pain when food is eaten. Liquid supplements may be more easily tolerated. However, supplements such as Boost and Ensure should be avoided because they promote **vagotomy syndrome** (dumping syndrome), which can occur with each meal or approximately 20 minutes to 2 hours after eating. The vagotomy syndrome occurs due to interruption of vagal nerve fibers, which in turn causes an alteration in the storage function of the stomach and the pyloric emptying mechanism. As a result, large amounts of solids and liquids rapidly "dump" into the duodenum. The patient experiences severe abdominal cramping, followed by a liquid bowel movement that may or may not be associated with diaphoresis, rapid heart rate or rapid respirations, or both. It can be quite disabling but typically resolves without incident, and the patient is left feeling extremely tired. The vagotomy syndrome is common following esophageal surgery, but as the patient's recovery progresses and the patient begins to eat soft foods and remains in an upright position for 2 hours after eating, the frequency and severity of episodes decrease.

Often, in either the preoperative or the postoperative period, an obstructed or nearly obstructed esophagus causes difficulty with excess saliva, and drooling becomes a problem. Oral suction may be used if the patient cannot handle oral secretions, or a wick-type gauze may be placed at the corner of the mouth to direct secretions to a dressing or emesis basin. The possibility that the patient may aspirate saliva into the tracheobronchial tree and develop pneumonia is of significant concern.

When the patient is ready to go home, the family is instructed about how to promote nutrition, what observations to make, what measures to take if complications occur, how to keep the patient comfortable, and how to obtain needed physical and emotional support.

CRITICAL THINKING EXERCISES

1 A patient presents to the medical clinic with symptoms of weight loss and difficulty in swallowing for the past 2 to 3 months. He states that he is only able to swallow liquids and some soft foods such as pudding. Explain what other questions you would ask this patient. What diagnostic tests would you anticipate would be prescribed for this patient? What instructions would you provide to the patient about preparation for these tests?

2 You are a nurse in the intensive care unit and have been assigned a new postoperative patient who has undergone resection of the esophagus to treat esophageal cancer. What nursing measures would be used to facilitate the patient's breathing and promote comfort? Describe the potential complications of esophageal resection and the assessment parameters that are used to detect the earliest signs and symptoms of these complications. What nursing measures are used to prevent these complications?

EBP 3 An elderly man is brought to the emergency department by the rescue squad. His daughter found him on the kitchen floor. A bottle of cleaning fluid with a poison label was open next to the kitchen sink. On admission the patient was in respiratory distress. Burns were observed around his mouth. What emergency care would be provided for this patient to prevent further trauma to the gastrointestinal and respiratory tracts? Identify the evidence that supports this care and evaluate the strength of the evidence. What needs should be considered prior to the patient's discharge?

chapter 36

Gastrointestinal Intubation and Special Nutritional Modalities

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

- 1 Describe the purposes and types of gastrointestinal intubation.
- 2 Identify the purposes and uses of parenteral nutrition.
- 3 Discuss nursing management of the patient who has a nasogastric, nasoenteric, gastrostomy, or jejunostomy tube.
- 4 Use the nursing process as a framework for care of the patient receiving special nutritional modalities.
- 5 Describe the nursing measures used to prevent complications from enteral and parenteral nutrition.

GLOSSARY

antireflux valve: valve that prevents return or backward flow of fluid

aspiration: removal of substance by suction; breathing of fluids or foods into the trachea and lungs

bolus: a feeding administered into the stomach in large amounts and at designated intervals

central venous access device (CVAD): a device designed and used for long-term administration of medications and fluids into central veins

cyclic feeding: periodic infusion of feedings given over a short period (8 to 18 hours)

decompression (intestinal): removal of gastric or intestinal contents to prevent gas and fluid distention

dumping syndrome: rapid emptying of the stomach contents into the small intestine; causes sweating, weakness, and diarrhea

duodenum: the first part of the small intestine, which arises from the pylorus of the stomach and extends to the jejunum

enteral nutrition: nutritional formula feedings introduced through a tube directly into the gastrointestinal tract

GLOSSARY (Continued)

gastrostomy: surgical creation of an opening into the stomach for the purpose of administering foods and fluids

intravenous fat emulsion (IVFE): an oil-in-water emulsion of oils, egg phospholipids, and glycerin

intubation: the insertion or placement of a tube into a body structure or passageway

jejunum: second portion of the small intestine, which extends from the duodenum to the ileum

lavage: flushing of the stomach with water or other fluids with a gastric tube to clear it

lumen: the channel within a tube or catheter

nasoduodenal tube: tube inserted through the nose into the proximal portion of the small intestine (ie, duodenum)

nasoenteric tube: tube inserted through the nose into the stomach and beyond the pylorus into the small intestine

nasogastric (NG) tube: tube inserted through the nose into the stomach

nasojejunal tube: tube inserted through the nose into the second portion of the small intestine (ie, jejunum)

orogastric tube: tube inserted through the mouth into the stomach

osmolality: ionic concentration of fluid

parenteral nutrition (PN): method of supplying nutrients to the body by an intravenous route

percutaneous endoscopic gastrostomy (PEG): a feeding tube inserted endoscopically into the stomach

peripherally inserted central catheter (PICC): a device used for intermediate-term intravenous therapy

peristalsis: wavelike movement that occurs involuntarily in the alimentary canal

pH: the degree of acidity or alkalinity of a substance or solution

radiopaque: can be easily localized on x-ray

stoma: artificially created opening between a body cavity (eg, intestine) and the body surface

stylet: a stiff wire placed in a catheter or other tube that allows the tube to maintain its shape during insertion

total nutrient admixture (TNA): an admixture of lipid emulsions, proteins, carbohydrates, electrolytes, vitamins, trace minerals, and water

This chapter presents several topics related to gastrointestinal intubation, including managing the care of patients with nasogastric, nasoenteric, and gastrostomy tubes, providing enteral tube feedings, gastric drainage, and teaching points concerning related home health care. In addition, parenteral nutrition is presented, including general indications for this nutritional modality and nursing care of patients receiving these support measures.

Gastrointestinal Intubation

Gastrointestinal (GI) **intubation** is the insertion of a flexible tube into the stomach, beyond the pylorus into the **duodenum** (the first section of the small intestine) or the **jejunum** (the second section of the small intestine). The tube may be inserted through the mouth, the nose, or the abdominal wall. The tubes are of various lengths, depending on their intended use. GI intubation may be performed for the following reasons:

- To decompress the stomach and remove gas and fluid
- To **lavage** (flush with water or other fluids) the stomach and remove ingested toxins or other harmful materials
- To diagnose disorders of GI motility and other disorders
- To administer medications and feedings
- To compress a bleeding site
- To aspirate gastric contents for analysis

Tube Types

A variety of tubes are used for decompression, aspiration, and lavage. An **orogastric tube** is a large-bore tube inserted through the mouth with a wide outlet for removal of gastric contents; it is used primarily in the emergency department or an intensive care setting (see Chapter 71). A **nasogastric (NG) tube** such as the Sengstaken-Blakemore tube is used to treat bleeding esophageal varices (see Chapter 39). Other tubes are used to administer feedings and medications. The tubes are made of various materials, including rubber, polyurethane, and silicone. They vary in length, size, purpose, and placement in the GI tract (Table 36-1). Any solution administered through a tube is poured through a syringe, delivered by gravity drip, or regulated by an electric pump. Removal of gases or fluids by **aspiration**

(suctioning) is accomplished with a syringe or mechanical suction.

Gastric Tubes

An NG tube is introduced through the nose into the stomach, often before or during surgery or at the bedside. NG tubes may be used to administer medications for up to 4 weeks, to give feedings, or to remove fluid and gas from the upper GI tract by the process known as **decompression**. Commonly used gastric tubes include the Levin tube and the gastric sump tube.

Levin Tube

The Levin tube has a single **lumen** and is made of plastic or rubber. This tube is connected to low intermittent suction (30 to 40 mm Hg) to avoid erosion or tearing of the stomach lining, which can result from constant adherence of the tube's lumen to the mucosa of the stomach.

Gastric Sump

The gastric sump (Salem) tube is a **radiopaque** (easily seen on x-ray), clear plastic, double-lumen NG tube that is passed into the stomach in the same way as the Levin tube. The inner, smaller lumen (known as the blue port) vents the larger suction-drainage tube to the atmosphere by means of an opening at the distal end of the tube. The sump tube can protect fragile gastric mucosa by maintaining a low (25 mm Hg) continuous force of suction at the drainage opening. The suction lumen is irrigated as prescribed to maintain patency.

The blue vent lumen should be kept above the patient's waist to prevent reflux of gastric contents through it; otherwise it acts as a siphon. A one-way **antireflux valve** seated in the blue pigtail can prevent the reflux of gastric contents out the vent lumen (Fig. 36-1). The valve is removed for irrigation of the suction lumen. To reestablish a buffer of air between the gastric contents and the valve, 20 mL of air is injected through the blue vent and the valve is reinserted.

Enteric Tubes

Nasoenteric tubes are used for providing nutrients. Nasally inserted feeding tubes placed in the duodenum are called **nasoduodenal tubes**; whereas those placed in the jejunum (the portion of the small intestine distal to the duodenum) are **nasojejunal tubes**. They can be inserted before or

Table 36-1 NASOGASTRIC AND NASOENTERIC FEEDING TUBES

Tube Type	Length (cm)	Size (French)	Lumen	Other Characteristics
Nasogastric Tubes				
Levin (plastic or rubber)	125	14–18	Single	Circular markings at intervals along the tube serve as guidelines for insertion
Gastric sump or Salem (plastic)	120	12–18	Double	Smaller lumen acts as a vent
Moss	90	12–16	Triple	Contains both a gastric decompression lumen and a duodenal lumen for postoperative feedings
Sengstaken-Blakemore (rubber)			Triple	Two lumens are used to inflate the gastric and esophageal balloons, and one tube is reserved for suction or drainage
Nasoenteric Feeding Tubes				
Dobhoff or EnteraFlo (polyurethane or silicone rubber)	160–175	8–12	Single	Tungsten-weighted tip, radiopaque, stylet

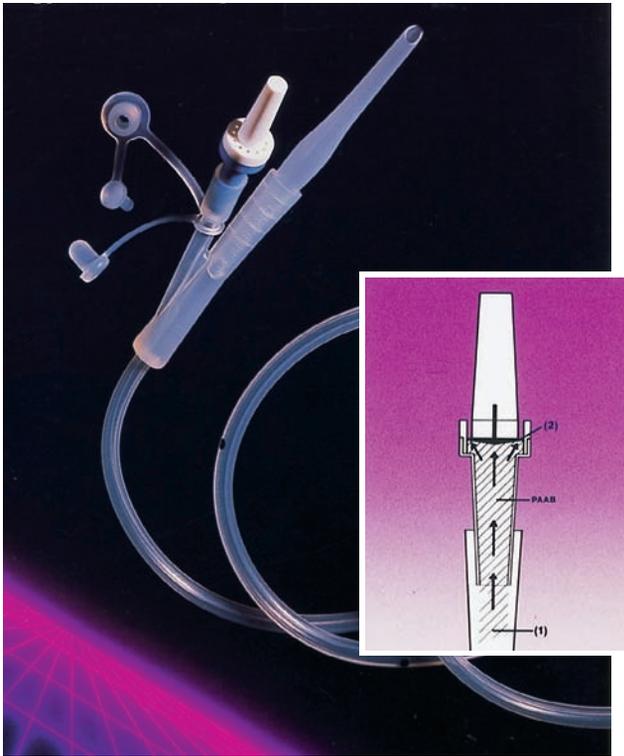

Figure 36-1 Gastric sump tube (Salem) equipped with a one-way valve that allows air to enter and can prevent reflux of gastric contents. The antireflux valve is designed with a pressure-activated air buffer (PAAB). The buffer is activated (1) and the valve closes (2) when pressure from gastric contents enters the tubing. (Argyle Silicone Salem Sump Tube with preattached Argyle Salem Sump Anti-Reflux Valve courtesy of Sherwood Medical, St. Louis, MO.)

during surgery, by interventional radiologists assisted by fluoroscopy, or at the bedside. The tubing is soft and pliable, and therefore it may kink when a **stylet** is not used, particularly if the patient is uncooperative or unable to swallow. However, caution is required when inserting feeding tubes with a stylet because there is a risk of tissue puncture or placement error.

After insertion, the tip of the tube is initially located in the stomach; it usually takes 24 hours for the tube to pass through the stomach and into the intestine by **peristalsis**. Surgically and endoscopically placed enteric tubes are inserted directly into the duodenum or jejunum. Polyurethane or silicone rubber feeding tubes are typically soft and have narrow diameters (6 to 12 Fr) to ensure patient comfort. Tungsten tips can facilitate migration of the tube's tip from the stomach into the intestine.

Nursing Management

Preparing the Patient

The nurse explains the purpose of the tube to the patient prior to insertion to promote cooperation during the procedure. The general activities related to inserting the tube are then reviewed, including the fact that the procedure may cause gagging until the tube has passed beyond the throat.

Inserting the Tube

Before inserting one of these tubes, the nurse determines the length that will be needed to reach the stomach or the small intestine. A mark is made on the tube to indicate the desired length. This length is traditionally determined by (1) measuring the distance from the tip of the nose to the earlobe and from the earlobe to the xiphoid process, and (2) adding 6 inches for NG placement or 8 to 10 inches for intestinal placement, although studies do not necessarily confirm that this is a reliable technique (Cirgen Ellett, Beckstrand, Flueckiger, et al., 2005) (Chart 36-1; Fig. 36-2).

While the tube is being inserted, the patient usually sits upright with a towel or other protective barrier spread bib-fashion over the chest. The nostril may be swabbed or the oropharynx sprayed with tetracaine or benzocaine to numb the nasal passage and suppress the gag reflex. To make the tube easier to insert, it should be lubricated with a water-soluble lubricant unless it has a dry coating (hydromer), which, when moistened, provides its own lubrication. Gloves should be worn during the procedure. The nostrils are inspected for any obstruction and the more patent nostril is selected for use. The tip of the patient's nose is tilted, and the tube is aligned to enter the nostril. When the tube reaches the nasopharynx, the patient is instructed to lower the head slightly and to begin to swallow as the tube is advanced. The patient may also be encouraged to sip water through a straw to facilitate advancement of the tube if this action is not contraindicated. The oropharynx is inspected to ensure that the tube has not coiled in the pharynx or mouth.

Confirming Placement

To ensure patient safety, it is essential to confirm that the tube has been placed correctly: The tube may be inadvertently inserted in the lungs, most commonly in the right main bronchus (Metheny, 2006). Inappropriate placement may occur in patients with decreased levels of consciousness, confused mental states, poor or absent cough and gag reflexes, or agitation during insertion. The presence of an endotracheal tube or its recent removal also increases the risk of inadvertent placement of the tube in the lung (Ackerman & Mick, 2006). Initially, an x-ray should be used to confirm tube placement (Elpern, Killeen, Talla, et al., 2007). However, each time liquids or medications are administered, as well as once a shift for continuous feedings, the tube must be checked to ensure that it remains properly placed. Use of a combination of the following methods is recommended:

- Measurement of tube length. It is necessary to measure the length of the exposed portion of the tube and document the length. Every shift the nurse measures this length and compares it with the original measurement. An increase in the length of exposed tube may indicate dislodgement.
- Visual assessment of aspirate color. Gastric aspirate is most frequently cloudy and green, tan, off-white, or brown. Intestinal aspirate is primarily clear and yellow to bile colored.
- pH measurement of aspirate. The pH of gastric aspirate is acidic (1 to 5). The pH of intestinal aspirate is typically 6 or higher, and the pH of respiratory aspirate

CHART
36-1

NURSING RESEARCH PROFILE

Predicting the Insertion Distance for Placing Gastric Tubes

Cirgin Ellett, M., Beckstrand, J., Flueckiger, J., et al. (2005). Predicting the insertion distance for placing gastric tubes. *Clinical Nursing Research*, 14(1), 11–26.

Purpose

Errors in safe and effective gastric tube placement are common. Researchers conducted this study to develop a clinically useful method to estimate the length of tube insertion to achieve reliable gastric placement of these tubes.

Design

An extensive review of the nursing and medical literature and discussions with clinicians yielded 20 “external measures” that included anatomical lengths (eg, nose to xiphoid, lower incisor to midumbilicus) that could be used to predict gastric tube length from the nares to the point in the stomach just beyond the lower esophageal sphincter (LES). These external measures, along with gender, height, weight, and body mass index, comprised the 24 variables tested in a predictor model. The convenience sample included 76 adults who were enrolled in esophageal motility studies at a university medical center. These participants each had an esophageal motility probe inserted through their nares to

their LESs. An ultrasound transducer probe was used to verify the LES locations.

Findings

Three variables used together accurately predicted appropriate placement of nasally inserted tubes in the stomach: gender, length from nares to umbilicus, and height. Researchers created a gender-specific nomogram that included a patient’s height and weight to find the predicted insertion distance or tube length. This new method correctly estimated gastric tube insertion distance from the nares to the LES 85.3% of the time, and it may be an improvement over the more commonly used but invalidated method of measuring from the nares to the earlobe to the xiphoid to estimate correct tube insertion length.

Nursing Implications

The availability of a valid nomogram for use by nurses and other clinicians at the bedside could facilitate improved methods for gastric tube placement. Safe and successful insertion increases patient comfort and decreases incidence of complications such as inadvertent pulmonary placement. Validated tools using evidence-based practice are the best resources in nursing care, and facilities and health care providers should encourage use of these tools.

is more alkaline (7 or greater). An enteral tube with a pH sensor that can facilitate distinguishing between gastric and small intestinal placement of the tube is commercially available.

- Air auscultation. Studies have found that the traditional method of injecting air through the tube while

auscultating the epigastric area with a stethoscope to detect air insufflation is an unreliable indicator of gastric placement.

Each of these methods of confirming tube placement has its advantages and disadvantages (Table 36-2). One new method under study uses tubes with an end-tidal carbon

Measuring distance from nostril to tip of earlobe.

Measuring distance from earlobe to tip of xiphoid process.

Have the patient sit in a neutral position with head facing forward. Place the distal tip of the tubing at the tip of the patient’s nose (N); extend tube to the tragus (tip) of the ear (E), and then extend the tube straight down to the tip of the xiphoid (X). The tube is placed 6–10 cm beyond that measured length.

Figure 36-2 Measuring length of nasogastric tube for placement into stomach.

Table 36-2 ASSESSING FOR GASTRIC TUBE PLACEMENT

Assessment Method	Advantages	Limitations
X-ray visualization of tube tip	Most accurate method to verify tube placement	Costly Patient exposed to radiation dose from x-ray
Measure exposed tube length	Ease of use	Only indicates change in position, not location
Visual assessment of the color of the aspirate	Helpful in distinguishing between gastric (cloudy and green, tan, off-white, or brown) and intestinal (clear and yellow to bile colored) placement	Little value in ruling out respiratory placement Aspirate often looks like the feeding formula
pH measurement of aspirate	Ease of use Helpful in distinguishing between gastric (1 to 5) and intestinal (6 or higher) placement Can be used to monitor the advancement of the tube into the small intestine	Several interventions alter aspirate pH: antacids, gastric resection, grossly bloody samples, continuous tube feedings Availability of pH monitoring equipment not universally available
Air auscultation	Ease of use	Accuracy highly variable Normal bowel and bronchial breath sounds may interfere with interpretation Small-bore tubes allow less air flow

dioxide detector that changes color when the tube tip is inappropriately placed in the trachea but not when it is properly placed in the stomach (Roberts, Echevarria & Gabriel, 2007). Another new method uses a copper wire coiled around the stylet of the feeding tube that generates an electromagnetic signal. This signal may be detected via a device that is placed over the patient’s xiphoid process and is visualized by computer imaging (Ackerman & Mick, 2006).

Ensuring bedside placement of postpyloric feeding tubes into the duodenum can be a challenge. If the feeding tube is inserted using endoscopy, appropriate confirmation is ensured. Other placement methods are less invasive and less costly. An external magnet device can sometimes be used to help guide a postpyloric feeding tube that has a magnetized tip. A prokinetic agent such as intravenous (IV) metoclopramide (Reglan) can be administered to facilitate peristaltic movement of the feeding tube into the duodenum. Placing the patient on his or her right side is also helpful in facilitating appropriate movement and placement.

After the correct position of the tip of the tube has been confirmed, the NG tube is secured to the nose (Fig. 36-3).

A liquid skin barrier (eg, Bard Protective Barrier) should be applied to the skin. The area is then covered with a strip of hypoallergenic tape or a transparent adhesive dressing (eg, Op-Site), and the tube is placed over the tape and secured with a second piece of tape.

Clearing Tube Obstruction

If it is difficult to infuse or aspirate warm water into a clogged feeding tube, several declogging steps can be taken, including air insufflation and infusion of digestive enzymes (Table 36-3). A prescription for a solution of digestive enzymes mixed with sodium bicarbonate is fairly effective; however, confirmation of correct placement of the tube is essential prior to using this and all other techniques. The patient’s position should be changed with each attempt. Mechanical methods of declogging such as the insertion of endoscopy or cytology brushes and commercial declogger devices into the feeding tube should be performed only by experienced providers. Cola and cranberry juice have been previously recommended as effective, noninvasive means of declogging tubes, but this practice is no longer advocated.

Figure 36-3 Securing nasogastric (NG) tubes. **A**, The NG tube is secured to the nose with tape to prevent injury to the nasopharyngeal passages. **B**, The tubing is secured to the patient’s gown with tape attached to a safety pin to prevent tension on the tube.

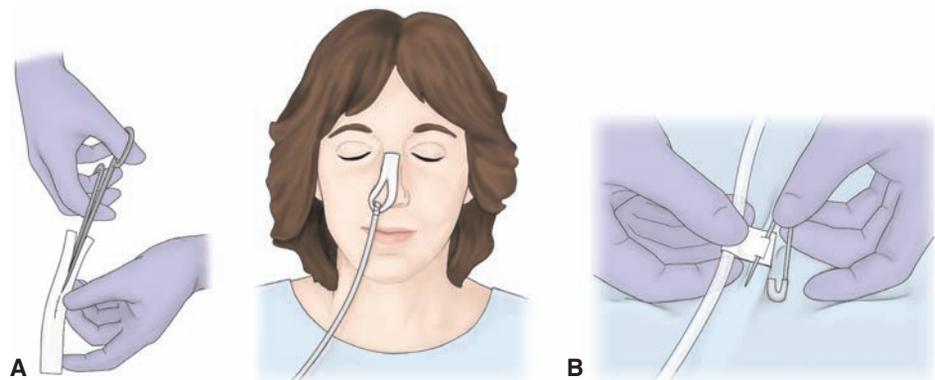

Table 36-3 DECCLOGGING AN ENTERAL FEEDING TUBE

Method	Steps
Air insufflation	<ul style="list-style-type: none"> • Inject 20 mL of air through the tube with a 30- to 60-mL syringe; pull plunger back • If ineffective, inject an additional 20 mL of air • Replace the large syringe with a 10-mL syringe • Aspirate again • If unsuccessful, notify the physician
Digestive enzymes and warm water, using one of the following* <ul style="list-style-type: none"> • A pancrelipase solution[†] buffered with a sodium bicarbonate tablet—the following are dissolved together in 5 mL warm water: <ul style="list-style-type: none"> • 1 crushed pancrelipase tablet or 1/4 teaspoon of pancrelipase powder • 1 crushed non-enteric-coated sodium bicarbonate (324 mg) tablet or 1/8 teaspoon of baking soda • A commercially available enzyme product[†] such as Clog Zapper (Corpak) 	<ul style="list-style-type: none"> • Insert a 30- to 50-mL syringe • Aspirate as much liquid as possible from the feeding tube • Under manual pressure, instill 5 mL of warm water with the syringe for 1 minute • Use a back-and-forth motion with the plunger to help dislodge the occlusion • Clamp the tube for 5 to 15 minutes • Follow above steps with enzyme solution instead of water • Repeat once if necessary

*Must obtain a prescription/order to administer.

[†]Verify tube placement before administration.

NURSING ALERT

Feeding tubes are more successfully declogged when intervention is initiated immediately after the obstruction is noted and if the obstruction is close to the proximal tube opening.

Monitoring the Patient and Maintaining Tube Function

If the NG tube is used for decompression, it is connected to suction or a collection bag. If it is used for enteral nutrition, the end of the tube is plugged between feedings. Displacement of the tube may be caused by tension on the tube with patient movement, coughing, suctioning, or airway intubation. If the NG tube is removed inadvertently in a patient who has undergone esophageal or gastric surgery, it is usually replaced by the physician with care to avoid trauma to the suture line.

It is important to keep an accurate record of all fluid intake, feedings, and irrigation. To maintain patency, the tube is irrigated every 4 to 6 hours with water or normal saline, depending on the patient's electrolyte levels. The nurse records the amount, color, and type of any drainage every 4 to 8 hours. When double-lumen or triple-lumen tubes are used, each lumen is labeled according to its intended use for aspiration or feeding.

Providing Oral and Nasal Hygiene

Regular, conscientious oral and nasal hygiene is a vital part of patient care because the tube causes discomfort and pressure and may be in place for several days. The nose is inspected daily for skin irritation, and the nasal tape is changed every 2 to 3 days. If the nasal and pharyngeal mucosa are excessively dry, steam or cool vapor inhalations may be beneficial. Throat lozenges, an ice collar, chewing gum, or sucking on hard candies (if permitted) and limiting talking also assist in relieving patient discomfort.

Monitoring and Managing Potential Complications

Patients with NG or nasogastric intubation are susceptible to a variety of problems, including fluid volume deficit, pulmonary complications, and tube-related irritations. These potential complications require careful ongoing assessment.

Symptoms of fluid volume deficit include dry skin and mucous membranes, decreased urinary output, lethargy, and increased heart rate. Assessment involves maintaining an accurate record of intake and output. This includes measuring fluid intake from tube feeding and flushes, oral liquids, and IV fluids. Output of urine, emesis, NG drainage, and diarrhea should also be measured. Laboratory values, particularly blood urea nitrogen and creatinine, are monitored. The nurse assesses 24-hour fluid balance and reports negative fluid balance (output greater than intake), increased NG output, interruption of IV therapy, or any other disturbance in fluid intake or output.

Pulmonary complications from NG intubation can occur because coughing and clearing of the pharynx are impaired. Tubes may become dislodged, retracting the distal end above the esophagogastric sphincter, which places the patient at increased risk of aspiration. Medications such as antacids and metoclopramide can be administered to decrease potential problems. Signs and symptoms of complications include coughing during the administration of foods or medications, difficulty clearing the airway, tachypnea, and fever. Assessment includes regular auscultation of lung sounds and monitoring of vital signs. The nurse also carefully confirms the proper placement of the tube before instilling any fluids or medications.

Removing the Tube

Before removing a decompression tube, the nurse may intermittently clamp it for a trial period of several hours to ensure that the patient does not experience nausea, vomiting, or distention. Before any tube is removed, it is flushed with 10 mL of water or normal saline to ensure that it is free of

debris and away from the gastric lining. Gloves are worn when removing the tube. The tube is withdrawn gently and slowly for 15 to 20 cm (6 to 8 in) until the tip reaches the esophagus; the remainder is withdrawn rapidly from the nostril. If the tube does not come out easily, force should not be used, and the problem should be reported to the physician. As the tube is withdrawn, it is concealed in a towel to prevent secretions from soiling the patient or nurse. After the tube is removed, the nurse provides oral hygiene.

Administering Tube Feedings

Enteral nutrition feedings are given to meet nutritional requirements when oral intake is inadequate or not possible and the middle and lower portions of the GI tract are functioning normally. These tube feedings are delivered to the stomach, distal duodenum, or proximal jejunum and help preserve GI integrity by preserving normal intestinal and hepatic metabolism. Tube feedings have several advantages over parenteral nutrition: They are lower in cost, safe, usually well tolerated by the patient, and easy to use both in extended care facilities and in the patient's home.

Nasoduodenal or nasojejunal feeding is indicated when the esophagus and stomach need to be bypassed or when the patient is at risk for aspiration. For feedings longer than 4 weeks, gastrostomy or jejunostomy tubes are preferred for administration of medications or food. Indications for enteral nutrition are summarized in Table 36-4.

Osmolality

The **osmolality** of normal body fluids is approximately 300 mOsm/kg. The body attempts to keep the osmolality of the contents of the stomach and intestines at this level. Osmolality is an important consideration for patients receiving tube feedings through the duodenum or jejunum because

feeding formulas with a high osmolality may lead to undesirable effects. When a concentrated solution of high osmolality is taken in large amounts, water moves rapidly to the stomach and intestines from fluid surrounding the organs and the vascular compartment. The patient has a feeling of fullness, nausea, and diarrhea; this can cause dehydration, hypotension, and tachycardia, collectively termed **dumping syndrome**. Patients vary in the degree to which they tolerate the effects of high osmolality; the nurse needs to be knowledgeable about the patient's formula and take steps to prevent this undesired effect.

Formulas

The choice of formula to be delivered by tube feeding is influenced by the status of the GI tract and the nutritional needs of the patient. The formula characteristics that are considered include the chemical composition of the nutrient source (protein, carbohydrates, fat), caloric density, osmolality, fiber content, vitamins, minerals, and cost. A wide variety of containers, delivery systems, and enteral pumps are available for use with tube feedings.

Various tube feeding formulas are available commercially. Polymeric formulas are composed of protein, carbohydrates, and fats in a high molecular-weight form. Chemically defined formulas contain easier to absorb nutrients. Modular products contain only one major nutrient, such as protein, and are used to enhance commercially prepared products. Disease-specific formulas are available as adjuncts to treat various conditions. Fiber in some formulas helps decrease the occurrence of diarrhea. Some feedings are given as supplements, and others are administered to meet the patient's nutritional needs. Dietitians collaborate with physicians and nurses to determine the best formula for each patient.

Administration Methods

The tube feeding method chosen depends on the location of the tube in the GI tract, patient tolerance, convenience, and cost. Many patients do not tolerate NG and nasogastric tube feedings well. Often a medium-bore or fine-bore Silastic nasogastric tube is better tolerated; however, a small-bore tube requires diligent flushing to remain patent.

Both bolus and intermittent gravity tube feeding methods are practical and inexpensive, but they may be poorly tolerated and time-consuming. A **bolus** feeding can be administered by gravity into the stomach (usually by gastrostomy tube) through a large syringe (Fig. 36-4). Bolus feedings of 300 to 500 mL require 10 to 15 minutes to complete. Raising or lowering the syringe above the abdominal wall regulates the rate of flow. The amount given is often determined by the patient's reaction. If the patient feels full, it may be desirable to give smaller volumes more frequently. The intermittent gravity drip feeding method requires administering feedings over 30 minutes at designated intervals by a reservoir enteral bag and tubing. This method is commonly used when the patient is at home.

Continuous feeding is the delivery of feedings incrementally over long periods. It is associated with reduced rates of aspiration, distention, nausea, vomiting, and diarrhea. Typically, feedings are administered into the small intestine. Rates

Table 36-4 CONDITIONS REQUIRING ENTERAL THERAPY

Condition or Need	Examples
Preoperative bowel preparation	After administration of larger-volume cathartics
Gastrointestinal problems	Fistula, short-bowel syndrome, mild pancreatitis, Crohn's disease, ulcerative colitis, nonspecific maldigestion or malabsorption
Cancer therapy	Radiation, chemotherapy
Convalescent care	Surgery, injury, severe illness
Coma, semi-consciousness*	Stroke, head injury, neurologic disorder, neoplasm
Hypermetabolic conditions	Burns, trauma, multiple fractures, sepsis, AIDS, organ transplantation
Alcoholism, chronic depression, anorexia nervosa*	Chronic illness, psychiatric or neurologic disorder
Debilitation*	Disease or injury
Maxillofacial or cervical surgery	Disease or injury
Oropharyngeal or esophageal paralysis*	Disease or injury, neoplasm, inflammation, trauma, respiratory failure

*Because some of these patients are at risk for regurgitating or vomiting and aspirating administered formula, each condition must be considered individually.

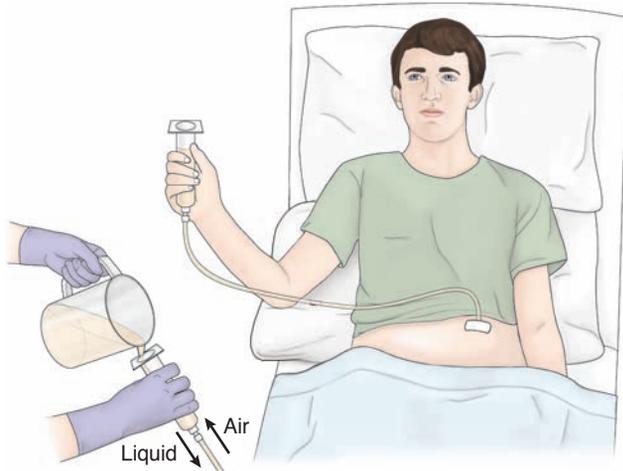

Figure 36-4 Bolus gastrostomy feeding by gravity. Syringe is raised perpendicular to the abdomen so that feeding can enter by gravity.

vary depending on the caloric density of the formula and the energy needs of the patient. The overall goal is to achieve positive nitrogen balance and weight maintenance or gain without producing discomfort or diarrhea. Enteral pumps control the delivery rate of feeding formula (Fig. 36-5). They allow for a constant flow rate and can infuse a viscous formula through a small-diameter feeding tube. However, they are relatively heavy and must be attached to an IV pole, and they are expensive. Furthermore, they allow the patient less flexibility than intermittent feedings. Portable lightweight enteral pumps that are easier to handle are available for home use. In addition, most feeding pumps have built-in alarms that signal when the bag is empty, the battery is low, or the

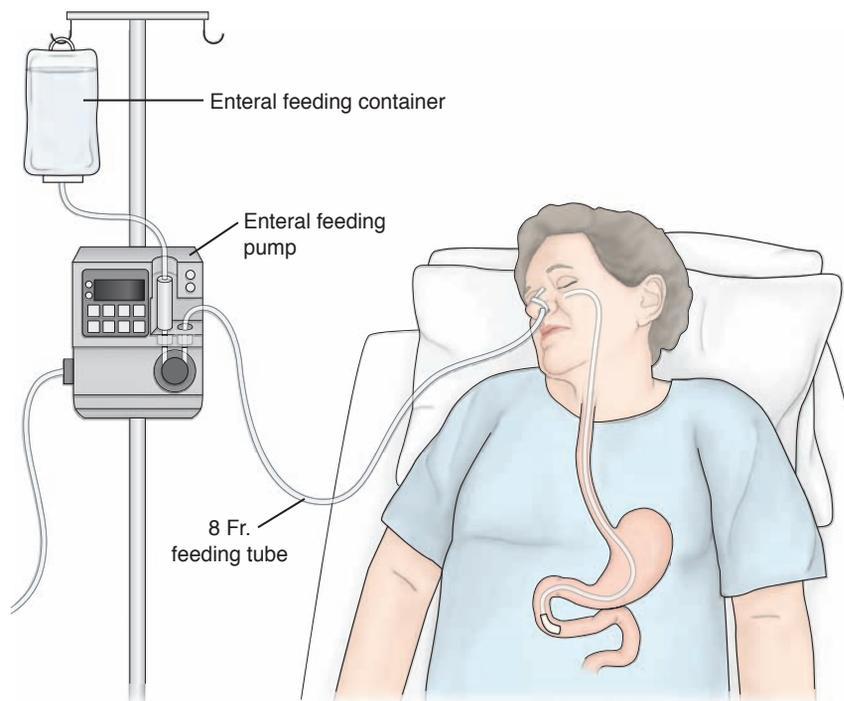

Figure 36-5 Nasoenteric tube feeding by continuous controlled pump. The head of the bed should be elevated to prevent aspiration.

tube is occluded. The patient and caregiver need to be aware of these alarms and know how to “troubleshoot” the pump.

An alternative to the continuous infusion method is **cyclic feeding**, in which the infused feeding is given over 8 to 18 hours. Feedings may be infused at night to avoid interrupting the patient’s lifestyle. Cyclic infusions may be appropriate for patients who are being weaned from tube feedings to an oral diet, for patients who cannot eat enough and need supplements, and for patients at home who need daytime hours free from the pump.

Key assessment findings for patients receiving tube feedings are noted in Chart 36-2.

Maintaining Feeding Equipment and Nutritional Balance

The temperature and volume of the feeding, the flow rate, and the patient’s total fluid intake are important factors to be considered when tube feedings are administered. The schedule of tube feedings, including the correct quantity and frequency, is maintained. The nurse must carefully monitor the drip rate and avoid administering fluids too rapidly.

Residual gastric volumes are measured before each intermittent feeding and every 4 to 8 hours during continuous feedings. Any aspirated fluid is readministered to the patient. A systematic review of the literature conducted by Keithley and Swanson (2004) suggested that there is little correlation between residual volumes and tube feeding tolerance. Furthermore, gastric residual volumes obtained from large diameter sump tubes can be greater than those obtained from smaller diameter tubes. Therefore, it is recommended that tube feedings be continued in patients with gastric residual volumes that exceed 200 mL as long as there is close monitoring of gastric residual volume trends, x-ray study results, and the patient’s physical status. If excessive

CHART
36-2

Assessing Patients Receiving Tube Feedings

Be alert for the following assessment findings:

- Tube placement, patient's position (head of bed elevated 30 to 45 degrees), and formula flow rate
- Patient's ability to tolerate the formula; observe for fullness, bloating, distention, nausea, vomiting, and stool pattern
- Clinical responses, as noted in laboratory findings (blood urea nitrogen, serum protein, prealbumin, electrolytes, renal function, hemoglobin, hematocrit)
- Signs of dehydration (dry mucous membranes, thirst, decreased urine output)
- Amount of formula actually taken in by the patient
- Elevated blood glucose level, decreased urinary output, sudden weight gain, and periorbital or dependent edema
- Infection control practices: replace any formula administered by an open system every 4 hours with fresh formula; change tube feeding container and tubing every 24 to 72 hours
- Residual volume before each feeding or, in the case of continuous feedings, every 4 hours; return the aspirate to the stomach
- Intake and output
- Weekly weights
- Recommendations made on dietitian consult

residual volumes (ie, more than 200 mL) occur twice, the nurse notifies the physician.

NURSING ALERT

Although a residual volume of 200 mL or greater is generally considered a cause for concern in patients at high risk for aspiration, feedings do not necessarily need to be withheld in all patients.

Maintaining tube function is an ongoing responsibility of the nurse, patient, and primary caregiver. To ensure patency and to decrease the chance of bacterial growth, crusting, or occlusion of the tube, at least 30 to 50 mL of water or normal saline is administered in each of the following instances:

- Before and after each dose of medication and tube feeding
- After checking for gastric residuals and gastric pH
- Every 4 to 6 hours with continuous feedings
- If the tube feeding is discontinued or interrupted for any reason
- When the tube is not being used, where a minimum of twice-daily flushing is recommended

Any water or normal saline used to irrigate these tubes must be recorded as fluid intake. One study suggests that tap water may injure the small bowel and supports the practice of flushing postpyloric nasoduodenal or jejunostomy tubes with normal saline (Schloerb, Wood, Casillan, et al., 2004).

Important complications of enteral therapy are noted in Table 36-5.

Providing Medications by Tube

When different types of medications are prescribed, a bolus method is used for administration that is compatible with

the medication's preparation (Table 36-6). The tube is flushed with 30 to 50 mL of water after medication administration, and this is recorded as intake. Medications should not be mixed with the feeding formula. When small-bore feeding tubes for continuous infusion are irrigated after administration of medications, a 30-mL or larger syringe is used because the pressure generated by smaller syringes could rupture the tube.

NURSING ALERT

Administering medications through postpyloric enteric tubes may adversely affect their absorption; therefore, this should be avoided if possible.

Maintaining Delivery Systems

Tube feeding formula is delivered to patients by either an open or a closed system. The open system is packaged as a liquid or as a powder to be mixed with water. The feeding container (which is hung on a pole) and the tubing used with the open system are usually changed every 24 hours. To avoid bacterial contamination, the amount of feeding formula in the bag should never exceed what should be infused in a 4-hour period. Closed delivery systems use a pre-filled, sterile container that is spiked with enteral tubing.

Maintaining Normal Bowel Elimination Pattern

Patients receiving NG or nasoenteric tube feedings can experience diarrhea or constipation. Pasty, unformed stool is expected with enteral therapy because many formulas have little or no residue. Dumping syndrome also leads to diarrhea; and measures for managing the GI symptoms (diarrhea, nausea) associated with the dumping syndrome are presented in Chart 36-3. Other possible causes of diarrhea can include:

- Malnutrition: A decrease in the intestinal absorptive area can cause diarrhea.
- Medication therapy: Elixir-based medications often contain sorbitol, which can act as a cathartic.
- *Clostridium difficile* colitis: Antibiotic therapy often decreases the normal bacteria present in the intestine. The resultant abnormal growth of this microbe occurs most commonly in hospitalized patients treated with antibiotics and causes significant, potentially lethal diarrhea.

Reducing the Risk for Aspiration

Aspiration pneumonia occurs when regurgitated stomach contents or enteral feedings from an improperly positioned feeding tube are instilled into the pharynx or the trachea or when oral secretions are aspirated. Feeding patients through tubes placed beyond the pylorus can decrease the frequency of feeding regurgitation and aspiration. In addition, feedings and medications should always be administered with the patient in the semi-Fowler's position, and the patient's head should be elevated at least 30 to 45 degrees to reduce the risk of reflux and pulmonary aspiration. This position is maintained at least 1 hour after completion of an intermittent tube feeding and is maintained at all times for patients receiving continuous tube feedings.

Table 36-5 COMPLICATIONS OF ENTERAL THERAPY		Selected Nursing Interventions	
Complications	Causes	Therapeutic	Preventive
Gastrointestinal			
Diarrhea	Hyperosmolar feedings	Assess fluid balance and electrolyte levels; report findings	Appropriate rate of infusion and temperature of formula
	Rapid infusion/bolus feedings Cold formula	Implement changes in tube feeding formula or rate	Avoid multiple elixirs and pro-motility medications
Nausea/vomiting	Medications, especially antibiotic therapy	Review medications	
	Change in formula or rate Inadequate gastric emptying	Review medications	Check residuals; if ≥ 200 mL, reinstill and recheck; report if residual is consistently high
Gas/bloating/cramping	Air in tube	Notify physician if persistent	Keep tubing free of air
Constipation	Excess fiber		
	Lack of fiber Inadequate fluid intake/ dehydration Opioid use	Check fiber and water content; report findings	Administer adequate amount of hydration as flushes Consider cathartic
Mechanical			
Aspiration pneumonia	Improper tube placement	Assess respiratory status and notify physician	Implement reliable method for checking tube placement
	Vomiting with aspiration of tube feeding Flat in bed		Keep head of bed elevated 30 degrees
Tube displacement	Excessive coughing/vomitus Tension on the tube or unsecured tube	Stop feeding and notify physician	Check tube placement before administering feeding
Tube obstruction	Tracheal suctioning		
	Airway intubation Inadequate flushing/formula rate Inadequate crushing of medications and flushing after administration	Follow policy for declogging feeding tubes (see Table 36-3)	Obtain liquid medications when possible Flush tube and crush medications adequately
Nasopharyngeal irritation	Tube position/improper taping Use of large tubes	Assess nasopharyngeal mucous membranes every 8 hours	Tape tube to prevent pressure on nares Reposition tape
Metabolic			
Hyperglycemia	Glucose intolerance High carbohydrate content of the feeding	Check blood glucose levels routinely Dietary consult to reevaluate feeding regimen	
Dehydration and azotemia (excessive urea in the blood)	Hyperosmolar feedings with insufficient fluid intake	Report signs and symptoms of dehydration Implement changes in tube feeding formula, rate, or ratio to water	Provide adequate hydration through flushes

Maintaining Adequate Hydration

The nurse carefully monitors hydration because in many cases the patient cannot communicate the need for water. Water flushes are administered every 4 to 6 hours and after feedings to prevent hypertonic dehydration. The feed-

ing is initially given as a continuous drip, which helps the patient develop tolerance, especially for hyperosmolar solutions. Key nursing interventions include observing for signs of dehydration (eg, dry mucous membranes, thirst, decreased urine output); administering water routinely;

Table 36-6 PREPARING MEDICATION FOR DELIVERY BY FEEDING TUBE	
Medication Form	Preparation
Liquid	None
Simple compressed tablets	Crush and dissolve in water
Buccal or sublingual tablets	Administer as prescribed
Soft gelatin capsules filled with liquid	Make an opening in capsule and squeeze out contents
Enteric-coated tablets	Do not crush; change in form is required
Timed-release tablets	Do not crush tablets because doing so may release too much drug too quickly (overdose); check with pharmacist for alternative formulation
Timed-release capsules or sustained-release capsules	Some can be opened and contents added to tube-feeding formula; <i>always</i> check with pharmacist before doing this

Chart 36-3 • Preventing Dumping Syndrome

The following strategies may help prevent some of the uncomfortable signs and symptoms of dumping syndrome related to tube feeding:

- Slow the formula instillation rate to provide time for carbohydrates and electrolytes to be diluted.
- Administer feedings at room temperature, because temperature extremes stimulate peristalsis.
- Administer feeding by continuous drip (if tolerated) rather than by bolus, to prevent sudden distention of the intestine.
- Advise the patient to remain in semi-Fowler's position for 1 hour after the feeding; this position prolongs intestinal transit time by decreasing the effect of gravity.
- Instill the minimal amount of water needed to flush the tubing before and after a feeding, because fluid given with a feeding increases intestinal transit time.

and monitoring intake, output, residual volume, and fluid balance.

Promoting Coping Ability

The psychosocial goal of nursing care is to support and encourage the patient to accept physical changes and to convey hope that daily progressive improvement is possible. If the patient is having difficulty adjusting to the treatment, the nurse intervenes by encouraging self-care, within the parameters of the patient's activity level. In addition, the nurse reinforces an optimistic approach by identifying indicators of progress (daily weight trends, electrolyte balance, absence of nausea and diarrhea).

Promoting Home and Community-Based Care**Teaching Patients Self-Care**

Patients who require long-term tube feedings have conditions such as having had recent surgery or having an obstruction of the upper GI tract or decreased level of consciousness. For a patient to be considered for tube feeding at home, the patient should:

- Be medically stable and successfully tolerating 60% to 70% of the feeding regimen.
- Be capable of self-care or have a caregiver willing to assume the responsibility.
- Have access to supplies and interest in learning how to administer tube feedings at home.

Preparation of the patient for home administration of enteral feedings begins while the patient is still hospitalized. Ideally, the nurse teaches while administering the feedings so that the patient and caregiver can observe the mechanics and participate in the procedure, ask questions, and express any concerns. Before discharge, the nurse provides information about the equipment needed, formula purchase and storage, and administration of the feedings (frequency, quantity, rate of instillation).

Family members who will be active in the patient's home care are encouraged to participate in teaching sessions. Available printed information about the equipment, the formula, and the procedure is reviewed. Arrangements are made to obtain the equipment and formula and have it ready for use before the patient's discharge.

Continuing Care

Referral to a home care agency is important so that a nurse can supervise and provide support during the first feeding at home. Additional visits will depend on the skill and comfort of the patient or caregiver in administering the feedings. During all visits, the nurse monitors the patient's physical status (weight, vital signs, activity level) and the ability of the patient and family to administer the tube feedings correctly. In addition, the nurse assesses for any complications. The patient or caregiver is encouraged to record times and amounts of feedings and any symptoms that occur. The nurse can review the record with the patient and caregiver during home visits.

Gastrostomy and Jejunostomy

A **gastrostomy** is a surgical procedure in which an opening is created into the stomach for the purpose of administering foods and fluids via a feeding tube or for gastric decompression in the setting of intestinal obstruction. A gastrostomy is preferred to deliver enteral nutritional support longer than 4 weeks. Gastrostomy is also preferred over NG feedings in the patient who is comatose because the gastroesophageal sphincter remains intact, making regurgitation and aspiration less likely than with NG feedings. Gastrostomy tubes may be placed surgically through an abdominal incision with sutures to secure the tube to the anterior gastric wall and the creation of a tunnel brought out through the abdomen to form a permanent **stoma**. A jejunostomy is similarly placed, but the distal end extends beyond the pylorus into the jejunum.

Insertion of a **percutaneous endoscopic gastrostomy (PEG)** requires the services of a provider skilled in endoscopy or interventional radiology. After a local anesthetic is administered, a cannula is inserted into the stomach through a small abdominal incision and an endoscope is inserted via the patient's mouth and upper GI tract. The PEG tube is guided down the esophagus, into the stomach, and out through the abdominal incision. A mushroom catheter tip or internal fasteners secure the tube against the stomach wall. An external crossbar or bumper keeps the catheter in place (Fig. 36-6A). If an endoscope cannot be passed through the esophagus, then the gastrostomy can be attempted under x-ray guidance through the abdominal wall.

The initial PEG device can be removed and replaced once the tract is well established, typically 3 to 6 weeks after insertion. Replacement of the PEG device is indicated for a clogged or fractured tube. The PEG should be fitted securely to the stoma to prevent leakage of gastric secretions and is maintained in place through gentle traction between the internal and anchoring devices. Enough space should remain between the skin and the external anchor to allow a gauze pad to be placed between them (Fig. 36-7).

An alternative to the PEG device is a low-profile gastrostomy device (LPGD) (see Fig. 36-6B). LPGDs may be inserted 3 to 6 months after initial gastrostomy tube placement. These devices are inserted flush with the skin; they eliminate the possibility of tube migration and have antireflux valves to prevent gastric leakage. Patients requiring

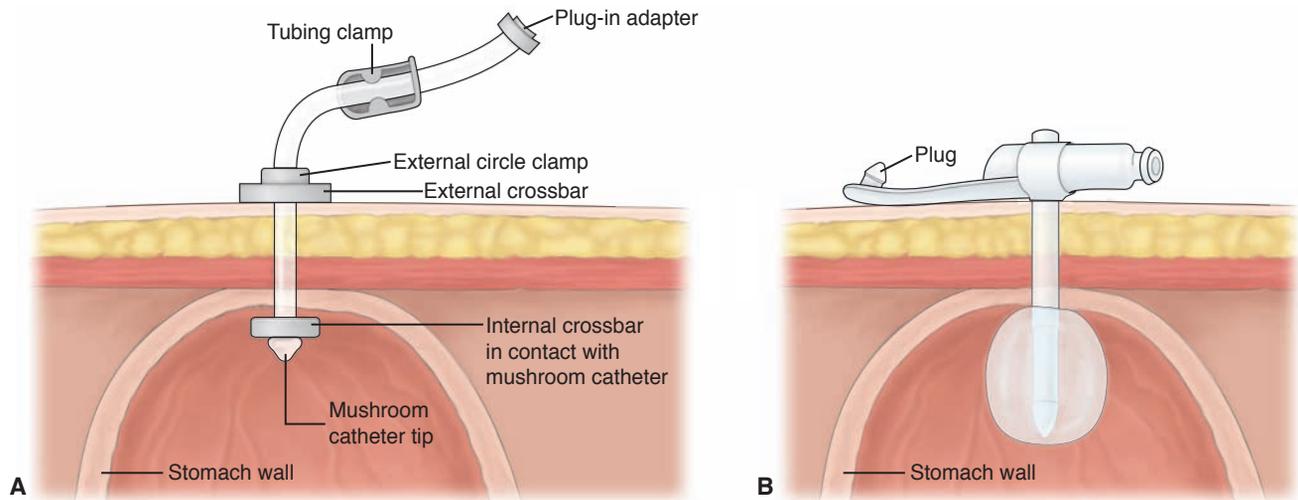

Figure 36-6 A, A detail of the abdomen and the percutaneous endoscopic gastrostomy (PEG) tube, showing catheter fixation. B, A detail of the abdomen and the nonobturated low-profile gastrostomy device (LPGD), showing balloon fixation.

lifelong enteral support are able to conceal the feeding tube access site under their clothing. However, it is not possible to assess residual volumes with LPGDs (ie, they have one-way valves), and they also require a special adaptor to connect the device to the feeding container.

NURSING PROCESS

THE PATIENT WITH A GASTROSTOMY OR JEJUNOSTOMY

Assessment

The focus of the preoperative assessment is to determine the patient's ability both to understand and cooperate with the procedure. The nurse assesses the ability of both patient and family to adjust to a change in body image and to participate in self-care. There are multiple medical and ethical issues that the patient, the caregivers, and the physician should discuss together (Chart 36-4).

Figure 36-7 Protection at the gastrostomy site. A percutaneous endoscopic gastrostomy (PEG) tube may be protected by a dressing that allows access to the tube but covers the exit site.

The purpose of the procedure and expected postoperative course should be explained. The patient needs to know that the feeding tube will bypass the mouth and esophagus so that liquid feedings can be administered directly into the stomach or intestine. If the feeding tube is expected to be permanent, the patient should be made aware of this. If the procedure is being performed to relieve discomfort, prolonged vomiting, debilitation, or an inability to eat, the patient may find it more acceptable.

In the postoperative period, the patient's fluid and nutritional needs are assessed to ensure proper intake and GI function. The nurse inspects the tube for proper maintenance and the incision for signs of infection. As the nurse evaluates patients' responses to the change in body image and their understanding of the feeding methods, interventions are identified to help them cope with the tube and learn self-care measures.

Diagnosis

Nursing Diagnoses

Based on the assessment data, the major nursing diagnoses in the postoperative period may include the following:

- Acute pain
- Risk for infection related to presence of wound and tube
- Risk for impaired skin integrity at tube insertion site
- Disturbed body image related to presence of tube

Collaborative Problems/Potential Complications

Potential complications that may develop include the following:

- Wound infection, cellulitis, and leakage
- GI bleeding
- Premature dislodgement of the tube

Planning and Goals

The major goals for the patient may include minimizing pain, preventing infection, maintaining skin integrity, enhancing coping, adjusting to changes in body image, and preventing complications.

CHART
36-4

Ethics and Related Issues

Is It Ethical to Withhold or Withdraw Nutrition and Hydration?

Situation

It is generally agreed that patients (or their designated decision makers) can refuse life-saving treatment, particularly if the means of treatment are extraordinary (eg, ventilators, dialysis machines, extracorporeal oxygenators). Extraordinary means include medications, treatments, and procedures that can be obtained only at excessive cost, pain, or inconvenience and offer no reasonable hope of benefit. Nutrition and hydration therapy, however, are perceived as ordinary means by many.

Ordinary means are those medications, treatments, and procedures that offer a reasonable hope of benefit and can be obtained without excessive expense, pain, or inconvenience. Additionally, withdrawing or withholding nutrition and hydration can in and of itself cause death. Thus, some have argued that nutrition and hydration should always be provided to every patient, regardless of the patient's preference or condition.

Dilemma

The patient's desire to have nutrition or hydration withdrawn or withheld may conflict with the reluctance of others to harm the patient by withdrawing the food and water needed for survival (autonomy versus nonmaleficence).

Discussion

Answer the following questions using as an example a patient in a persistent vegetative state (ie, unable to express his or her wishes).

- What arguments would you offer *against* the withholding and withdrawing of nutrition and hydration?
- What arguments would you offer *in favor of* withholding and withdrawing of nutrition and hydration?
- Are foods and fluids always "ordinary means," or are there instances in which they might be considered "extraordinary"? Support your answer.
- What are some of the religious, cultural, and financial issues that can complicate family and caregiver decisions?
- Should an attempt be made to involve critically ill or sedated patients in their own end-of-life decisions when their death is clearly imminent? How does one balance the issues of patient autonomy versus beneficence in this situation?

Nursing Interventions

Meeting Nutritional Needs

The first fluid nourishment is administered soon after tube insertion and can consist of tap water, normal saline, or 10% dextrose. At first, this can be administered as a slow hourly infusion of 10 to 20 mL hourly or as small bolus volumes of 30 to 60 mL. The infusion rate or bolus amount administered is gradually increased. By the second day, formula feeding may begin, provided it is tolerated and no fluid leaks from around the tube.

Providing Tube Care and Preventing Infection

A thin gauze dressing should be applied between the tube insertion site and the gastrostomy tube. If the tube is not

sutured in place, a thin strip of adhesive tape is placed around the tube and firmly attached to the abdomen. The nurse verifies the tube's placement (eg, pH measurement of aspirate) and gently manipulates the tube or stabilizing disk once daily to prevent skin breakdown. Some gastrostomy tubes have balloons that are inflated with water to anchor the tube in the stomach.

If the tube has been placed to drain the stomach contents because of a GI obstruction, it can be connected to either low, intermittent suction or to a gravity drainage bag. This drainage should be measured and recorded because it is a significant indicator of GI function. A decrease in the amount of drainage may indicate that the tube can be clamped for periods of time, allowing greater freedom of movement. High output can result in significant fluid and electrolyte losses.

Providing Skin Care

The skin surrounding a gastrostomy requires special care because it may become irritated from the enzymatic action of gastric juices that may leak around the tube. Left untreated, the skin becomes macerated and painful. The nurse washes the area around the tube with soap and water daily, removes any encrustation, rinses the area well with water, and pats it dry. Skin at the exit site is evaluated daily for signs of breakdown, irritation, excoriation, and the presence of drainage or gastric leakage. The nurse encourages the patient and family members to participate in this evaluation and in hygiene activities.

Enhancing Body Image

Eating is a major physiologic and social function, and the patient with a gastrostomy has experienced a major change in body image. The patient is also aware that gastrostomy as a therapeutic intervention is performed only in the presence of a major, chronic, or perhaps terminal illness. It is necessary to evaluate the existing family support system because adjustment takes time and is facilitated by family acceptance.

Monitoring and Managing Potential Complications

During the postoperative course, the most common complications are wound infection or cellulitis at the exit site, bleeding, and dislodgement. Because many patients who receive tube feedings are debilitated and have compromised nutritional status, any signs of infection are promptly reported to the physician so that appropriate therapy can be instituted. Bleeding from the insertion site in the stomach can also occur and should be reported promptly. The nurse closely monitors the patient's vital signs and observes all operative site drainage, vomitus, and stool for evidence of bleeding. Dislodgement of a recently inserted tube requires immediate attention because the tract can close within 4 to 6 hours if the tube is not replaced promptly.

Promoting Home and Community-Based Care

TEACHING PATIENTS SELF-CARE. The patient with a gastrostomy or jejunostomy tube in the home setting must be capable of maintaining patency of the tube or have a caregiver who can do so. The nurse assesses the patient's level of knowledge and interest in learning about the tube, as well as an ability to understand how to flush, provide site care, and

administer feedings or facilitate decompression drainage. Teaching is similar to that described earlier. To facilitate self-care, the nurse encourages the patient to participate in flushing the tube, administering medications during hospitalization, and establishing as normal a routine as possible.

Adaptors are available that can be secured to the end of the tube to create a “Y” site for ease of flushing, suction, or medication delivery (Fig. 36-8). The flushing equipment is cleaned with warm, soapy water and rinsed after each use. The tube can be marked at skin level to provide the patient with a baseline for later comparison. The patient or caregiver should be advised to monitor the tube’s length and to notify the physician or home care nurse if the segment of the tube outside the body becomes shorter or longer.

CONTINUING CARE. Referral to a home care agency is important to ensure initial supervision and support for the patient and caregiver. The home care nurse assesses the patient’s status and progress and evaluates the care of the tube and healing status of the tube insertion site. Further instruction and supervision in the home setting may be required to help the patient and caregiver adapt to a physical environment and equipment that are different from the hospital setting. The nurse also reviews with the patient and caregiver complications to report and assists the patient and family in establishing as normal a routine as possible.

Evaluation

Expected Patient Outcomes

- Maintains adequate fluid balance
 - Maintains or gains weight
 - Has normal electrolyte values
 - Is adequately hydrated
- Is free from infection and skin breakdown
 - Is afebrile
 - Has no drainage from the incision
 - Demonstrates intact skin surrounding the exit site

- Adjusts to change in body image
 - Is able to discuss expected changes
 - Verbalizes concerns
- Demonstrates skill in tube care
 - Handles equipment competently
 - Demonstrates how to maintain tube patency
 - Keeps an accurate record of intake and output
- Avoids complications
 - Exhibits adequate wound healing
 - Has no abnormal bleeding from puncture site
 - Tube remains intact for the duration of therapy

Parenteral Nutrition

Parenteral nutrition (PN) is a method of providing nutrients to the body by an IV route. The nutrients are a complex admixture containing proteins, carbohydrates, fats, electrolytes, vitamins, trace minerals, and sterile water in a single container. The goals of PN are to improve nutritional status, establish a positive nitrogen balance, maintain muscle mass, promote weight maintenance or gain, and enhance the healing process.

Establishing Positive Nitrogen Balance

Most IV fluids do not provide sufficient calories or protein to meet the body’s daily requirements. PN solutions can provide enough calories and nitrogen to meet the patient’s daily nutritional needs. The patient with fever, trauma, burns, major surgery, or hypermetabolic disease requires additional daily calories. When highly concentrated dextrose is administered, caloric requirements are satisfied and the body uses amino acids for protein synthesis rather than for energy. Additionally, electrolytes such as calcium, phosphorus, magnesium, and sodium chloride are added to the solution to maintain proper electrolyte balance and to transport glucose and amino acids across cell membranes.

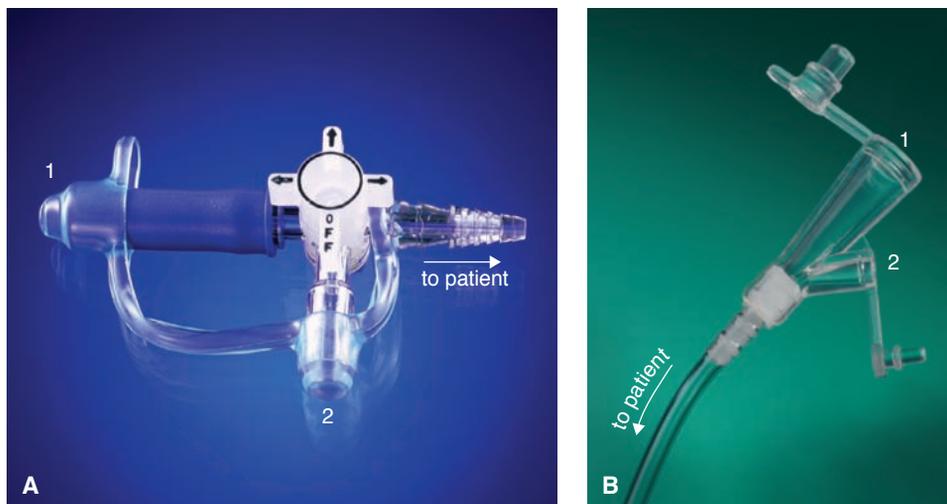

Figure 36-8 A, The Lopez valve and the B, Bard adaptor allow feeding to (1) continue through the main port (2) while providing a second port for flushing and medication delivery.

The volume of fluid necessary to provide these calories peripherally can surpass fluid tolerance. To provide the required calories in a smaller volume, it is necessary to increase the concentration of nutrients and use a route of administration that rapidly dilutes incoming nutrients to the proper levels of body tolerance. Typically, a large, high-flow vein such as the subclavian vein or superior vena cava is the preferred site.

Clinical Indications

The indications for PN include an inability to ingest adequate oral food or fluids within 7 days. Enteral nutrition should be considered before parenteral support because it assists in maintaining gut mucosal integrity and is typically associated with fewer complications. In both the home and hospital setting, PN is indicated in the situations listed in Table 36-7.

Formulas

A total of 1 to 3 L of solution is administered over a 24-hour period. The label of the solution is verified with the physician's order. **Intravenous fat emulsions (IVFEs)** may be infused simultaneously with PN through a Y connector close to the infusion site and should not be filtered. Usually 500 mL of a 10% IVFE or 250 mL of 20% IVFE is administered over 6 to 12 hours, one to three times a week. IVFEs can provide up to 30% of the total daily calorie intake.

NURSING ALERT

Before PN infusion is administered, the solution must be inspected for separation, oily appearance, or any precipitate. If any of these are present, it is not used.

IVFEs can be mixed by the pharmacy staff with other components of PN to create a “three-in-one formulation” commonly called a **total nutrient admixture (TNA)**. A special final filter (1.5-micron filter) is used with this solution. Advantages of TNA over PN are cost savings in preparation and equipment, decreased risk of catheter or nutrient contamination, decreased nursing time, and increased patient convenience and satisfaction. Ideally, the

pharmacist, nutritionist, and physician should collaborate to determine the specific formula needed.

Initiating Therapy

PN solutions are initiated slowly and advanced gradually each day to the desired rate as the patient's fluid and dextrose tolerance permits. The patient's laboratory test results and response to PN therapy are monitored on an ongoing basis by the physician. Standing orders are initiated for weighing the patient; monitoring intake, output, and blood glucose; and baseline and periodic monitoring of complete blood count, platelet count, and chemistry panel, including serum carbon dioxide, magnesium, phosphorus, and triglycerides. A 24-hour urine nitrogen determination may be performed for analysis of nitrogen balance. In most hospitals, the PN solutions are prescribed on a daily standard PN order form. The formulation of the PN solutions is calculated carefully each day to meet the complete nutritional needs of the individual patient.

Administration Methods

Various vascular access devices are used to administer PN solutions in clinical practice. PN may be administered through either peripheral or central IV lines, depending on the patient's condition and the anticipated length of therapy.

NURSING ALERT

An infusion pump is always used for administration of PN.

Peripheral Method

To supplement oral intake, peripheral parenteral nutrition (PPN) may be prescribed. PPN is administered through a peripheral vein; this is possible because the solution is less hypertonic than a full-calorie parenteral nutrition solution. PPN formulas are not nutritionally complete because of their low dextrose content. Lipids are administered simultaneously to buffer the PPN and to protect the peripheral vein from irritation. The usual length of therapy using PPN is 5 to 7 days.

NURSING ALERT

Formulations with dextrose concentrations of more than 10% should not be administered through peripheral veins because they irritate the intima (innermost walls) of small veins, causing chemical phlebitis.

Central Method

Because central parenteral solutions (CPNs) have five or six times the solute concentration of blood (and exert an osmotic pressure of about 2000 mOsm/L), they are administered into the vascular system through a catheter inserted into a high-flow, large blood vessel (eg, the subclavian vein). Concentrated solutions are then very rapidly diluted to isotonic levels by the blood in this vessel.

Four types of **central venous access devices (CVADs)** are available: nontunneled (or percutaneous) central

Table 36-7 INDICATIONS FOR PARENTERAL NUTRITION

Condition or Need	Examples
Insufficient oral or enteral intake	Severe burns, malnutrition, short bowel syndrome, acquired immunodeficiency syndrome (AIDS), sepsis, cancer
Impaired ability to ingest or absorb food orally or enterally	Paralytic ileus, Crohn's disease, short gut, postradiation enteritis, high-output enterocutaneous fistula
The patient is unwilling or unable to ingest adequate nutrients orally or enterally	Major psychiatric illness
Preoperative and postoperative nutritional needs are prolonged	Extensive bowel surgery, acute pancreatitis

catheters, peripherally inserted central catheters, tunneled catheters, and implanted ports.

Nontunneled Central Catheters

Nontunneled central catheters are used for short-term (less than 6 weeks) IV therapy in acute care settings. The subclavian vein is the most common vessel used because the subclavian area provides a stable insertion site to which the catheter can be anchored, is easily compressible (facilitating control of hemorrhage), allows the patient freedom of movement, and provides easy access to the dressing site. The jugular vein should only be used as a last resort and then only for 1 to 2 days. Single-lumen, double-lumen, and triple-lumen central catheters are available for central lines, but the Centers for Disease Control and Prevention (CDC) recommends that single-lumen catheters be used for CPN whenever practicable (CDC, 2002). For a patient with limited IV access, a triple-lumen subclavian catheter can be used because it offers three ports for various uses (Fig. 36-9). The distal lumen can be used to infuse blood or other viscous fluids. The middle lumen is reserved for PN infusion. The proximal port can be used for administration of blood or medications. A port not being used for fluid administration can be used for obtaining blood specimens if indicated.

If a single-lumen central catheter is used for administering PN, various restrictions apply. Blood should not be drawn from or transfused through the line because red blood cells may coat the lumen of the catheter and reduce the flow of the nutritional solution. Medications should not be administered through it because of potential incompatibilities with the components of the nutritional solution. If medica-

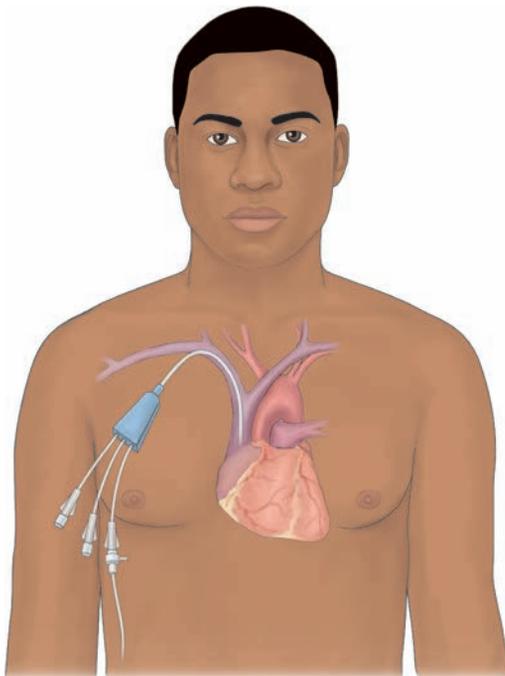

Figure 36-9 Subclavian triple-lumen catheter used for parenteral nutrition and other adjunctive therapy. The catheter is threaded through the subclavian vein into the vena cava. Each lumen is an avenue for solution administration. The lumens are secured with threaded needleless adapters or Luer-Lok-type caps when the device is not in use.

tions must be given, they must be infused through a separate peripheral IV line.

Insertion. The procedure is explained so that the patient is aware of what to expect. The patient is placed supine in the Trendelenburg position to produce dilation of neck and shoulder vessels, which makes entry easier and decreases the risk of air embolus. The skin is cleansed with chlorhexidine to remove surface oils. To afford maximal accuracy in the placement of the catheter, the patient is instructed to turn his or her head away from the site of venipuncture and to remain motionless while the catheter is inserted and the wound is dressed.

The nurse assists during the insertion process by maintaining the sterile field and supporting the patient throughout the procedure. Full-length sterile drapes are applied and sterile gloves and masks are donned. Lidocaine is injected to anesthetize the skin and underlying issues. A large-bore needle on a syringe is inserted and moved parallel to and beneath the clavicle until it enters the vein. A radiopaque wire is inserted through the needle into the vein. The catheter is then advanced over the wire, the needle is withdrawn, and the hub of the catheter is attached to the IV tubing. Until the syringe is detached from the needle and the catheter is inserted, the patient may be asked to perform the Valsalva maneuver. The patient is instructed to take a deep breath, hold it, and bear down with the mouth closed to produce a positive phase in central venous pressure, thereby lessening the possibility of air being drawn into the circulatory system (air embolism). The catheter is sutured to the skin. A transparent dressing is applied using strict sterile technique.

The position of the tip of the catheter is checked with x-ray or fluoroscopy to confirm its location in the superior vena cava at the junction of the right atrium and to rule out a pneumothorax resulting from inadvertent puncture of the pleura. Once the catheter's position is confirmed, the prescribed CPN solution can be started. The initial rate of infusion is usually low and the rate is gradually increased to the target rate.

An injection site cap is attached to the end of each central catheter lumen, creating a closed system. IV infusion tubing is connected to the insertion site cap of the central catheter with a threaded needleless adapter or Luer-Lok device. To ensure patency, all lumens are initially flushed with diluted heparin or normal saline after each intermittent infusion and after blood drawing; this flushing is necessary daily when the catheter is not in use. Force is never used to flush the catheter. If resistance is met, aspiration may restore lumen patency; if this is not effective, the physician is notified. Low-dose tissue plasminogen activator may be prescribed to dissolve a clot or fibrin sheath. If attempts to clear the lumen are ineffective, the catheter should be changed.

Peripherally Inserted Central Catheters

Peripherally inserted central catheters (PICCs) are used for intermediate-term (several days to months) IV therapy in the hospital, long-term care, or home setting. These catheters may be inserted at the bedside or in the outpatient setting by a physician or specially trained nurse. The basilic or cephalic vein is accessed above the antecubital space, and the catheter is threaded to the superior vena cava. Taking of blood pressure and blood specimens from the

extremity with the PICC is avoided. (See Chapter 14 and Chapter 16, Figure 16–6.)

Tunneled Central Catheters

Tunneled central catheters are for long-term use and may remain in place for many years. These catheters are cuffed and can have single or double lumens; examples are the Hickman, Groshong, and Permacath. These catheters are inserted surgically. They are threaded under the skin (reducing the risk of ascending infection) to the subclavian vein and advanced into the superior vena cava.

Implanted Ports

Implanted ports are also used for long-term IV therapy; examples include the Port-A-Cath, Mediport, Hickman Port, and P.A.S. Port. Instead of exiting from the skin, as do the Hickman and Groshong catheters, the end of the catheter is attached to a small chamber that is placed in a subcutaneous pocket, either on the anterior chest wall or on the forearm. The port requires minimal care and allows the patient complete freedom of activity. Implanted ports are more expensive than the external catheters, and access requires passing a special noncoring needle (Huber-tipped) through the skin into the chamber to initiate IV therapy (see Chapter 16).

Discontinuing Parenteral Nutrition

The PN solution is discontinued gradually to allow the patient to adjust to decreased levels of glucose. If the PN solution is abruptly terminated, isotonic dextrose can be administered for 1 to 2 hours to prevent rebound hypoglycemia. Specific symptoms of rebound hypoglycemia include weakness, faintness, sweating, shakiness, feeling cold, confusion, and increased heart rate. Once all IV therapy is completed, the nontunneled central venous catheter or PICC is removed and an occlusive dressing is applied to the exit site. Tunneled catheters and implanted ports are removed only by the physician.

NURSING PROCESS

THE PATIENT RECEIVING PARENTERAL NUTRITION

Assessment

The nurse assists in identifying patients unable to tolerate oral or enteral feedings who may be candidates for PN. Indicators include significant weight loss (10% or more of usual weight), a decrease in oral food intake for more than 1 week, muscle wasting, decreased tissue healing, abnormal urea nitrogen excretion, and persistent vomiting and diarrhea. The nurse carefully monitors the patient's hydration status, electrolyte levels, and calorie intake.

Diagnosis

Nursing Diagnoses

Based on the assessment data, the major nursing diagnoses may include the following:

- Imbalanced nutrition, less than body requirements, related to inadequate oral intake of nutrients

- Risk for infection related to contamination of the central catheter site or infusion line
- Risk for imbalanced fluid volume related to altered infusion rate
- Anxiety related to catheter care and securement

Collaborative Problems/Potential Complications

The most common complications are pneumothorax, air embolism, a clotted or displaced catheter, sepsis, hyperglycemia, rebound hypoglycemia, and fluid overload. These problems and the associated collaborative interventions are described in Table 36-8.

Planning and Goals

The major goals for the patient may include optimal level of nutrition, absence of infection, adequate fluid volume, optimal level of activity (within individual limitations), knowledge of and skill in self-care, and absence of complications.

Nursing Interventions

Maintaining Optimal Nutrition

A continuous, uniform infusion of PN solution over a 24-hour period is desired. However, in some cases (eg, home care patients), cyclic PN may be appropriate. With cyclic PN, PN is infused during a set period of time. The time periods for infusion are sufficient to meet the patient's nutritional and pharmacologic needs. Ideally, cyclic PN is infused over a 10- to 15-hour period that continues through the night.

The patient is initially weighed daily (this may be decreased to two or three times per week once stable) at the same time of the day under the same conditions for accurate comparison. Under the PN regimen, satisfactory weight maintenance or gain can usually be achieved. It is important to keep accurate intake and output records and calculations of fluid balance. A calorie count is kept of any oral nutrients. Trace elements (copper, zinc, chromium, manganese, and selenium) are included in PN solutions and are individualized for each patient.

Preventing Infection

The high dextrose and fat content of PN solutions makes them an ideal culture medium for bacterial and fungal growth, and CVADs provide a port of entry. Gram-positive cocci, Gram-negative bacilli, and *Candida* species are frequently isolated as causes of catheter-related bloodstream infections. Common organisms include *Staphylococcus aureus*, *S. epidermidis*, *Pseudomonas aeruginosa*, *Acinetobacter*, and *Klebsiella pneumoniae*. Meticulous aseptic technique is essential to prevent infection any time the IV line setup is manipulated.

The primary sources of microorganisms for catheter-related bloodstream infections are the skin and the catheter hub. The catheter site is covered with an occlusive gauze dressing that is usually changed using sterile technique every 24 to 72 hours. Alternatively, the site may be covered with a transparent dressing that is changed weekly. Besides allowing frequent examination of the catheter site without changing the dressing, the transparent dressing also adheres well and is more comfortable for the patient. The CDC (2002) recommends changing CVAD dressings more often than every 7 days only if they are damp, bloody, loose, or soiled.

Complications	Cause	Nursing Actions and Collaborative Interventions	
		Treatment	Prevention
Pneumothorax	Improper catheter placement and inadvertent puncture of the pleura	Place patient in Fowler's position. Offer reassurance. Monitor vital signs. Prepare for thoracentesis or chest tube insertion.	Assist patient to remain still in Trendelenburg position during catheter insertion.
Embolism	Disconnected tubing	Replace tubing immediately and notify physician.	Examine all tubing connection sites for their security.
	Cap missing from port Blocked segment of vascular system	Replace cap and notify physician. Turn patient on left side and place in the head-low position. Notify physician.	
Clotted catheter line	Inadequate/infrequent heparin flushes	At direction of physician, flush with thrombolytic medication as prescribed.	Flush lines per established protocols. Monitor infusion rate hourly and inspect the integrity of the line.
	Disruption of infusion		
Catheter displacement and contamination	Excessive movement, possibly with a nonsecured catheter	Stop the infusion and notify the physician.	Examine all tubing connection sites. Avoid interrupting the main line or piggybacking other lines.
	Separation of tubing and contamination		
Sepsis	Separation of dressings	Reinforce or change dressing quickly using aseptic technique. Discard. Notify pharmacist.	Maintain sterile technique when changing tubing, dressing, or total nutrient admixture bag.
	Contaminated solution	Notify physician. Monitor vital signs.	
Hyperglycemia	Infection at insertion site of catheter	Notify physician; addition of insulin to PN solution may be prescribed.	Monitor glucose levels (blood and urine). Monitor urine output. Observe for stupor, confusion, or lethargy.
	Glucose intolerance		
Fluid overload	Fluid infusing rapidly	Decrease infusion rate. Monitor vital signs. Notify physician. Treat respiratory distress by sitting patient upright and administering oxygen as needed, if prescribed.	Use infusion pump. Verify correct infusion rate ordered.
Rebound hypoglycemia	Feedings stopped too abruptly	Monitor for symptoms (weakness, tremors, diaphoresis, headache, hunger, and apprehension); notify physician.	Gradually wean patient from PN.

During dressing changes, the nurse and patient wear masks to reduce the possibility of airborne contamination. Sterile technique is used. The area is checked for leakage, bloody or purulent drainage, a kinked catheter, and skin reactions such as inflammation, redness, swelling, or tenderness. The nurse wears sterile gloves and cleanses the area with tincture of 2% iodine or a chlorhexidine solution on sterile gauze. The site is cleaned thoroughly using a circular motion from the site outward to approximately 3 inches; this procedure is repeated two times. Then the same cleaning procedure is performed, using 2-by-2-inch gauze pads moistened with sterile water or saline solution. Next, the catheter ports are cleaned from the exit site to the distal end with an alcohol wipe. The insertion site is then redressed.

When an extension set is used with a central catheter, it is considered an extension of the catheter itself. It is not routinely changed with dressing or tubing changes. The dressing and tubing are labeled with the date, time of insertion, time of dressing change, and initials of the person who carried out the procedure; this information is also documented in the patient's medical record.

The catheter is another major source of colonization and infection. Researchers have conducted studies on the use of catheters with antiseptic coatings, antimicrobial coatings, and impregnated antimicrobial cuffs with inconsistent findings (Bacuzzi, Cecchin, Del Bosco, et al., 2006). Other proposals for prevention of infection include prophylactic antibiotic therapy, antithrombotics, various exit-site dressings, and various disinfectants for cleansing catheter exit sites.

Maintaining Fluid Balance

To maintain an accurate rate of PN administration, an infusion pump is necessary. A designated rate is set in milliliters per hour, and the rate is checked every 3 to 4 hours. The infusion rate should not be increased or decreased to compensate for fluids that have infused too quickly or too slowly. If the solution runs out, 10% dextrose and water is infused until the next PN solution is available from the pharmacy.

If the rate is too rapid, hyperosmolar diuresis can occur. Excess glucose is excreted by the renal tubules, pulling large volumes of water into the tubules via osmosis, resulting in higher-than-normal urine output and intravascular fluid

CHART
36-5**Ethics and Related Issues****The Difficult Discharge: Safety Versus Autonomy****Situation**

Patients are sometimes discharged home at a lower level of physical and emotional function than when they entered the hospital. This can be secondary to the burden of disease or deterioration after a procedure. Facilitation of a timely, safe discharge can be a challenge for patients requiring home parenteral nutrition support, especially if multiple therapies are required. Although the hospital nursing staff initiates appropriate infusion teaching for both the patient and caregiver(s), a home care nurse does the majority of the assessment and instruction after discharge.

Dilemma

Most patients prefer home over the acute care hospital for many reasons, including the desire to be near family and pets and to convalesce in familiar surroundings. To accomplish this, patients or families sometimes describe a distorted scenario of what can be safely provided for the patient at home, facilitating a possibly unsafe discharge plan. Yet identifying and addressing this with the patient, family, and the medical team will likely delay the patient's discharge and disappoint the patient and family.

Discussion

Consider the elderly patient postsurgery who needs home parenteral nutrition but lives alone and does not have family nearby. He states that his neighbor (also elderly) will assist

him but is unclear about how much time the neighbor is willing to give and the competency of the neighbor's skill sets.

- You have shown the patient proper technique for central line flushing, but he seems hesitant to do it himself and is unable to demonstrate independence with this basic care. He asks that you "sign him off" on the teaching sheet so that he can be cleared for discharge. What are your legal obligations in this situation? What options should you pursue?
- After several teaching sessions, you continue to have concerns about the patient's ability to be independent. His neighbor has been unable to come to the hospital to participate in the care. You verbalize to the patient that you are concerned that home parenteral support may not be a safe option for him. He is very upset and tells you that he has the right to go home and cannot be kept against his will. You explain that you only want him to be safe and to get well at home. From what ethical principle(s) does this conflict originate? What resources do you have in the hospital that may assist you in transitioning this patient out of the hospital?
- The physician clears the patient for discharge late in the afternoon, noting that a home infusion company has been arranged. Supplies will be delivered this evening if the patient arrives home in time to accept the delivery and meet with the nurse. You know he has a 2-hour ride home and there is a likelihood that he will not be home in time. With whom do you discuss this? What is the logistical, financial, and emotional impact of possibly canceling his extensively planned discharge? What is the overriding issue?

volume deficit. If the flow rate is too slow, the patient does not receive the maximal benefit of calories and nitrogen. Intake and output are recorded every 8 hours so that fluid imbalance can be readily detected.

Encouraging Activity

Activities and ambulation are encouraged when the patient is physically able. With a catheter in the subclavian vein, the patient is free to move the extremities, and normal activity should be encouraged to maintain good muscle tone. If applicable, the teaching and exercise program initiated by occupational and physical therapists is reinforced.

Promoting Home and Community-Based Care

TEACHING PATIENTS SELF-CARE. Successful home PN requires teaching the patient and family specialized skills using an intensive training program and follow-up supervision in the home. This is best accomplished through a team effort. Initiation of a home program facilitates the patient's discharge from the hospital.

Ideal candidates for home PN are patients who have a reasonable life expectancy after return home, have a limited number of illnesses other than the one that has resulted in the need for PN, and are highly motivated and fairly self-sufficient. Ethical dilemmas occur when the patient and

CHART
36-6**Assessing for Home Nutrition Support**

Be alert for the following assessment findings:

- Water: necessary for hand washing and cleaning of work areas
- Electricity: reliable power source is needed to provide proper lighting and charging of pumps
- Refrigeration: must be adequate for accommodation of several bags of parenteral nutrition solution
- Telephone: necessary for contacting home health personnel, arranging for prompt delivery of supplies, and for emergency purposes
- Environment:
 - Should be free of rodents and insects
 - Should have storage that is not accessible to pets and small children
 - Should be assessed for stairs, carpets, and inaccessible areas, which can limit mobility with infusion pumps if the patient has a disability

Chart 36-7 • Teaching Patients About Home Parenteral Nutrition

An effective home care teaching program prepares the patient to store solutions, set up the infusion, flush the line with heparin, change the dressings, and troubleshoot for problems. The most common complication is sepsis. Strict aseptic technique is taught for hand hygiene, handling equipment, changing the dressing, and preparing the solution.

Troubleshooting Mechanical Difficulties

Mechanical problems can arise with the infusion pump or catheter site. The patient should measure the external length of the catheter; this measurement is used as a comparison if dislodgement is suspected. The patient should receive a list of instructions on how to recognize catheter problems, including leakage, loose cap, blood clot, and dislodgement and what to do for each problem.

Recognizing Metabolic Complications

The patient is given a list of signs and symptoms that indicate metabolic complications (neuropathies, mentation

changes, diarrhea, nausea, skin changes, decreased urine output) and directions on how to contact the home health care nurse or physician if any of these complications occurs. The patient is instructed to have routine serum chemistry and hematology tests as well.

Obtaining Psychosocial Support

The psychosocial aspects of home parenteral nutrition are as important as the physiologic and technical concerns. Patients must cope with the loss of eating and with changes in lifestyle brought on by sleep disturbances related to frequent urination during night time infusions. Major psychosocial reactions include depression, anger, withdrawal, anxiety, and impaired self-image. A successful home parenteral nutrition program depends on the patient's and family's motivation, emotional stability, and technical competence.

family, as well as the caregiver, do not thoroughly understand what is involved in home PN (Chart 36-5). In addition, the ability to learn, availability of family interest and support, adequate finances, and the physical plan of the home are factors that must be assessed when the decision about home PN is made (Chart 36-6).

Many home health care agencies have developed teaching brochures and videos for home PN treatment. Topics include catheter and dressing care, use of an infusion pump, administration of fat emulsions, and instillation of heparin flushes. Teaching begins in the hospital and continues in the home or ambulatory infusion center (Chart 36-7).

CONTINUING CARE. The home care nurse should be aware that the typical patient needs several instruction sessions for assessment of learning and reinforcement. For more information about home patient education, see Chart 36-8. For special considerations for elderly patients who go home with nutrition support, see Chart 36-9.

Evaluation**Expected Patient Outcomes**

Expected patient outcomes may include the following:

1. Attains or maintains nutritional balance
2. Is free of catheter-related infection
 - a. Is afebrile
 - b. Has no purulent drainage from the catheter insertion site
3. Is hydrated, as evidenced by good skin turgor
4. Achieves an optimal level of activity, within limitations
5. Demonstrates skill in managing PN regimen
6. Prevents complications
 - a. Maintains proper catheter and equipment function
 - b. Maintains metabolic balance within normal limits

CHART 36-8  **HOME CARE CHECKLIST**
The Patient Receiving Parenteral Nutrition

At the completion of the home care instruction, the patient or caregiver will be able to:	PATIENT	CAREGIVER
• Discuss goal and purpose of PN therapy.	✓	✓
• Discuss basic components of PN solution.	✓	✓
• List emergency phone numbers.	✓	✓
• Demonstrate how to handle PN solutions and medications correctly.	✓	✓
• Demonstrate how to operate infusion pump.	✓	✓
• Demonstrate how to prime tubing and filter.	✓	✓
• Demonstrate how to connect and disconnect PN infusion.	✓	✓
• Demonstrate how to perform catheter dressing changes.	✓	✓
• Demonstrate how to flush central line.	✓	✓
• Identify possible PN complications and interventions.	✓	✓

CHART
36-9GERONTOLOGIC CONSIDERATIONS
Home Parenteral and Enteral Nutrition

Age-related conditions that affect home nutrition support goals include the following:

- Arthritis: possible decreased hand dexterity and fine motor coordination
- Sensory impairment: inability to hear pump alarms; vision loss may affect ability to see pump menus or fill syringes
- Constipation: decreased overall bowel tone, which can cause intolerance of enteral feedings; assess water and fiber intake
- Impaired thirst may require close clinical management of fluid needs
- Obesity: decreased basal metabolic rate increases tendency toward weight gain; may require a kilocalorie reduction to compensate
- Diabetes mellitus: increased insulin resistance, which makes glucose control during parenteral nutrition infusion more challenging
- Depression/dementia: mood and memory disorders, which may present as low motivation to learn and adhere to the nutrition support regimen
- Multiple medications: conversion to an appropriate route or form is required

Adapted from White, J., Brewer, D., Stockton, M., et al. (2003). Nutrition in chronic disease management in the elderly. *Nutrition in Clinical Practice, 18*(1), 3–11.

CRITICAL THINKING EXERCISES

1 You prepare to administer a patient's scheduled bolus enteral tube feeding, and he states that he feels too full for another feeding. It has been 4 hours since his last feeding. His stomach is somewhat distended but he has bowel sounds. What are some of the causes of abdominal fullness and distention? How would patterns of elimination affect these signs and symptoms? Whom should you consult?

EBP 2 A female patient has recently been diagnosed with a partial gastric outlet obstruction related to a duodenal mass. She initially required parenteral nutrition but is now tolerating nasogastric tube feedings and is scheduled for surgery in 1 week. She does not like that she has a visible tube in place and asks that she be placed back on her previous parenteral nutrition regimen until surgery. In responding to this patient, what evidence-based knowledge would you use to explain the rationale of enteral nutrition as more appropriate than parenteral nutrition? What is the strength of that evidence? How can you address her concerns regarding her change in body image?

3 A male patient has been struggling with mild obesity all his life and now has new x-ray evidence of small bowel inflammation and strictures from Crohn's disease. He will require several weeks of preoperative parenteral nutrition. He does not want a central access catheter placed and prefers to continue with simple IV fluids so that he can lose weight. What can you tell him about the nutritional advantages of total nutrient admixture (TNA) when compared with simple hydration fluids? Identify any advantages and disadvantages of significant weight loss in this preoperative period of acute illness.

4 You are preparing to administer a gravity bolus enteral tube feeding to a patient assigned to your care and remember that the patient has been experiencing significant diarrhea over the past 2 days. What types of medications could be contributing to the diarrhea? A consultation with a dietitian may be beneficial to assess what possible issues often implicated in diarrhea? What

suggestions would you make to the physician to further assess this problem?

chapter 37

Management of Patients With Gastric and Duodenal Disorders

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

- 1 Compare the etiology, clinical manifestations, and management of acute gastritis, chronic gastritis, and peptic ulcer.
- 2 Describe nursing management of patients with gastritis.
- 3 Use the nursing process as a framework for care of patients with peptic ulcer.
- 4 Describe the dietary, pharmacologic, and surgical treatment of peptic ulcer.
- 5 Describe the nursing management of patients who undergo surgical procedures to treat obesity.
- 6 Use the nursing process as a framework for care of patients with gastric cancer.
- 7 Use the nursing process as a framework for care of patients undergoing gastric surgery.
- 8 Identify the complications of gastric surgery and their prevention and management.
- 9 Describe the home health care needs of the patient who has had gastric surgery.

GLOSSARY

- achlorhydria:** lack of hydrochloric acid in digestive secretions of the stomach
- antrectomy:** removal of the pyloric (antrum) portion of the stomach with anastomosis (surgical connection) to the duodenum (gastroduodenostomy or Billroth I) or anastomosis to the jejunum (gastrojejunostomy or Billroth II)
- bariatric:** relating to obesity; term derives from two Greek words meaning "weight" and "treatment"
- dumping syndrome:** physiologic response to rapid emptying of gastric contents into the jejunum, manifested by nausea, weakness, sweating, palpitations, syncope, and possibly diarrhea; occurs in patients who have had partial gastrectomy and gastrojejunostomy
- duodenum:** first portion of the small intestine, between the stomach and the jejunum
- enteroclysis:** fluoroscopic x-ray of the small intestine; a tube is placed from the nose or mouth through the esophagus

GLOSSARY (Continued)

and the stomach to the duodenum, a barium-based liquid contrast material is infused through the tube, and x-rays are taken as it travels through the duodenum

gastric: refers to the stomach

gastric outlet obstruction: any condition that mechanically impedes normal gastric emptying; there is obstruction of the channel of the pylorus and duodenum through which the stomach empties

gastritis: inflammation of the stomach

Helicobacter pylori: a spiral-shaped gram-negative bacterium that colonizes the gastric mucosa; is involved in most cases of peptic ulcer disease

hematemesis: vomiting of blood

histamine-2 (H₂) receptor antagonist: a pharmacologic agent that inhibits histamine action at the H₂ receptors of the stomach, resulting in inhibition of gastric acid secretion

ligament of Treitz: suspensory ligament of the duodenum; important anatomic landmark used to divide the gastrointestinal tract into an upper and a lower portion

melena: tarry or black stools; indicative of blood in stools

morbid obesity: more than twice ideal body weight, 100 pounds or more over ideal body weight, or body mass index exceeding 40 kg/m²

omentum: fold of the peritoneum that surrounds the stomach and other organs of the abdomen

peritoneum: thin membrane that lines the inside of the wall of the abdomen and covers all the abdominal organs

proton pump inhibitors: pharmacologic agents that block acid secretion by irreversibly binding to and inhibiting the hydrogen-potassium adenosine triphosphatase pump system at the secretory surface of gastric parietal cells; most potent inhibitors of gastric acid secretion

pyloroplasty: surgical procedure to increase the opening of the pyloric orifice

pylorus: opening between the stomach and the duodenum

pyrosis: heartburn

serosa: thin membrane that covers the outer surface of the stomach; visceral peritoneum covering the outer surface of the stomach

stenosis: narrowing or tightening of an opening or passage in the body

A person's nutritional status depends not only on the type and amount of intake but also on the functioning of the gastric and intestinal portions of the gastrointestinal (GI) system. This chapter describes disorders of the stomach and duodenum, their treatment, and related nursing care.

Gastritis

Gastritis (inflammation of the **gastric** or stomach mucosa) is a common GI problem. Gastritis may be acute, lasting several hours to a few days, or chronic, resulting from repeated exposure to irritating agents or recurring episodes of acute gastritis.

Acute gastritis is often caused by dietary indiscretion—a person eats food that is irritating, too highly seasoned, or contaminated with disease-causing microorganisms. Other causes of acute gastritis include overuse of aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs), excessive alcohol intake, bile reflux, and radiation therapy. A more severe form of acute gastritis is caused by the ingestion of strong acid or alkali, which may cause the mucosa to become gangrenous or to perforate. Scarring can occur, resulting in pyloric **stenosis** or obstruction. Acute gastritis also may develop in acute illnesses, especially when the patient has had major traumatic injuries; burns; severe infection; hepatic, renal, or respiratory failure; or major surgery. Gastritis may be the first sign of an acute systemic infection.

Chronic gastritis and prolonged inflammation of the stomach may be caused either by benign or malignant ulcers of the stomach or by the bacteria *Helicobacter pylori*. Chronic gastritis is sometimes associated with autoimmune diseases such as pernicious anemia; dietary factors such as caffeine; the use of medications such as NSAIDs or

bisphosphonates (eg, alendronate [Fosamax], risedronate [Actonel], ibandronate [Boniva]); alcohol; smoking; or chronic reflux of pancreatic secretions and bile into the stomach.

Pathophysiology

In gastritis, the gastric mucous membrane becomes edematous and hyperemic (congested with fluid and blood) and undergoes superficial erosion (Fig. 37-1). It secretes a scanty amount of gastric juice, containing very little acid but much mucus. Superficial ulceration may occur and can lead to hemorrhage.

Clinical Manifestations

The patient with acute gastritis may have a rapid onset of symptoms, such as abdominal discomfort, headache, lassitude, nausea, anorexia, vomiting, and hiccupping, which can last from a few hours to a few days. The patient with chronic gastritis may complain of anorexia, heartburn after eating, belching, a sour taste in the mouth, or nausea and vomiting. Some patients may have only mild epigastric discomfort or report intolerance to spicy or fatty foods or slight pain that is relieved by eating. Patients with chronic gastritis from vitamin deficiency usually have evidence of malabsorption of vitamin B₁₂ caused by the production of antibodies that interfere with the binding of vitamin B₁₂ to intrinsic factor. However, some patients with chronic gastritis have no symptoms.

Assessment and Diagnostic Findings

Gastritis is sometimes associated with **achlorhydria** or **hypochlorhydria** (absence or low levels of hydrochloric acid [HCl]) or with **hyperchlorhydria** (high levels of HCl). Diagnosis can be determined by an upper GI x-ray series or endoscopy and histologic examination of a tissue specimen

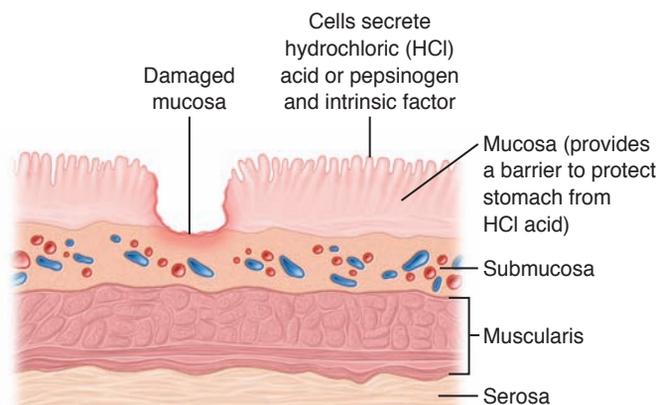

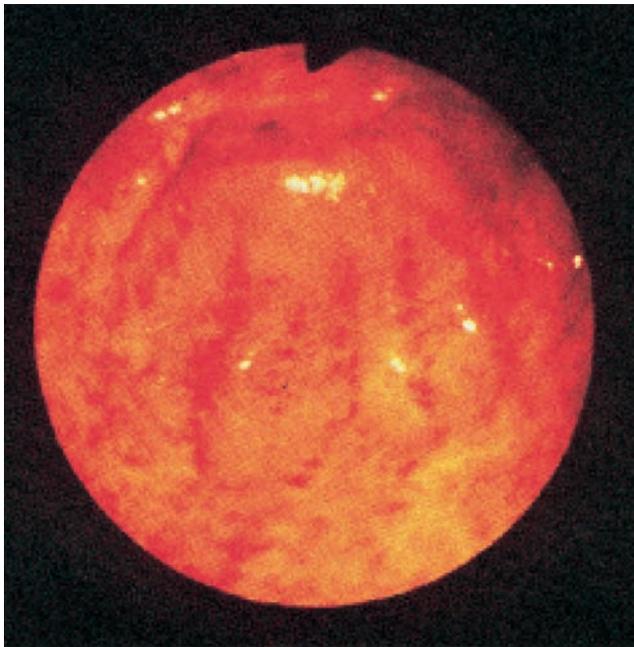

Figure 37-1 Endoscopic view of erosive gastritis (*left*). Damage from irritants (*right*) results in increased intracellular pH, impaired enzyme function, disrupted cellular structures, ischemia, vascular stasis, and tissue death. Reproduced with permission from Porth, C. M. & Matfin, G. (2009). *Pathophysiology: Concepts of altered health states* (8th ed.). Philadelphia: Lippincott Williams & Wilkins.

obtained by biopsy. Diagnostic measures for detecting *H. pylori* infection may be used and are discussed in the section on peptic ulcers.

Medical Management

The gastric mucosa is capable of repairing itself after an episode of gastritis. As a rule, the patient recovers in about 1 day, although the appetite may be diminished for an additional 2 or 3 days. Acute gastritis is also managed by instructing the patient to refrain from alcohol and food until symptoms subside. When the patient can take nourishment by mouth, a nonirritating diet is recommended. If the symptoms persist, intravenous (IV) fluids may need to be administered. If bleeding is present, management is similar to the procedures used to control upper GI tract hemorrhage discussed later in this chapter.

If gastritis is caused by ingestion of strong acids or alkalis, emergency treatment consists of diluting and neutralizing the offending agent. To neutralize acids, common antacids (eg, aluminum hydroxide) are used; to neutralize an alkali, diluted lemon juice or diluted vinegar is used. If corrosion is extensive or severe, emetics and lavage are avoided because of the danger of perforation and damage to the esophagus.

Therapy is supportive and may include nasogastric (NG) intubation, analgesic agents and sedatives, antacids, and IV fluids. Fiberoptic endoscopy may be necessary. In extreme cases, emergency surgery may be required to remove gangrenous or perforated tissue. A gastric resection or a gastrojejunostomy (anastomosis of jejunum to stomach to detour around the pylorus) may be necessary to treat pyloric obstruction, a narrowing of the pyloric orifice, which cannot be relieved by medical management.

Chronic gastritis is managed by modifying the patient's diet, promoting rest, reducing stress, recommending avoidance of alcohol and NSAIDs, and initiating pharmacotherapy. *H. pylori* may be treated with selected drug combinations (Table 37-1).

Nursing Management

Reducing Anxiety

If the patient has ingested acids or alkalis, emergency measures may be necessary. The nurse offers supportive therapy to the patient and family during treatment and after the ingested acid or alkali has been neutralized or diluted. In some cases, the nurse may need to prepare the patient for additional diagnostic studies (endoscopies) or surgery. The patient may be anxious because of pain and planned treatment modalities. The nurse uses a calm approach to assess the patient and to answer all questions as completely as possible. It is important to explain all procedures and treatments based on the patient's level of understanding.

Promoting Optimal Nutrition

For acute gastritis, the nurse provides physical and emotional support and helps the patient manage the symptoms, which may include nausea, vomiting, heartburn, and fatigue. The patient should take no foods or fluids by mouth—possibly for a few days—until the acute symptoms subside, thus allowing the gastric mucosa to heal. If IV therapy is necessary, the

nurse monitors fluid intake and output along with serum electrolyte values. After the symptoms subside, the nurse may offer the patient ice chips followed by clear liquids. Introducing solid food as soon as possible may provide adequate oral nutrition, decrease the need for IV therapy, and minimize irritation to the gastric mucosa. As food is introduced, the nurse evaluates and reports any symptoms that suggest a repeat episode of gastritis.

The nurse discourages the intake of caffeinated beverages, because caffeine is a central nervous system stimulant that increases gastric activity and pepsin secretion. It also is important to discourage alcohol use. Discouraging cigarette smoking is important because nicotine reduces the secretion of pancreatic bicarbonate, which inhibits the neutralization of gastric acid in the duodenum (Suzuki, Matsuo, Ito, et al., 2006). When appropriate, the nurse initiates and refers the patient for alcohol counseling and smoking cessation programs.

Promoting Fluid Balance

Daily fluid intake and output are monitored to detect early signs of dehydration (minimal fluid intake of 1.5 L/day, minimal output of 30 mL/h). If food and oral fluids are withheld, IV fluids (3 L/day) usually are prescribed and a record of fluid intake plus caloric value (1 L of 5% dextrose in water = 170 calories of carbohydrate) needs to be maintained. Electrolyte values (sodium, potassium, chloride) are assessed every 24 hours to detect any imbalance.

The nurse must always be alert for any indicators of hemorrhagic gastritis, which include **hematemesis** (vomiting of blood), tachycardia, and hypotension. If these occur, the physician is notified and the patient's vital signs are monitored as the patient's condition warrants. Guidelines for managing upper GI tract bleeding are discussed later in this chapter.

Relieving Pain

Measures to help relieve pain include instructing the patient to avoid foods and beverages that may be irritating to the gastric mucosa and instructing the patient about the correct use of medications to relieve chronic gastritis. The nurse must regularly assess the patient's level of pain and the extent of comfort achieved through the use of medications and avoidance of irritating substances.

Promoting Home and Community-Based Care

Teaching Patients Self-Care

The nurse evaluates the patient's knowledge about gastritis and develops an individualized teaching plan that includes information about stress management, diet, and medications (Chart 37-1). Dietary instructions take into account the patient's daily caloric needs, food preferences, and pattern of eating. The nurse and patient review foods and other substances to be avoided (eg, spicy, irritating, or highly seasoned foods; caffeine; nicotine; alcohol). Consultation with a dietitian may be recommended.

Providing information about prescribed antibiotics, bismuth salts, medications to decrease gastric secretion, and medications to protect mucosal cells from gastric secretions may help the patient to better understand why these

Table 37-1 PHARMACOTHERAPY FOR PEPTIC ULCER DISEASE AND GASTRITIS		
Pharmacologic Agent	Major Action	Key Nursing Considerations
Antibiotics		
Amoxicillin (Amoxil)	A bactericidal antibiotic that assists with eradicating <i>H. pylori</i> bacteria in the gastric mucosa	<ul style="list-style-type: none"> • May cause diarrhea • Should not be used in patients allergic to penicillin
Clarithromycin (Biaxin)	Exerts bactericidal effects to eradicate <i>H. pylori</i> bacteria in the gastric mucosa	<ul style="list-style-type: none"> • May cause GI upset, headache, altered taste • Many drug–drug interactions (eg, cisapride, colchicine, lovastatin, warfarin [Coumadin])
Metronidazole (Flagyl)	A synthetic antibacterial and antiprotozoal agent that assists with eradicating <i>H. pylori</i> bacteria in the gastric mucosa when administered with other antibiotics and proton pump inhibitors	<ul style="list-style-type: none"> • Should be administered with meals to decrease GI upset; may cause anorexia and metallic taste • Patient should avoid alcohol; Flagyl increases blood-thinning effects of warfarin (Coumadin)
Tetracycline	Exerts bacteriostatic effects to eradicate <i>H. pylori</i> bacteria in the gastric mucosa	<ul style="list-style-type: none"> • May cause photosensitivity reaction; warn patient to use sunscreen • May cause GI upset • Must be used with caution in patients with renal or hepatic impairment • Milk or dairy products may reduce effectiveness
Antidiarrheal		
Bismuth subsalicylate (Pepto-Bismol)	Suppresses <i>H. pylori</i> bacteria in the gastric mucosa and assists with healing of mucosal ulcers	<ul style="list-style-type: none"> • Given concurrently with antibiotics to eradicate <i>H. pylori</i> infection • Should be taken on empty stomach
Histamine-2 (H₂) Receptor Antagonists		
Cimetidine (Tagamet)	Decreases amount of HCl produced by stomach by blocking action of histamine on histamine receptors of parietal cells in the stomach	<ul style="list-style-type: none"> • Least expensive of H₂ receptor antagonists • May cause confusion, agitation, or coma in the elderly or those with renal or hepatic insufficiency • Long-term use may cause diarrhea, dizziness, gynecomastia • Many drug–drug interactions (eg, amiodarone, amitriptyline, benzodiazepines, metoprolol, nifedipine, phenytoin, warfarin [Coumadin])
Famotidine (Pepcid)	Same as for cimetidine	<ul style="list-style-type: none"> • Best choice for critically ill patient because it is known to have the least risk of drug–drug interactions; does not alter liver metabolism • Prolonged half-life in patients with renal insufficiency
Nizatidine (Axid)	Same as for cimetidine	<ul style="list-style-type: none"> • Short-term relief for GERD • Used for treatment of ulcers and GERD • Prolonged half-life in patients with renal insufficiency • May cause headache, dizziness, diarrhea, nausea/vomiting, GI upset as well as urticaria
Ranitidine (Zantac)	Same as for cimetidine	<ul style="list-style-type: none"> • Prolonged half-life in patients with renal and hepatic insufficiency • Causes fewer side effects than cimetidine • May cause headache, dizziness, constipation, nausea and vomiting, or abdominal discomfort
Proton Pump Inhibitors of Gastric Acid (PPIs)		
Esomeprazole (Nexium)	Decreases gastric acid secretion by slowing the hydrogen-potassium adenosine triphosphatase (H ⁺ , K ⁺ -ATPase) pump on the surface of the parietal cells of the stomach	<ul style="list-style-type: none"> • Used mainly for treatment of duodenal ulcer disease and <i>H. pylori</i> infection • A delayed-release capsule that is to be swallowed whole and taken before meals
Lansoprazole (Prevacid)	Decreases gastric acid secretion by slowing the H ⁺ , K ⁺ -ATPase pump on the surface of the parietal cells	<ul style="list-style-type: none"> • A delayed-release capsule that is to be swallowed whole and taken before meals
Omeprazole (Prilosec)	Same as for lansoprazole	<ul style="list-style-type: none"> • A delayed-release capsule that is to be swallowed whole and taken before meals • May cause diarrhea, nausea, constipation, abdominal pain, vomiting, headache, or dizziness
Pantoprazole (Protonix)	Same as for lansoprazole	<ul style="list-style-type: none"> • A delayed-release capsule that is to be swallowed whole and taken before meals • May cause diarrhea and hyperglycemia, headache, abdominal pain, and abnormal liver function tests
Rabeprazole (AcipHex)	Same as for lansoprazole	<ul style="list-style-type: none"> • A delayed-release tablet to be swallowed whole • May cause abdominal pain, diarrhea, nausea, and headache • Drug–drug interactions with digoxin, iron, and warfarin (Coumadin)

Continued on following page

Table 37-1 PHARMACOTHERAPY FOR PEPTIC ULCER DISEASE AND GASTRITIS (Continued)

Pharmacologic Agent	Major Action	Key Nursing Considerations
Prostaglandin E ₁ Analogue Misoprostol (Cytotec)	Synthetic prostaglandin; protects the gastric mucosa from agents that cause ulcers; also increases mucous production and bicarbonate levels	<ul style="list-style-type: none"> • Used to prevent ulceration in patients using NSAIDs • Administer with food • May cause diarrhea and cramping (including uterine cramping)
Sucralfate (Carafate)	Creates a viscous substance in the presence of gastric acid that forms a protective barrier, binding to the surface of the ulcer, and prevents digestion by pepsin	<ul style="list-style-type: none"> • Used mainly for the treatment of duodenal ulcers • Should be taken without food but with water • Other medications should be taken 2 h before or after this medication • May cause constipation or nausea

GERD, gastroesophageal reflux disease; GI, gastrointestinal; NSAID, nonsteroidal anti-inflammatory drug.

medications assist in recovery and prevent recurrence. The importance of completing the medication regimen as prescribed to eradicate *H. pylori* infection must be reinforced to the patient and any caregivers.

Continuing Care

The nurse reinforces previous teaching and conducts ongoing assessment of the patient's symptoms and progress. Patients with malabsorption of vitamin B₁₂ need information about lifelong vitamin B₁₂ injections; the nurse may instruct a family member or caregiver how to administer the injections or make arrangements for the patient to receive the injections from a health care provider. Finally, the nurse emphasizes the importance of keeping follow-up appointments with health care providers.

Peptic Ulcer Disease

A peptic ulcer may be referred to as a gastric, duodenal, or esophageal ulcer, depending on its location. A peptic ulcer is an excavation (hollowed-out area) that forms in the mucosal wall of the stomach, in the **pylorus** (the opening between the stomach and duodenum), in the **duodenum** (the first part of the small intestine), or in the esophagus. Erosion of a circumscribed area of mucous membrane is the cause (Fig. 37-2). This erosion may extend as deeply as the muscle layers or through the muscle to the **peritoneum**.

Peptic ulcers are more likely to occur in the duodenum than in the stomach. As a rule they occur alone, but they

may occur in multiples. Chronic gastric ulcers tend to occur in the lesser curvature of the stomach, near the pylorus. Table 37-2 compares the features of gastric and duodenal ulcers. Esophageal ulcers occur as a result of the backward flow of HCl from the stomach into the esophagus (gastroesophageal reflux disease [GERD]).

Peptic ulcer disease occurs with the greatest frequency in people between 40 and 60 years of age. It is relatively uncommon in women of childbearing age, but it has been observed in children and even in infants. After menopause, the incidence of peptic ulcers in women is almost equal to that in men. Peptic ulcers in the body of the stomach can occur without excessive acid secretion.

In the past, stress and anxiety were thought to be causes of ulcers, but research has documented that peptic ulcers result from infection with the gram-negative bacteria *H. pylori*, which may be acquired through ingestion of food and water. Person-to-person transmission of the bacteria also occurs through close contact and exposure to emesis. Although *H. pylori* infection is common in the United States, most infected people do not develop ulcers. It is not known why *H. pylori* infection does not cause ulcers in all people, but most likely the predisposition to ulcer formation depends on certain factors, such as the type of *H. pylori* and other as yet unknown factors (Makola, Peura & Crowe, 2007).

In addition, excessive secretion of HCl in the stomach may contribute to the formation of peptic ulcers, and stress may be associated with its increased secretion. The ingestion of milk and caffeinated beverages, smoking, and alcohol also

CHART 37-1 HOME CARE CHECKLIST *The Patient With Gastritis*

At the completion of the home care instruction, the patient or caregiver will be able to:	PATIENT	CAREGIVER
• Identify foods and other substances that may cause gastritis.	✓	✓
• Report inability to ingest adequate solids and liquids.	✓	✓
• Describe medication regimen.	✓	✓
• State need for vitamin B ₁₂ injections if patient has pernicious anemia.	✓	✓
• State schedule of follow-up appointments with health care provider.	✓	✓

Figure 37-2 Deep peptic ulcer. From Rubin, R., Strayer, D. S., Rubin, E., et al. (2008). *Rubin's pathology: Clinicopathologic foundations of medicine* (5th ed.). Philadelphia: Lippincott Williams & Wilkins.

may increase HCl secretion. Stress and eating spicy foods may make peptic ulcers worse.

Familial tendency also may be a significant predisposing factor. People with blood type O are more susceptible to peptic ulcers than are those with blood type A, B, or AB. There also is an association between peptic ulcers and chronic pulmonary disease or chronic renal disease. Other predisposing factors associated with peptic ulcer include chronic use of NSAIDs, alcohol ingestion, and excessive smoking.

Table 37-2 COMPARISON OF DUODENAL AND GASTRIC ULCERS

Duodenal Ulcer	Gastric Ulcer
Incidence	
Age 30–60	Usually 50 and over
Male:female = 2–3:1	Male:female = 1:1
80% of peptic ulcers are duodenal	15% of peptic ulcers are gastric
Signs, Symptoms, and Clinical Findings	
Hypersecretion of stomach acid (HCl)	Normal—hyposecretion of stomach acid (HCl)
May have weight gain	Weight loss may occur
Pain occurs 2–3 h after a meal; often awakened 1–2 AM; ingestion of food relieves pain	Pain occurs ½ to 1 h after a meal; rarely occurs at night; may be relieved by vomiting; ingestion of food does not help, sometimes increases pain
Vomiting uncommon	Vomiting common
Hemorrhage less likely than with gastric ulcer, but if present, melena more common than hematemesis	Hemorrhage more likely to occur than with duodenal ulcer; hematemesis more common than melena
More likely to perforate than gastric ulcers	
Malignancy Possibility	
Rare	Occasionally
Risk Factors	
<i>H. pylori</i> , alcohol, smoking, cirrhosis, stress	<i>H. pylori</i> , gastritis, alcohol, smoking, use of NSAIDs, stress

NSAID, nonsteroidal anti-inflammatory drug.

Peptic ulcers are found in rare cases in patients with tumors that cause secretion of excessive amounts of the hormone gastrin. The Zollinger-Ellison syndrome (ZES) consists of severe peptic ulcers, extreme gastric hyperacidity, and gastrin-secreting benign or malignant tumors of the pancreas.

Pathophysiology

Peptic ulcers occur mainly in the gastroduodenal mucosa because this tissue cannot withstand the digestive action of gastric acid (HCl) and pepsin. The erosion is caused by the increased concentration or activity of acid–pepsin or by decreased resistance of the mucosa. A damaged mucosa cannot secrete enough mucus to act as a barrier against HCl. The use of NSAIDs inhibits the secretion of mucus that protects the mucosa. Patients with duodenal ulcers secrete more acid than normal, whereas patients with gastric ulcers tend to secrete normal or decreased levels of acid. Damage to the gastroduodenal mucosa results in decreased resistance to bacteria, and thus infection from *H. pylori* bacteria may occur.

ZES is suspected when a patient has several peptic ulcers or an ulcer that is resistant to standard medical therapy. It is identified by the following: hypersecretion of gastric juice, duodenal ulcers, and gastrinomas (islet cell tumors) in the pancreas. Ninety percent of tumors are found in the “gastric triangle,” which encompasses the cystic and common bile ducts, the second and third portions of the duodenum, and the junction of the head and body of the pancreas. Approximately one third of gastrinomas are malignant. Diarrhea and steatorrhea (unabsorbed fat in the stool) may be evident. The patient may have coexisting parathyroid adenomas or hyperplasia and may therefore exhibit signs of hypercalcemia. The most common symptom is epigastric pain. *H. pylori* is not a risk factor for ZES (Sesler, 2007).

Stress ulcer is the term given to the acute mucosal ulceration of the duodenal or gastric area that occurs after physiologically stressful events, such as burns, shock, severe sepsis, and multiple organ traumas. These ulcers, which are clinically different from peptic ulcers, are most common in ventilator-dependent patients after trauma or surgery. Fiberoptic endoscopy within 24 hours of trauma or surgery reveals shallow erosions of the stomach wall; by 72 hours, multiple gastric erosions are observed. As the stressful condition continues, the ulcers spread. When the patient recovers, the lesions are reversed. This pattern is typical of stress ulceration.

Differences of opinion exist as to the actual cause of mucosal ulceration in stress ulcers. Usually, the ulceration is preceded by shock; this leads to decreased gastric mucosal blood flow and to reflux of duodenal contents into the stomach. In addition, large quantities of pepsin are released. The combination of ischemia, acid, and pepsin creates an ideal climate for ulceration (Sesler, 2007).

Stress ulcers should be distinguished from Cushing’s ulcers and Curling’s ulcers, two other types of gastric ulcers. Cushing’s ulcers are common in patients with head injury and brain trauma. They may occur in the esophagus, stomach, or duodenum and are usually deeper and more penetrating than stress ulcers. Curling’s ulcer is frequently observed about 72 hours after extensive burns and involves the antrum of the stomach or the duodenum.

Clinical Manifestations

Symptoms of an ulcer may last for a few days, weeks, or months and may disappear only to reappear, often without an identifiable cause. Many people with ulcers have no symptoms, and perforation or hemorrhage may occur in 20% to 30% of patients who had no preceding manifestations.

As a rule, the patient with an ulcer complains of dull, gnawing pain or a burning sensation in the midepigastrium or the back. It is believed that the pain occurs when the increased acid content of the stomach and duodenum erodes the lesion and stimulates the exposed nerve endings. Another theory suggests that contact of the lesion with acid stimulates a local reflex mechanism that initiates contraction of the adjacent smooth muscle. Pain is usually relieved by eating, because food neutralizes the acid, or by taking alkali; however, once the stomach has emptied or the alkali's effect has decreased, the pain returns. Sharply localized tenderness can be elicited by applying gentle pressure to the epigastrium at or slightly to the right of the midline.

Other symptoms include **pyrosis** (heartburn), vomiting, constipation or diarrhea, and bleeding. Pyrosis is a burning sensation in the stomach and esophagus that moves up to the mouth. Heartburn is often accompanied by sour eructation, or burping, which is common when the patient's stomach is empty.

Although vomiting is rare in uncomplicated duodenal ulcer, it may be a symptom of a complication of an ulcer. It results from obstruction of the pyloric orifice, caused by either muscular spasm of the pylorus or mechanical obstruction from scarring or acute swelling of the inflamed mucous membrane adjacent to the ulcer. Vomiting may or may not be preceded by nausea; usually it follows a bout of severe pain and bloating, which is relieved by vomiting. Emesis often contains undigested food eaten many hours earlier. Constipation or diarrhea may occur, probably as a result of diet and medications.

Fifteen percent of patients with peptic ulcer experience bleeding. Patients may present with GI bleeding as evidenced by the passage of **melena** (tarry stools). A small portion of patients who bleed from an acute ulcer have only very mild symptoms or none at all (Barba, Fitzgerald & Wood, 2007).

Assessment and Diagnostic Findings

A physical examination may reveal pain, epigastric tenderness, or abdominal distention. A barium study of the upper GI tract may show an ulcer; however, endoscopy is the preferred diagnostic procedure because it allows direct visualization of inflammatory changes, ulcers, and lesions. Through endoscopy, a biopsy of the gastric mucosa and of any suspicious lesions can be obtained. Endoscopy may reveal lesions that, because of their size or location, are not evident on x-ray studies.

Stools may be tested periodically until they are negative for occult blood. Gastric secretory studies are of value in diagnosing achlorhydria and ZES. *H. pylori* infection may be determined by endoscopy and histologic examination of a tissue specimen obtained by biopsy, or a rapid urease test of

the biopsy specimen. Other less invasive diagnostic measures for detecting *H. pylori* include serologic testing for antibodies against the *H. pylori* antigen, stool antigen test, and urea breath test.

Medical Management

Once the diagnosis is established, the patient is informed that the condition can be controlled. Recurrence may develop; however, peptic ulcers treated with antibiotics to eradicate *H. pylori* have a lower recurrence rate than those not treated with antibiotics. The goals are to eradicate *H. pylori* and to manage gastric acidity. Methods used include medications, lifestyle changes, and surgical intervention.

Pharmacologic Therapy

Currently, the most commonly used therapy for peptic ulcers is a combination of antibiotics, proton pump inhibitors, and bismuth salts that suppress or eradicate *H. pylori*. Recommended therapy for 10 to 14 days includes triple therapy with two antibiotics (eg, metronidazole [Flagyl] or amoxicillin [Amoxil] and clarithromycin [Biaxin]) plus a proton pump inhibitor (eg, lansoprazole [Prevacid], omeprazole [Prilosec], or rabeprazole [Aciphex]), or quadruple therapy with two antibiotics (metronidazole and tetracycline) plus a proton pump inhibitor and bismuth salts (Pepto-Bismol). Research is being conducted to develop a vaccine against *H. pylori* (Kabir, 2007).

Histamine-2 (H₂) receptor antagonists and **proton pump inhibitors** are used to treat NSAID-induced ulcers and other ulcers not associated with *H. pylori* infection. Table 37-3 provides information about the medication regimens used for peptic ulcer disease. (Table 37-1 presents details about specific medications.)

The patient is advised to adhere to and complete the medication regimen to ensure complete healing of the ulcer. Because most patients become symptom-free within a week, the nurse stresses to the patient the importance of following the prescribed regimen so that the healing process can continue uninterrupted and the return of chronic ulcer symptoms can be prevented. Rest, sedatives, and tranquilizers may be added for the patient's comfort and are prescribed as needed. Maintenance dosages of H₂ receptor antagonists are usually recommended for 1 year.

For patients with ZES, hypersecretion of acid may be controlled with high doses of H₂ receptor antagonists. These patients may require twice the normal dose, and dosages usually need to be increased with prolonged use. Octreotide (Sandostatin), a medication that suppresses gastrin levels, also may be prescribed.

Patients at risk for stress ulcers (eg, patients with head injury or extensive burns) may be treated prophylactically with IV H₂ receptor antagonists and cytoprotective agents (eg, misoprostol, sucralfate) because of the risk of upper GI tract hemorrhage.

Stress Reduction and Rest

Reducing environmental stress requires physical and psychological modifications on the patient's part as well as the aid and cooperation of family members and significant others. The nurse assists the patient to identify situations

Indications	Drug Regimen	Comments
Ulcer healing	H₂ receptor antagonists Ranitidine 150 mg bid or 300 mg at bedtime Cimetidine 400 mg bid or 800 mg at bedtime Famotidine 20 mg bid or 40 mg at bedtime Nizatidine 150 mg bid or 300 mg at bedtime Proton pump inhibitors (PPIs) Omeprazole 20 mg daily Lansoprazole 30 mg daily Rabeprazole 20 mg daily Pantoprazole 40 mg daily Esomeprazole 40 mg daily	Should be used for 6 weeks for duodenal ulcer; 8 weeks for gastric ulcer Should be used for 4 weeks for duodenal ulcer and 6 weeks for gastric ulcer Healing occurs in 90% of patients who are compliant with therapy
Initial <i>H. pylori</i> therapy	First-line therapy: PPI twice a day plus clarithromycin 500 mg twice a day plus amoxicillin 1000 mg twice a day or metronidazole 500 mg twice a day for 10–14 days Second-line therapy: Pepto-Bismol 2 tabs four times a day plus tetracycline 250 mg four times a day plus metronidazole 250 mg four times a day (optional: add PPI daily) for 14 days	Efficacy of therapy is approximately 85% Qid dosing may decrease compliance
Therapy for retreatment of <i>H. pylori</i> therapy failure	Repeat first-line therapy, substitute metronidazole for amoxicillin (or vice versa) for 14 days; may add Pepto-Bismol Add second-line <i>H. pylori</i> therapy Peptic ulcer healing doses of PPIs (above) Misoprostol 200 µg twice a day	Efficacy of retreatment not known; success of more than 2 courses of treatment is very low
Prophylactic therapy for NSAID ulcers		Prevents recurrent ulceration in approximately 80%–90% of patients

NSAID, nonsteroidal anti-inflammatory drug.

that are stressful or exhausting. A hectic lifestyle and an irregular schedule may aggravate symptoms and interfere with regular meals taken in relaxed settings along with the regular administration of medications. The patient may benefit from regular rest periods during the day, at least during the acute phase of the disease. Biofeedback, hypnosis, behavior modification, massage, or acupuncture may be helpful.

Smoking Cessation

Studies have shown that smoking decreases the secretion of bicarbonate from the pancreas into the duodenum, resulting in increased acidity of the duodenum. Research indicates that continued smoking may significantly inhibit ulcer repair (Suzuki, et al., 2006). Therefore, the patient is strongly encouraged to stop smoking.

Dietary Modification

The intent of dietary modification for patients with peptic ulcers is to avoid oversecretion of acid and hypermotility in the GI tract. These can be minimized by avoiding extremes of temperature of food and beverage and overstimulation from consumption of meat extracts, alcohol, coffee (including decaffeinated coffee, which also stimulates acid secretion) and other caffeinated beverages, and diets rich in milk and cream (which stimulate acid secretion). In addition, an effort is made to neutralize acid by eating three regular meals a day. Small, frequent feedings are not necessary as long as an antacid or a histamine blocker is taken. Diet compatibility becomes an individual matter: The patient eats foods that are tolerated and avoids those that produce pain.

Surgical Management

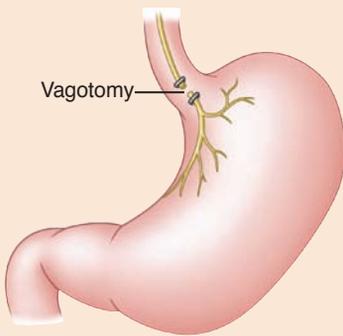

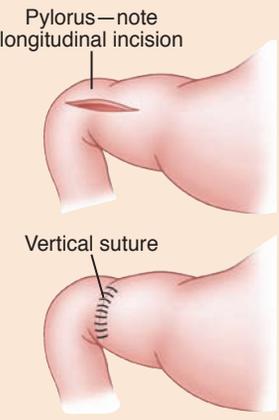

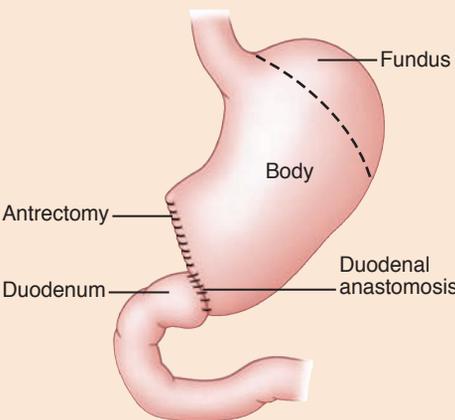

The introduction of antibiotics to eradicate *H. pylori* and of H₂ receptor antagonists as treatment for ulcers has greatly reduced the need for surgical intervention. However, surgery is usually recommended for patients with intractable ulcers (those that fail to heal after 12 to 16 weeks of medical treatment), life-threatening hemorrhage, perforation, or obstruction and for those with ZES that is unresponsive to medications (Ramakrishnan & Salinas, 2007). Surgical procedures include vagotomy, with or without **pyloroplasty** (transecting nerves that stimulate acid secretion and opening the pylorus), and **antrectomy**, which is removal of the pyloric (antrum) portion of the stomach with anastomosis (surgical connection) to either the duodenum (gastroduodenostomy or Billroth I) or jejunum (gastrojejunostomy or Billroth II) (Table 37-4; see also the section on gastric surgery later in this chapter).

Patients who require surgery may have had a long illness. They may be discouraged and have had interruptions in their work and pressures in their family life that affect their outlook on surgery and resolution of their disease.

Follow-Up Care

Recurrence of peptic ulcer disease within 1 year may be prevented with the prophylactic use of H₂ receptor antagonists taken at a reduced dose. Not all patients require maintenance therapy; it may be prescribed only for those with two or three recurrences per year, those who have had a complication such as bleeding or gastric outlet obstruction, or those who are candidates for gastric surgery but for whom it poses too high a risk. The likelihood of

Table 37-4 SURGICAL PROCEDURES FOR PEPTIC ULCER DISEASE

Operation	Description	Comments
<p>Vagotomy</p> 	<p>Severing of the vagus nerve. Decreases gastric acid by diminishing cholinergic stimulation to the parietal cells, making them less responsive to gastrin. May be performed via open surgical approach, laparoscopy, or thoracoscopy</p>	<p>May be performed to reduce gastric acid secretion. A drainage type of procedure (see pyloroplasty) is usually performed to assist with gastric emptying (because there is total denervation of the stomach). Some patients experience problems with feeling of fullness, dumping syndrome, diarrhea, and gastritis.</p>
<p>Truncal vagotomy</p>	<p>Severs the right and left vagus nerves as they enter the stomach at the distal part of the esophagus</p>	<p>This type of vagotomy is most commonly used to decrease acid secretions and reduce gastric and intestinal motility. Recurrence rate of ulcer is 10%–15%.</p>
<p>Selective vagotomy</p>	<p>Severs vagal innervation to the stomach but maintains innervation to the rest of the abdominal organs</p>	<p>No dumping syndrome. No need for drainage procedure. Recurrence rate of ulcer is 10%–15%.</p>
<p>Proximal (parietal cell) gastric vagotomy without drainage</p>	<p>Denervates acid-secreting parietal cells but preserves vagal innervation to the gastric antrum and pylorus</p>	<p>Usually accompanies truncal and selective vagotomies, which produce delayed gastric emptying due to decreased innervation.</p>
<p>Pyloroplasty</p> 	<p>Longitudinal incision is made into the pylorus and transversely sutured closed to enlarge the outlet and relax the muscle</p>	<p>Usually accompanies truncal and selective vagotomies, which produce delayed gastric emptying due to decreased innervation.</p>
<p>Antrectomy Billroth I (gastroduodenostomy)</p> 	<p>Removal of the lower portion of the antrum of the stomach (which contains the cells that secrete gastrin) as well as a small portion of the duodenum and pylorus. The remaining segment is anastomosed to the duodenum</p>	<p>May be performed in conjunction with a truncal vagotomy. The patient may have problems with feeling of fullness, dumping syndrome, and diarrhea. Recurrence rate of ulcer is <1%.</p>

Continued on following page

Table 37-4 SURGICAL PROCEDURES FOR PEPTIC ULCER DISEASE (Continued)

Operation	Description	Comments
Billroth II (gastrojejunostomy)	Removal of lower portion (antrum) of stomach with anastomosis to jejunum. Dotted lines show portion removed (antrectomy). A duodenal stump remains and is oversewn.	Dumping syndrome, anemia, malabsorption, weight loss. Recurrence rate of ulcer is 10%–15%.

recurrence is reduced if the patient avoids smoking, coffee (including decaffeinated coffee) and other caffeinated beverages, alcohol, and ulcerogenic medications (eg, NSAIDs).

NURSING PROCESS

THE PATIENT WITH PEPTIC ULCER DISEASE

Assessment

The nurse asks the patient to describe the pain and strategies used to relieve it (eg, food, antacids). The patient usually describes peptic ulcer pain as burning or gnawing; it occurs about 2 hours after a meal and frequently awakens the patient between midnight and 3 AM. Taking antacids, eating, or vomiting often relieves the pain. If the patient reports a recent history of vomiting, the nurse determines how often emesis has occurred and notes important characteristics of the vomitus: Is it bright red, does it resemble coffee grounds, or is there undigested food from previous meals? Has the patient noted any bloody or tarry stools?

The nurse also asks the patient to list his or her usual food intake for a 72-hour period and to describe food habits (eg, speed of eating, regularity of meals, preference for spicy foods, use of seasonings, use of caffeinated beverages and decaffeinated coffee). Lifestyle and other habits are a concern as well. Does the patient use irritating substances? For example, does he or she smoke cigarettes? If yes, how many? Does the patient ingest alcohol? If yes, how much and how often? Are NSAIDs used? The nurse inquires about the patient's level of anxiety and his or her perception of current stressors. How does the patient express anger or cope with stressful situations? Is the patient experiencing occupational stress or problems within the family? Is there a family history of ulcer disease?

The nurse assesses the patient's vital signs and reports tachycardia and hypotension, which may indicate anemia from GI bleeding. The stool is tested for occult blood, and a physical examination, including palpation of the abdomen for localized tenderness, is performed.

Diagnosis

Nursing Diagnoses

Based on the assessment data, the patient's nursing diagnoses may include the following:

- Acute pain related to the effect of gastric acid secretion on damaged tissue
- Anxiety related to an acute illness
- Imbalanced nutrition related to changes in diet
- Deficient knowledge about prevention of symptoms and management of the condition

Collaborative Problems/Potential Complications

Potential complications may include the following:

- Hemorrhage
- Perforation
- Penetration
- Pyloric obstruction (gastric outlet obstruction)

Planning and Goals

The goals for the patient may include relief of pain, reduced anxiety, maintenance of nutritional requirements, knowledge about the management and prevention of ulcer recurrence, and absence of complications.

Nursing Interventions

Relieving Pain

Pain relief can be achieved with prescribed medications. The patient should avoid aspirin, foods and beverages that contain caffeine, and decaffeinated coffee. In addition, meals should be eaten at regularly paced intervals in a relaxed

setting. Some patients benefit from learning relaxation techniques to help manage stress and pain.

Reducing Anxiety

The nurse assesses the patient's level of anxiety. Patients with peptic ulcers are usually anxious, but their anxiety is not always obvious. Appropriate information is provided at the patient's level of understanding, all questions are answered, and the patient is encouraged to express fears openly. Explaining diagnostic tests and administering medications as scheduled also help reduce anxiety. The nurse interacts with the patient in a relaxed manner, helps identify stressors, and explains various coping techniques and relaxation methods, such as biofeedback, hypnosis, or behavior modification. The patient's family is also encouraged to participate in care and to provide emotional support.

Maintaining Optimal Nutritional Status

The nurse assesses the patient for malnutrition and weight loss. After recovery from an acute phase of peptic ulcer disease, the patient is advised about the importance of complying with the medication regimen and dietary restrictions.

Monitoring and Managing Potential Complications

HEMORRHAGE. Gastritis and hemorrhage from peptic ulcer are the two most common causes of upper GI tract bleeding (which may also occur with esophageal varices, as discussed in Chapter 39). Hemorrhage, the most common complication, occurs in 10% to 20% of patients with peptic ulcers. Bleeding may be manifested by hematemesis or melena (Ramakrishnan & Salinas, 2007). The vomited blood can be bright red, or it can have a dark "coffee grounds" appearance from the oxidation of hemoglobin to methemoglobin. When the hemorrhage is large (2000 to 3000 mL), most of the blood is vomited. Because large quantities of blood may be lost quickly, immediate correction of blood loss may be required to prevent hemorrhagic shock. When the hemorrhage is small, much or all of the blood is passed in the stools, which appear tarry black because of the digested hemoglobin. Management depends on the amount of blood lost and the rate of bleeding.

The nurse assesses the patient for faintness or dizziness and nausea, which may precede or accompany bleeding. It is important to monitor vital signs frequently and to evaluate the patient for tachycardia, hypotension, and tachypnea. Other nursing interventions include monitoring the hemoglobin and hematocrit, testing the stool for gross or occult blood, and recording hourly urinary output to detect anuria or oliguria (absence of or decreased urine production).

Many times the bleeding from a peptic ulcer stops spontaneously; however, the incidence of recurrent bleeding is high. Because bleeding can be fatal, the cause and severity of the hemorrhage must be identified quickly and the blood loss treated to prevent hemorrhagic shock. The nurse monitors the patient carefully so that bleeding can be detected quickly. If bleeding recurs within 48 hours after medical therapy has begun, or if more than 6 to 10 units of blood are required within 24 hours to maintain blood volume, the patient is likely to require surgery. Some physicians recommend surgical intervention if a patient hemorrhages three

times. Other criteria for surgery are the patient's age (massive hemorrhaging is three times more likely to be fatal in those older than 60 years of age), a history of chronic duodenal ulcer, and a coincidental gastric ulcer. The area of the ulcer is removed or the bleeding vessels are ligated. Many patients also undergo procedures (eg, vagotomy and pyloroplasty, gastrectomy) aimed at controlling the underlying cause of the ulcers (see Table 37-4).

Other related nursing and collaborative interventions include the following:

- Inserting a peripheral IV line for the infusion of saline or lactated Ringer's solution and blood products. The nurse may need to assist with the placement of a central venous catheter for rapid infusion of large amounts of blood and fluids as well as hemodynamic monitoring. Blood component therapy is initiated if there are signs of shock (eg, tachycardia, sweating, coldness of the extremities).
- Inserting an NG tube to distinguish fresh blood from "coffee grounds" material, to aid in the removal of clots and acid, to prevent nausea and vomiting, and to provide a means of monitoring further bleeding
- Administering an NG lavage of saline solution. The temperature of the solution (cold or room temperature) is a topic of controversy (Yamada & Alpers, 2003).
- Inserting an indwelling urinary catheter and monitoring urinary output
- Monitoring oxygen saturation and administering oxygen therapy
- Placing the patient in the recumbent position with the legs elevated to prevent hypotension, or placing the patient on the left side to prevent aspiration from vomiting
- Treating hemorrhagic shock (described in Chapter 15)

If bleeding cannot be managed by the measures described, other treatment modalities such as endoscopy may be used to halt bleeding and avoid surgical intervention. There is debate regarding how soon endoscopy should be performed. Some clinicians believe endoscopy should be performed within the first 24 hours after hemorrhaging has ceased. Others believe endoscopy may be performed during acute bleeding, as long as the esophageal or gastric area can be visualized (blood may decrease visibility).

For patients who are unable to undergo surgery, selective embolization may be used. This procedure involves forcing emboli of autologous blood clots with or without Gelfoam (absorbable gelatin sponge) through a catheter in the artery to a point above the bleeding lesion. This procedure is performed by an interventional radiologist (Ramakrishnan & Salinas, 2007; Singh, Denyer & Patel, 2007).

PERFORATION AND PENETRATION. Perforation is the erosion of the ulcer through the gastric **serosa** into the peritoneal cavity without warning. It is an abdominal catastrophe and requires immediate surgery. Penetration is erosion of the ulcer through the gastric serosa into adjacent structures such as the pancreas, biliary tract, or gastrohepatic **omentum**. Symptoms of penetration include back and epigastric pain not relieved by medications that were effective in the past. Like perforation, penetration usually requires surgical intervention.

CHART
37-2

HOME CARE CHECKLIST

The Patient With Peptic Ulcer Disease

At the completion of the home care instruction, the patient or caregiver will be able to:	PATIENT	CAREGIVER
• State the medication regimen and importance of complying with medication schedule.	✓	✓
• State dietary restrictions and foods that may exacerbate condition (caffeinated and decaffeinated products, milk).	✓	✓
• Identify smoking cessation groups.	✓	
• Identify methods to reduce stress.	✓	✓
• State signs and symptoms of complications:	✓	✓
Hemorrhage—cool skin, confusion, increased heart rate, labored breathing, blood in stool	✓	✓
Penetration and perforation—severe abdominal pain, rigid and tender abdomen, vomiting, elevated temperature, increased heart rate		
Pyloric obstruction—nausea and vomiting, distended abdomen, abdominal pain		
• State need for follow-up medical care.	✓	✓

Signs and symptoms of perforation include the following:

- Sudden, severe upper abdominal pain (persisting and increasing in intensity); pain may be referred to the shoulders, especially the right shoulder, because of irritation of the phrenic nerve in the diaphragm
- Vomiting
- Collapse (fainting)
- Extremely tender and rigid (boardlike) abdomen
- Hypotension and tachycardia, indicating shock

Because chemical peritonitis develops within a few hours of perforation and is followed by bacterial peritonitis, the perforation must be closed as quickly as possible and the abdominal cavity lavaged of stomach or intestinal contents. In some patients, it may be safe and advisable to perform surgery to treat the ulcer disease in addition to suturing the perforation.

During surgery and postoperatively, the stomach contents are drained by means of an NG tube. The nurse monitors fluid and electrolyte balance and assesses the patient for localized infection or peritonitis (increased temperature, abdominal pain, paralytic ileus, increased or absent bowel sounds, abdominal distention). Antibiotic therapy is administered parenterally as prescribed.

PYLORIC OBSTRUCTION. Pyloric obstruction, also called **gastric outlet obstruction (GOO)**, occurs when the area distal to the pyloric sphincter becomes scarred and stenosed from spasm or edema or from scar tissue that forms when an ulcer alternately heals and breaks down. The patient may have nausea and vomiting, constipation, epigastric fullness, anorexia, and, later, weight loss.

In treating the patient with pyloric obstruction, the first consideration is to insert an NG tube to decompress the stomach. Confirmation that obstruction is the cause of the discomfort is accomplished by assessing the amount of fluid aspirated from the NG tube. A residual of more than 400 mL strongly suggests obstruction. Usually an upper GI study or endoscopy is performed to confirm pyloric obstruction. Decompression of the stomach and management of extracellular fluid volume and electrolyte balances may improve the patient's condition and avert the need for surgical inter-

vention. A balloon dilation of the pylorus via endoscopy may be beneficial. If the obstruction is unrelieved by medical management, surgery (in the form of a vagotomy and antrectomy or gastrojejunostomy and vagotomy) may be required.

Promoting Home and Community-Based Care

TEACHING PATIENTS SELF-CARE. The nurse instructs the patient about the factors that relieve and those that aggravate the condition. The nurse reviews information about medications to be taken at home, including name, dosage, frequency, and possible side effects, stressing the importance of continuing to take medications even after signs and symptoms have decreased or subsided (Chart 37-2). The nurse instructs the patient to avoid certain medications and foods that exacerbate symptoms as well as substances that have acid-producing potential (eg, alcohol; caffeinated and decaffeinated beverages such as coffee, tea, and colas). It is important to counsel the patient to eat meals at regular times and in a relaxed setting and to avoid overeating. If relevant, the nurse also informs the patient about the irritant effects of smoking on the ulcer and provides information about smoking cessation programs.

NURSING ALERT

The nurse reviews with the patient and family the signs and symptoms of complications to be reported. These complications include hemorrhage (cool skin, confusion, increased heart rate, labored breathing, and blood in the stool), penetration and perforation (severe abdominal pain, rigid and tender abdomen, vomiting, elevated temperature, and increased heart rate), and pyloric obstruction (nausea, vomiting, distended abdomen, and abdominal pain).

CONTINUING CARE. The nurse reinforces the importance of follow-up care for approximately 1 year, the need to report recurrence of symptoms, and the need for treating possible problems that occur after surgery, such as intolerance to dairy products and sweet foods. The nurse also reminds the patient

and family of the importance of participating in health promotion activities and recommended health screening.

Evaluation

Expected Patient Outcomes

Expected patient outcomes may include the following:

1. Reports freedom from pain between meals
2. Reports feeling less anxiety
3. Complies with therapeutic regimen
 - a. Avoids irritating foods and beverages
 - b. Eats regularly scheduled meals
 - c. Takes medications as prescribed
 - d. Uses coping mechanisms to deal with stress
4. Maintains weight
5. Exhibits no complications

Morbid Obesity

Morbid obesity is a term applied to people who are more than two times their ideal body weight or whose body mass index (BMI) exceeds 40 kg/m² (see Chapter 5). Another definition of morbid obesity is body weight that is more than 100 pounds greater than the ideal body weight (Fabricatore & Wadden, 2006; Kushner, 2007). In the United States, where morbid obesity is a rapidly growing problem, approximately 65% of people are overweight (Brethauer, Chand & Schauer, 2006; Harrington, 2007).

Patients with morbid obesity are at higher risk for health complications, such as diabetes, heart disease, stroke, hypertension, gallbladder disease, osteoarthritis, sleep apnea and other breathing problems, and some forms of cancer (uterine, breast, colorectal, kidney, and gallbladder). They frequently suffer from low self-esteem, impaired body image, and depression.

Medical Management

Conservative management of obesity consists of placing the person on a weight loss diet in conjunction with behavioral modification and exercise; however, dietary and behavioral approaches to obesity have had limited success. Depression may contribute to weight gain, and treatment of the depression with an antidepressant may be helpful (Barth & Jensen, 2006; Clayton, 2007; Kloiber, Ising & Reppermund, 2007).

Pharmacologic Management

Several medications are approved for obesity. Sibutramine HCl (Meridia), which requires a prescription, decreases appetite by inhibiting the reuptake of serotonin and norepinephrine. It may increase blood pressure and should not be taken by people with a history of coronary artery disease, angina pectoris, dysrhythmias, or kidney disease; by those taking antidepressants or monoamine oxidase inhibitors; or by pregnant or nursing women. Other side effects of sibutramine include dry mouth, insomnia, headache, diaphoresis, and increased heart rate. Orlistat (Xenical), which is available both by prescription and over the counter as Alli, reduces caloric intake by binding to gastric and pancreatic lipase to

prevent digestion of fats. Side effects of orlistat include increased frequency of bowel movements, gas with oily discharge, decreased food absorption, decreased bile flow, and decreased absorption of some vitamins. A multivitamin is usually recommended. Orlistat should not be taken by pregnant or nursing women or transplant recipients.

Rimonabant (Acomplia), the newest medication used to treat obesity, blocks the cannabinoid-1 receptor that is thought to play an important role in some aspects of human metabolism, including obesity. It stimulates weight reduction and improves cardiovascular disease risk factors in obese patients with metabolic syndrome. The most common side effects include depression, anxiety, agitation, and sleep disorders. Other mild, transient effects are nausea, vomiting, diarrhea, headache, and dizziness.

Unfortunately, these medications rarely result in loss of more than 10% of total body weight. Furthermore, studies are needed to evaluate their long-term efficacy and risks (Fabricatore & Wadden, 2006; Lean & Mullan, 2007; Bray & Ryan, 2007).

Surgical Management

Bariatric surgery, or surgery for morbid obesity, is performed only after other nonsurgical attempts at weight control have failed. The National Institute of Diabetes and Digestive and Kidney Disease reports that the number of bariatric procedures has increased from approximately 13,000 per year in 1998 to more than 121,000 in 2004 (WIN, 2007). Bariatric surgical procedures work by restricting a patient's ability to eat (restrictive procedure), interfering with ingested nutrient absorption (malabsorptive procedures), or both. Different bariatric surgical procedures entail different lifestyle modifications, and patients must be well informed about the specific lifestyle changes, eating habits, and bowel habits that may result from a particular procedure. Studies have shown that the average weight loss after bariatric surgery in the majority of patients is approximately 61% of previous body weight; comorbid conditions such as diabetes mellitus, hypertension, and sleep apnea resolve; and dyslipidemia improves (Zingmond, McGory & Ko, 2005; Kini, Herron & Yanagisawa, 2007). Bariatric surgery has been extended to carefully selected adolescents because of its results in adults (Brethauer, et al., 2006; Van Sickle, 2007).

Patient selection is critical, and the preliminary process may necessitate months of counseling, education, and evaluation by a multidisciplinary team, including social workers, dietitians, a nurse counselor, a psychologist or psychiatrist, and a surgeon (Chart 37-3). Because bariatric surgery involves such a drastic change in the functioning of the digestive system, patients need counseling before and after the surgery. Guidelines have been developed to assist in the care of patients having bariatric surgery (AORN Bariatric Surgery Guideline, 2004). After bariatric surgery, all patients require lifelong monitoring of weight loss, comorbidities, metabolic and nutritional status, and dietary and activity behaviors because they are at risk for developing malnutrition or weight gain (Brethauer, et al., 2006; Tucker, Szomstein & Rosenthal, 2007). Women of child-bearing age who have bariatric surgery are advised to use contraceptives for approximately 2 years after surgery to avoid pregnancy until their weight stabilizes.

Chart 37-3 • Selection Criteria for Bariatric Surgery

Body mass index (BMI) ≥ 40 kg/m² with no comorbidities
 BMI ≥ 35 kg/m² with obesity-associated comorbidity
 >95th percentile of weight for age + severe comorbidity
 Failure of previous nonsurgical attempts at weight loss, including nonprofessional programs
 Expectation that patient will adhere to postoperative care, follow-up visits, and recommended medical management, including the use of dietary supplements

Exclusions

Reversible endocrine or other disorders that can cause obesity
 Current drug or alcohol abuse
 Uncontrolled, severe psychiatric illness
 Lack of comprehension of risk, benefits, expected outcomes, alternatives, and lifestyle changes required with bariatric surgery

Adapted from Mechanick, J., Kushner, R. & Sugerman, H. (2008). AACE/TOS/ASMBS bariatric surgery guidelines. *Endocrine Practice*, 14(suppl. 1), 318–336.

The first surgical procedure used to treat morbid obesity was jejunioileal bypass. This procedure, which resulted in significant complications, has been largely replaced by gastric restriction procedures. Roux-en-Y gastric bypass, gastric banding, vertical-banded gastroplasty, and biliopancreatic diversion with duodenal switch are the current procedures of choice. These procedures may be performed by laparoscopy or by an open surgical technique.

The Roux-en-Y gastric bypass is recommended for long-term weight loss. It is a combined restrictive and malabsorptive procedure. Gastric banding and vertical-banded gastroplasty are restrictive procedures, and biliopancreatic diversion with duodenal switch combines gastric restriction with intestinal malabsorption. See Figure 37-3A–D for additional details about these procedures. After weight loss, the patient may need surgical intervention for body contouring. This may include lipoplasty to remove fat deposits or a panniculectomy to remove excess abdominal skinfolds.

Bariatric surgical procedures have their own unique complications in addition to those associated with any major abdominal surgery. The most common complications are bleeding, blood clots, bowel obstruction, incisional or ventral hernias, and infection from a leak at the anastomosis. Prevention of complications is critical. Other postoperative problems that may occur include nausea, usually as a result of overfilling the stomach pouch or improper chewing; dumping syndrome associated with the consumption of simple sugars; and changes in bowel function, including diarrhea and constipation. Long-term complications related to nutritional deficiency may occur.

Nursing Management

Nursing management focuses on care of the patient after surgery. General postoperative nursing care is similar to that for a patient recovering from a gastric resection, but with great attention given to the risks of complications associated with morbid obesity. Complications that may occur in

CHART
37-4

PATIENT EDUCATION Dietary Guidelines for the Patient Who Has Had Bariatric Surgery

- Eat three meals per day (containing protein and fiber).
- Include two protein snacks per day.
- Restrict total meal size to less than 1 cup.
- Eat slowly.
- Chew thoroughly.
- Eat only foods packed with nutrients (eg, peanut butter, cheese, chicken, fish, beans).
- Do not eat and drink at the same time.
- Drink plenty of water, from 90 minutes after each meal to 15 minutes before the next meal.
- Avoid liquid calories, such as alcoholic beverages, fruit drinks, and regular soda (cola).
- Walk for at least 30 minutes per day.

Tucker, O., Szomstein S. & Rosenthal, R. (2007). Nutritional consequences of weight-loss surgery. *Medical Clinics of North America*, 91(3), 499–514.

the immediate postoperative period include peritonitis, stomal obstruction, stomal ulcers, atelectasis and pneumonia, thromboembolism, and metabolic imbalances resulting from prolonged vomiting and diarrhea or altered gastrointestinal function. After bowel sounds have returned and oral intake is resumed, six small feedings consisting of a total of 600 to 800 calories per day are provided, and fluids are encouraged to prevent dehydration.

The patient is usually discharged in 4 days (23 to 72 hours for patients who have had laparoscopic procedures) with detailed dietary instructions (Chart 37-4). The nurse instructs the patient to report excessive thirst or concentrated urine, both of which are indications of dehydration. Psychosocial interventions are also essential for these patients. Efforts are directed at helping them modify their eating behaviors and cope with changes in body image. The nurse explains that noncompliance by eating too much or too fast or eating high-calorie liquids and soft foods results in vomiting and painful esophageal distention. The nurse discusses dietary instructions and the need for physical activity before discharge. The nurse also emphasizes the importance of routine follow-up outpatient appointments to ensure medical management of any side effects, which may include increased risk of gallstones, nutritional and vitamin deficiencies, and potential to regain weight.

Patients who undergo laparoscopic or open Roux-en-Y procedures have one or more Jackson Pratt drains, which may remain in place after discharge. The nurse teaches the patient and family how to empty, measure, and record the amount of drainage.

Gastric Cancer

Although the incidence of gastric or stomach cancer continues to decrease in the United States, it still accounts for more than 11,000 deaths annually (American Cancer

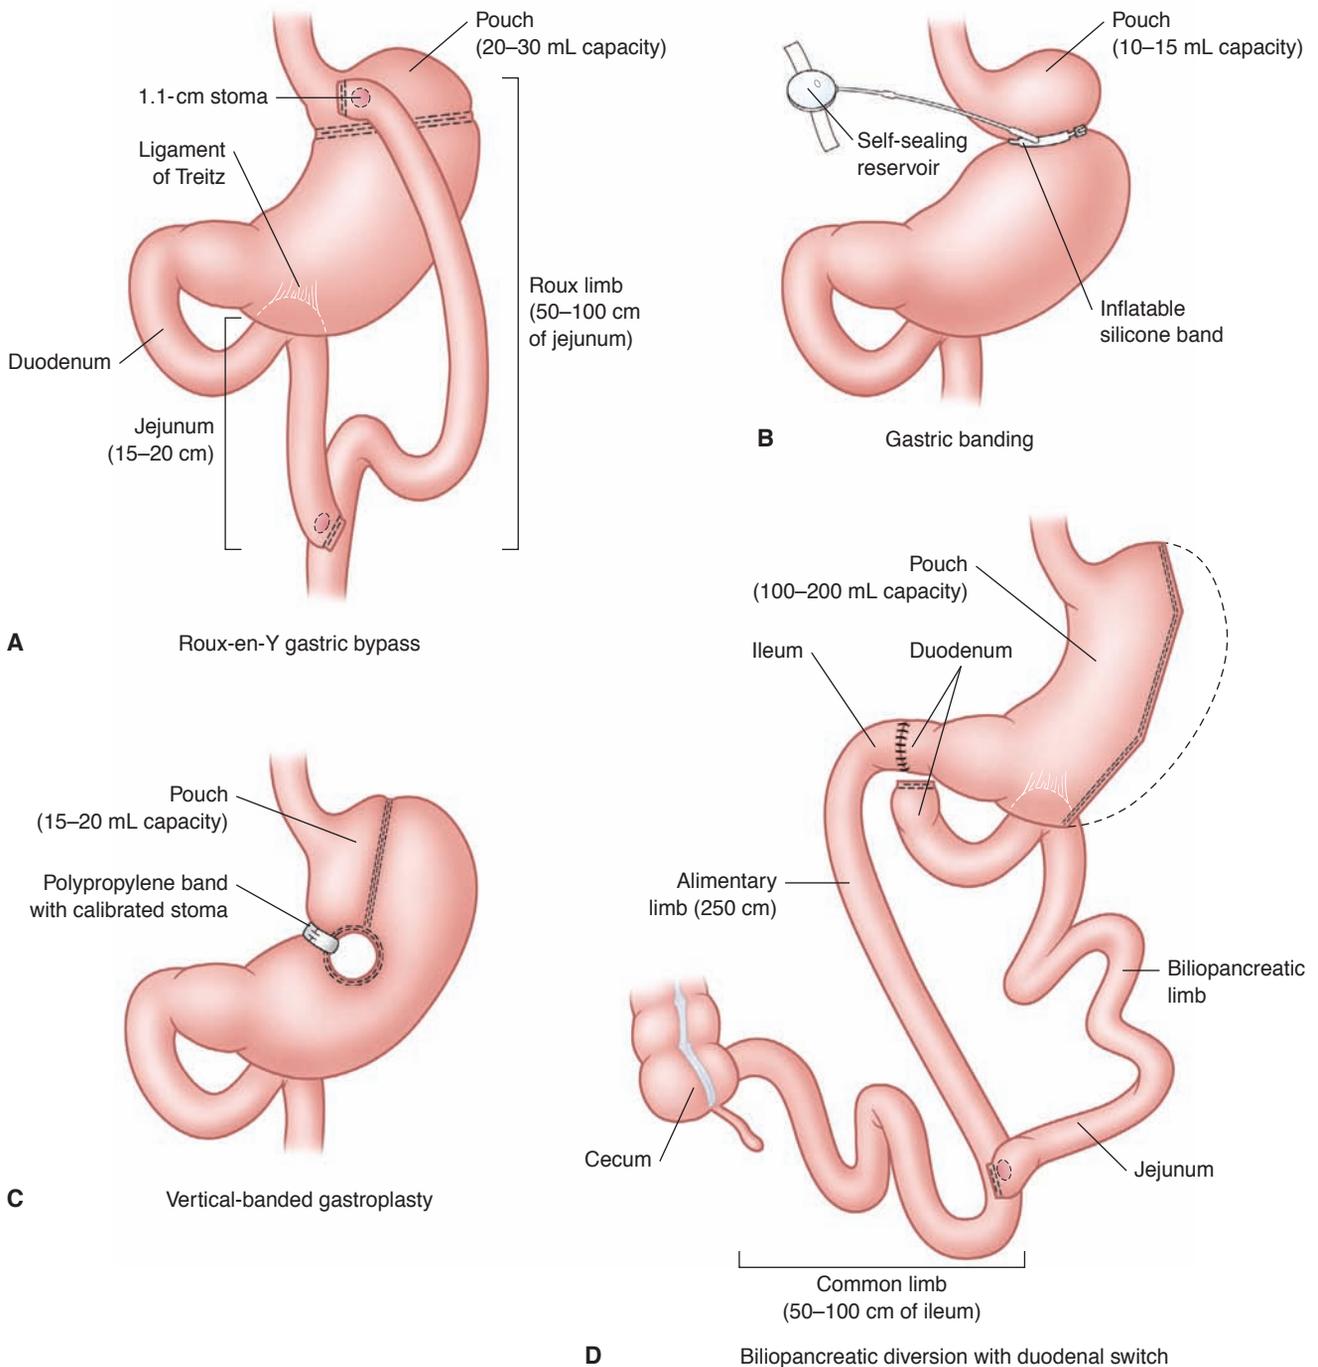

Figure 37-3 Surgical procedures for morbid obesity. **A**, Roux-en-Y gastric bypass. A horizontal row of staples across the fundus of the stomach creates a pouch with a capacity of 20 to 30 mL. The jejunum is divided distal to the ligament of Treitz and the distal end is anastomosed to the new pouch. The proximal segment is anastomosed to the jejunum. **B**, Gastric banding. A prosthetic device is used to restrict oral intake by creating a small pouch of 10 to 15 mL that empties through the narrow outlet into the remainder of the stomach. **C**, Vertical-banded gastroplasty. A vertical row of staples along the lesser curvature of the stomach creates a new, smaller stomach pouch of 10 to 15 mL. **D**, Biliopancreatic diversion with duodenal switch. Half of the stomach is removed, leaving a small area that holds about 60 mL. The entire jejunum is excluded from the rest of the gastrointestinal tract. The duodenum is disconnected and sealed off. The ileum is divided above the ileocecal junction and the distal end of the jejunum is anastomosed to the first portion of the duodenum. The distal end of the biliopancreatic limb is anastomosed to the ileum.

Society, 2009). The typical patient with gastric cancer is between 40 and 70 years of age, but gastric cancer can occur in people younger than 40 years of age. Men have a higher incidence of gastric cancer than women. Native Americans, Hispanic Americans, and African Americans are twice as likely as Caucasian Americans to develop gastric cancer. The incidence of gastric cancer is much greater in Japan, which has instituted mass screening programs for earlier diagnosis. Diet appears to be a significant factor: A diet high in smoked, salted, or pickled foods and low in fruits and vegetables may increase the risk of gastric cancer. Other factors related to the incidence of gastric cancer include chronic inflammation of the stomach, *H. pylori* infection, pernicious anemia, smoking, achlorhydria, gastric ulcers, previous subtotal gastrectomy (more than 20 years ago), and genetics. The prognosis is generally poor; the diagnosis is usually made late because most patients are asymptomatic during the early stages of the disease. Most cases of gastric cancer are discovered only after local invasion has advanced or metastases are present (Lim, Yum, Kim, et al., 2006).

Pathophysiology

Most gastric cancers are adenocarcinomas; they can occur anywhere in the stomach. The tumor infiltrates the surrounding mucosa, penetrating the wall of the stomach and adjacent organs and structures. The liver, pancreas, esophagus, and duodenum are often already affected at the time of diagnosis. Metastasis through lymph to the peritoneal cavity occurs later in the disease.

Clinical Manifestations

Symptoms of early disease, such as pain relieved by antacids, resemble those of benign ulcers and are seldom definitive, because most gastric tumors begin on the lesser curvature of the stomach, where they cause little disturbance of gastric function. Symptoms of progressive disease include dyspepsia (indigestion), early satiety, weight loss, abdominal pain just above the umbilicus, loss or decrease in appetite, bloating after meals, nausea and vomiting, and symptoms similar to those of peptic ulcer disease.

Assessment and Diagnostic Findings

The physical examination is usually not helpful in detecting the cancer because most early gastric tumors are not palpable. Advanced gastric cancer may be palpable as a mass. Ascites and hepatomegaly (enlarged liver) may be apparent if the cancer cells have metastasized to the liver. Palpable nodules around the umbilicus, called Sister Mary Joseph's nodules, are a sign of a GI malignancy, usually a gastric cancer. Esophagogastroduodenoscopy for biopsy and cytologic washings is the diagnostic study of choice, and a barium x-ray examination of the upper GI tract may also be performed. Endoscopic ultrasound is an important tool to assess tumor depth and any lymph node involvement. Computed tomography (CT) completes the diagnostic studies, particularly to assess for surgical resectability of the tumor before surgery is scheduled. CT of the chest, abdomen, and pelvis is valuable in staging gastric cancer.

Medical Management

There is no successful treatment for gastric carcinoma except removal of the tumor. If the tumor can be removed while it is still localized to the stomach, the patient may be cured. If the tumor has spread beyond the area that can be excised, cure is less likely. In many patients, effective palliation to prevent discomfort caused by obstruction or dysphagia may be obtained by resection of the tumor (see Gastric Surgery). A diagnostic laparoscopy may be the initial surgical approach to evaluate the gastric tumor, obtain tissue for pathologic diagnosis, and detect metastasis. The patient with a tumor that is deemed resectable undergoes an open surgical procedure to resect the tumor and appropriate lymph nodes. The patient with an unresectable tumor and advanced disease undergoes chemotherapy.

A total gastrectomy may be performed for a resectable cancer in the midportion or body of the stomach. The entire stomach is removed along with the duodenum, the lower portion of the esophagus, supporting mesentery, and lymph nodes. Reconstruction of the GI tract is performed by anastomosing the end of the jejunum to the end of the esophagus, a procedure called an esophagojejunostomy. A radical subtotal gastrectomy is performed for a resectable tumor in the middle and distal portions of the stomach. A Billroth I or a Billroth II operation (see Table 37-4) is performed. The Billroth I involves a limited resection and offers a lower cure rate than the Billroth II. The Billroth II procedure is a wider resection that involves removing approximately 75% of the stomach and decreases the possibility of lymph node spread or metastatic recurrence. A proximal subtotal gastrectomy may be performed for a resectable tumor located in the proximal portion of the stomach or cardia. A total gastrectomy or an esophagogastrectomy is usually performed in place of this procedure to achieve a more extensive resection.

Common problems of advanced gastric cancer that often require surgery include pyloric obstruction, bleeding, and severe pain. Gastric perforation is an emergency situation requiring surgical intervention. A gastric resection may be the most effective palliative procedure for advanced gastric cancer. Palliative procedures such as gastric or esophageal bypass, gastrostomy, or jejunostomy may temporarily alleviate symptoms such as nausea and vomiting. Palliative rather than radical surgery may be performed if there is metastasis to other vital organs, such as the liver, or to achieve a better quality of life.

If surgical treatment does not offer cure, treatment with chemotherapy may offer further control of the disease or palliation. Commonly used single-agent chemotherapeutic medications include 5-fluorouracil (5-FU), cisplatin (Platinol), doxorubicin (Adriamycin), etoposide (Etopophos), and mitomycin-C (Mutamycin). For improved response rates it is more common to administer combination therapy, primarily 5-FU-based therapy, with other agents. Studies are being conducted to assess the use of chemotherapy before surgery. Radiation therapy is mainly used for palliation in patients with obstruction, GI bleeding secondary to tumor, and significant pain. Assessment of tumor markers (blood analysis for antigens indicative of cancer) such as carcinoembryonic antigen (CEA), carbohydrate antigen (CA 19-9), and CA 50 may help determine the effectiveness of treatment. If

these values were elevated before treatment, they should decrease if the tumor is responding to the treatment (Gao, Zhang, Du, et al., 2007).

Gerontologic Considerations

Despite the decreased incidence of gastric cancer, the number of older patients (75 years of age and older) with gastric cancer is increasing (Orsenigo, Tomajer, Di Palo, et al., 2007). Sixty percent of cancer-related deaths occur in people 65 years of age and older (Jansen, Weert, Dulmen, et al., 2007). Confusion, agitation, and restlessness may be the only symptoms seen in elderly patients, who may have no gastric symptoms until their tumors are well advanced. At this time, they present with reduced functional ability and other signs and symptoms of malignancy.

Surgery is more hazardous for the elderly, and the risk increases with age. Gastric cancer should be treated with traditional surgery in older patients; the survival rate does not differ significantly from that of younger patients (Gasparini, Inelmen, Enzi, et al., 2006). Patient education is important to prepare older patients with cancer for treatment, to help them manage adverse effects, and to face the challenges that cancer and aging present.

NURSING PROCESS

THE PATIENT WITH GASTRIC CANCER

Assessment

The nurse obtains a dietary history from the patient, focusing on recent nutritional intake and status. Has the patient lost weight? If so, how much and over what period of time? Can the patient tolerate a full diet? If not, what foods can he or she eat? What other changes in eating habits have occurred? Does the patient have an appetite? Does the patient feel full after eating a small amount of food? Is the patient in pain? Do foods, antacids, or medications relieve the pain, make no difference, or worsen the pain? Is there a history of infection with *H. pylori*? Other health information to obtain includes the patient's smoking and alcohol history and family history (eg, any first- or second-degree relatives with gastric or other cancer). A psychosocial assessment, including questions about social support, individual and family coping skills, and financial resources, helps the nurse plan for care in acute and community settings.

After the interview, the nurse performs a complete physical examination, carefully assesses the patient's abdomen for tenderness or masses, and palpates and percusses the abdomen to detect ascites.

Nursing Diagnosis

Based on the assessment data, the patient's major nursing diagnoses may include the following:

- Anxiety related to the disease and anticipated treatment
- Imbalanced nutrition, less than body requirements, related to early satiety or anorexia
- Pain related to tumor mass
- Anticipatory grieving related to the diagnosis of cancer
- Deficient knowledge regarding self-care activities

Planning and Goals

The major goals for the patient may include reduced anxiety, optimal nutrition, relief of pain, and adjustment to the diagnosis and anticipated lifestyle changes.

Nursing Interventions

Reducing Anxiety

A relaxed, nonthreatening atmosphere is provided so the patient can express fears, concerns, and possibly anger about the diagnosis and prognosis. The nurse encourages the family or significant other to support the patient, offering reassurance and supporting positive coping measures. The nurse advises the patient about any procedures and treatments so that the patient knows what to expect.

Promoting Optimal Nutrition

The nurse encourages the patient to eat small, frequent portions of nonirritating foods to decrease gastric irritation. Food supplements should be high in calories, as well as vitamins A and C and iron, to enhance tissue repair. If the patient is unable to eat adequately prior to surgery to meet nutritional requirements, parenteral nutrition may be necessary. Because the patient may develop dumping syndrome when enteral feeding resumes after gastric resection, the nurse explains ways to prevent and manage it (six small feedings daily that are low in carbohydrates and sugar; fluids between meals rather than with meals) and informs the patient that symptoms often resolve after several months. If a total gastrectomy is performed, injection of vitamin B₁₂ will be required for life, because dietary vitamin B₁₂ is absorbed in the stomach. The nurse monitors the IV therapy and nutritional status and records intake, output, and daily weights to ensure that the patient is maintaining or gaining weight. The nurse assesses for signs of dehydration (thirst, dry mucous membranes, poor skin turgor, tachycardia, decreased urine output) and reviews the results of daily laboratory studies to note any metabolic abnormalities (sodium, potassium, glucose, blood urea nitrogen). Antiemetics are administered as prescribed.

Relieving Pain

The nurse administers analgesic agents as prescribed. A continuous IV infusion of an opioid may be necessary for postoperative or severe pain. The nurse routinely assesses the frequency, intensity, and duration of the pain to determine the effectiveness of the analgesic agent. The nurse works with the patient to help manage pain by suggesting nonpharmacologic methods for pain relief, such as position changes, imagery, distraction, relaxation exercises (using relaxation audiotapes), back rubs, massage, and periods of rest and relaxation.

Providing Psychosocial Support

The nurse helps the patient express fears, concerns, and grief about the diagnosis. It is important to answer the patient's questions honestly and to encourage the patient to participate in treatment decisions. Some patients mourn the loss of a body part and perceive their surgery as a type of mutilation. Some express disbelief and need time and support to accept the diagnosis.

CHART
37-5

HOME CARE CHECKLIST

The Patient With Gastric Cancer

At the completion of the home care instruction, the patient or caregiver will be able to:	PATIENT	CAREGIVER
• Demonstrate safe management of enteral or parenteral feedings, if applicable.	✓	✓
• Describe dietary restrictions.	✓	✓
• Identify potential side effects of chemotherapy or radiation therapy, if applicable.	✓	✓
• Identify signs and symptoms of wound infection.	✓	✓
• State signs and symptoms of obstruction or perforation.	✓	✓
• Describe follow-up needs.	✓	✓
• Make decisions about end-of-life care as appropriate.	✓	✓

The nurse offers emotional support and involves family members and significant others whenever possible. This includes recognizing mood swings and defense mechanisms (eg, denial, rationalization, displacement, regression) and reassuring the patient, family members, and significant others that emotional responses are normal and expected. The services of clergy, psychiatric clinical nurse specialists, psychologists, social workers, and psychiatrists are made available, if needed. The nurse projects an empathetic attitude and spends time with the patient. Many patients may begin to participate in self-care activities after they have acknowledged their loss.

Promoting Home and Community-Based Care

TEACHING PATIENTS SELF-CARE. Self-care activities depend on the type of treatments used—surgery, chemotherapy, radiation, or palliative care. Patient and family teaching include information about diet and nutrition, treatment regimens, activity and lifestyle changes, pain management, and possible complications (Chart 37-5). Consultation with a dietitian is essential to determine how the patient's nutritional needs can best be met at home. The nurse teaches the patient or caregiver about administration of enteral or parenteral nutrition. If chemotherapy or radiation is prescribed, the nurse provides explanations to the patient and family about what to expect, including the length of treatments, the expected side effects (eg, nausea, vomiting, anorexia, fatigue, neutropenia), and the need for transportation to appointments for treatment. Psychological counseling may also be helpful.

CONTINUING CARE. The need for ongoing care in the home depends on the patient's condition and treatment. The home care nurse reinforces nutritional counseling and supervises the administration of any enteral or parenteral feedings; the patient or caregiver must become skillful in administering the feedings and in detecting and preventing untoward effects or complications related to the feedings (see Chapter 36 to review management of enteral and parenteral feedings). The nurse teaches the patient or caregiver to record the patient's daily intake, output, and weight and explains strategies to manage pain, nausea, vomiting, or other symptoms. The nurse also teaches the patient or caregiver to recognize and report signs and symptoms of complications that require immediate attention, such as bleeding, obstruction, perforation, or any symptoms that become

progressively worse. It is important to explain the chemotherapy or radiation therapy regimen. The patient and family or significant other need to understand the care that will be needed during and after treatments (see Chapter 16). Because the prognosis for gastric cancer is poor, the nurse may need to assist the patient, family, or significant other with decisions regarding end-of-life care and make referrals as warranted.

Evaluation

Expected Patient Outcomes

Expected patient outcomes may include the following:

1. Reports less anxiety
 - a. Expresses fears and concerns about surgery
 - b. Seeks emotional support
2. Attains optimal nutrition
 - a. Eats small, frequent meals high in calories, iron, and vitamins A and C
 - b. Complies with enteral or parenteral nutrition as needed
3. Has decreased pain
4. Performs self-care activities and adjusts to lifestyle changes
 - a. Resumes normal activities within 3 months
 - b. Alternates periods of rest and activity
 - c. Manages enteral feedings
5. Prepares for the dying process
 - a. Acknowledges disease process
 - b. Reports control of symptoms
 - c. Verbalizes fears and concerns about dying; involves family/caregiver in discussions
 - d. Completes advance directives, and other appropriate documents

Gastric Surgery

Gastric surgery may be performed on patients with peptic ulcers who have life-threatening hemorrhage, obstruction, perforation, or penetration or whose condition does not respond to medication. It also may be indicated for patients with gastric cancer or trauma. Surgical procedures include a

vagotomy and pyloroplasty, a partial gastrectomy, or a total gastrectomy (see Table 37-4).

Nursing Management

Before surgery, the nurse assesses the patient's and family's knowledge of preoperative and postoperative surgical routines and the rationale for surgery. The nurse also assesses the patient's nutritional status: Has the patient lost weight? How much? Over how much time? Does the patient have nausea and vomiting? Has the patient had hematemesis? The nurse assesses for the presence of bowel sounds and palpates the abdomen to detect masses or tenderness.

After surgery, the nurse assesses the patient for complications secondary to the surgical intervention, such as hemorrhage, infection, abdominal distention, atelectasis, or impaired nutritional status (see Chapter 20).

In addition to the complications to which all postoperative patients are subject, the patient undergoing gastric surgery is at increased risk for:

- Hemorrhage
- Dietary deficiencies
- Bile reflux
- Dumping Syndrome

Reducing Anxiety

An important part of the preoperative nursing care involves allaying the patient's fears and anxieties about the impending surgery and its implications. The nurse encourages the patient to verbalize fears and concerns and answers the patient's and family's questions. If the patient has an acute obstruction, a perforated bowel, or an active GI hemorrhage, adequate psychological preparation may not be possible. In this event, the nurse caring for the patient after surgery should anticipate the concerns, fears, and questions that are likely to surface and should be available for support and further explanations.

Relieving Pain

After surgery, analgesic agents may be administered as prescribed to relieve pain and discomfort. It is important to provide adequate pain relief so the patient can perform pulmonary care activities (deep breathing and coughing) and leg exercises, turn from side to side, and ambulate. The nurse assesses the effectiveness of analgesic intervention and consults with other members of the health care team if pain is not adequately controlled. Positioning the patient in Fowler's position promotes comfort and allows emptying of the stomach after gastric surgery.

The nurse maintains functioning of the NG tube to prevent distention and secures the tube to prevent dislocation, which may result in increased pain and tension on the suture line. Normally, the amount of NG drainage after a total gastrectomy is minimal, because there is no reservoir where secretions can collect.

Increasing Knowledge

The nurse explains routine preoperative and postoperative procedures to the patient, which include preoperative medications, NG intubation, IV fluids, abdominal dressings, the possible need for a feeding tube, pain management, and

pulmonary care. These explanations need to be reinforced after surgery, especially if the patient had emergency surgery.

Resuming Enteral Intake

The patient's nutritional status is evaluated before surgery. If surgery is performed for gastric cancer, the patient is often malnourished and may require preoperative enteral or, more often, parenteral nutrition (see Chapter 36). After surgery, parenteral nutrition may be continued to meet caloric needs, to replace fluids lost through drainage and vomiting, and to support the patient metabolically until oral intake is adequate.

After the return of bowel sounds and removal of the NG tube, the nurse may give fluids, followed by food in small portions. Foods are gradually added until the patient is able to eat six small meals a day and drink 120 mL of fluid between meals. The key to increasing the dietary content is to offer food and fluids gradually as tolerated and to recognize that each patient's tolerance is different.

Recognizing Obstacles to Adequate Nutrition

Dysphagia and Gastric Retention

Dysphagia may occur in patients who have had a truncal vagotomy, a surgical procedure that may result in trauma to the lower esophagus. Gastric retention may be evidenced by abdominal distention, nausea, and vomiting. Regurgitation may also occur if the patient has eaten too much or too quickly. It also may indicate that edema along the suture line is preventing fluids and food from moving into the intestinal tract. If gastric retention occurs, it may be necessary to reinstate NPO (nothing by mouth) status and NG suction; pressure must be low in the remaining portion of the stomach to avoid disrupting the sutures.

Bile Reflux

Bile reflux gastritis and esophagitis may occur with the removal of the pylorus, which acts as a barrier to the reflux of duodenal contents. Burning epigastric pain and vomiting of bilious material manifest this condition. Eating or vomiting does not relieve the situation. Agents that bind with bile acid, such as cholestyramine (Questran), may be helpful. Aluminum hydroxide gel (an antacid) and metoclopramide hydrochloride (Reglan) have been used with limited success.

Dumping Syndrome

Dumping syndrome is an unpleasant set of vasomotor and GI symptoms that sometimes occur in patients who have had gastric surgery or a form of vagotomy. It may be the mechanical result of surgery in which a small gastric remnant is connected to the jejunum through a large opening. Foods high in carbohydrates and electrolytes must be diluted in the jejunum before absorption can take place, but the passage of food from the stomach remnant into the jejunum is too rapid to allow this to happen. The hypertonic intestinal contents draw extracellular fluid from the circulating blood volume into the jejunum to dilute the high concentration of electrolytes and sugars. The ingestion of

fluid at mealtime also causes the stomach contents to empty rapidly into the jejunum (Pedrazzani, Marrelli, Rampone, et al., 2007).

Early symptoms include a sensation of fullness, weakness, faintness, dizziness, palpitations, diaphoresis, cramping pains, and diarrhea. These symptoms resolve once the intestine has been evacuated. Later, there is a rapid elevation of blood glucose, followed by increased insulin secretion. This results in a reactive hypoglycemia, which also is unpleasant for the patient. Vasomotor symptoms that occur 10 to 90 minutes after eating are pallor, perspiration, palpitations, headache, and feelings of warmth, dizziness, and even drowsiness. Anorexia may also be a result of the dumping syndrome, because the person may be reluctant to eat.

Steatorrhea also may occur in the patient with gastric surgery. It is partially the result of rapid gastric emptying, which prevents adequate mixing with pancreatic and biliary secretions. In mild cases, reducing the intake of fat and administering an ant motility medication (eg, loperamide [Imodium]) may control steatorrhea.

Vitamin and Mineral Deficiencies

Other dietary deficiencies that the nurse should be aware of include malabsorption of organic iron, which may require supplementation with oral or parenteral iron, and a low serum level of vitamin B₁₂, which may require supplementation by the intramuscular route. Total gastrectomy results in lack of intrinsic factor, a gastric secretion required for the absorption of vitamin B₁₂ from the GI tract. Unless this vitamin is supplied by parenteral injection after gastrectomy, the patient inevitably suffers vitamin B₁₂ deficiency, which eventually leads to a condition identical to pernicious anemia. All manifestations of pernicious anemia, including macrocytic anemia and combined system disease (neurologic disorders of the central and peripheral nervous systems), may be expected to develop within a period of 5 years or less; they progress in severity thereafter and, in the absence of therapy, are fatal. This complication is avoided by the regular monthly intramuscular injection of vitamin B₁₂. This regimen should be started without delay after gastrectomy. Weight loss is a common long-term problem because the patient experiences early fullness, which suppresses the appetite.

Teaching Dietary Self-Management

Because the patient may experience any of the described conditions affecting nutrition, nursing intervention includes proper dietary instruction. The following teaching points are emphasized:

- To delay stomach emptying and dumping syndrome, the patient should assume a low Fowler's position during mealtime and then remain in that position for 20 to 30 minutes.
- Antispasmodics, as prescribed, also may aid in delaying the emptying of the stomach.
- Fluid intake with meals is discouraged; instead, fluids may be consumed up to 1 hour before or 1 hour after mealtime.
- Meals should contain more dry items than liquid items.

- The patient can eat fat as tolerated but should keep carbohydrate intake low and avoid concentrated sources of carbohydrates.
- The patient should eat smaller but more frequent meals.
- Dietary supplements of vitamins and medium-chain triglycerides and injections of vitamin B₁₂ and iron may be prescribed.

The nurse also gives instructions regarding enteral or parenteral supplementation if it is needed.

Monitoring and Managing Potential Complications

Occasionally hemorrhage complicates gastric surgery. The patient has the usual signs of rapid blood loss and shock (see Chapter 15) and may vomit considerable amounts of bright-red blood. The nurse assesses NG drainage for type and amount; some bloody drainage for the first 12 hours is expected, but excessive bleeding should be reported. The nurse also assesses the abdominal dressing for bleeding. Because this situation is upsetting to the patient and family, the nurse should remain calm. The nurse performs emergency measures, such as NG lavage and administration of blood and blood products, along with vigilant hemodynamic monitoring.

Promoting Home and Community-Based Care

Teaching Patients Self-Care

Patient teaching is based on the assessment of the patient's physical and psychological readiness to participate in self-care. The nurse provides information about nutrition, enteral or parenteral nutrition if required, nutritional supplements, pain management, and the symptoms of dumping syndrome and measures to prevent or minimize these symptoms (Chart 37-6). It is important to emphasize the continued need for vitamin B₁₂ injections.

Continuing Care

The patient and caregivers benefit from a team approach to discharge planning. The team members include the patient and caregiver along with the nurse, physician, dietitian, and social worker. Written or video instructions about meals, activities, medications, and follow-up care are helpful. After the patient is discharged from the hospital, the home care nurse helps with the transition to home by supervising the administration of any enteral or parenteral feedings and emphasizing information about detection and prevention of untoward effects or complications related to feedings. Information about community support groups and end-of-life care is provided to the patient, family, or significant other when indicated. See the Nursing Research Profile for further discussion of discharge planning (Chart 37-7).

Duodenal Tumors

Tumors of the duodenum are uncommon and are usually benign and asymptomatic. They are most often discovered at autopsy. Malignant tumors are more likely to cause specific signs and symptoms leading to diagnosis. Unfortunately, malignant tumors are often not discovered until they

CHART  **HOME CARE CHECKLIST**
37-6 *The Patient Undergoing Gastric Surgery*

At the completion of the home care instruction, the patient or caregiver will be able to:	PATIENT	CAREGIVER
• Demonstrate enteral or parenteral feedings as applicable.	✓	✓
• State necessary dietary changes.	✓	✓
• Use nutritional supplements as appropriate.	✓	
• Relieve pain with pharmacologic or nonpharmacologic interventions.	✓	✓
• Identify available support groups.	✓	✓
• Explain medication regimen.	✓	✓
• Identify the need for continued vitamin B ₁₂ injections.	✓	✓
• Identify signs and symptoms of complications.	✓	✓
• State schedule of follow-up appointments.	✓	✓

have metastasized to distant sites. Benign tumors may place patients at an increased risk for malignancy. The relative rarity of tumors of the duodenum and the nonspecific nature of their manifestations complicate their diagnosis and treatment.

Clinical Manifestations

Duodenal tumors often present insidiously with vague, non-specific symptoms. Most benign tumors are discovered incidentally on an x-ray study, during surgery, or at autopsy.

When the patient is symptomatic, benign tumors often present with intermittent pain. The next most common presentation is occult bleeding. Malignant tumors often result in symptoms that lead to their diagnosis, although these symptoms may reflect advanced disease. Most patients have sustained weight loss and are malnourished at diagnosis. Bleeding and pain are common. Perforation of the bowel occurs in approximately 10% of patients (Ramakrishnan & Salinas, 2007; Kostakou, Khaldi, Flossos, et al., 2007).

CHART **NURSING RESEARCH PROFILE**
37-7 *Discharge Planning to Facilitate Decision Making*

McMurray, A., Johnson, P., Wallis, M., et al. (2007). General surgical patients' perspectives of the adequacy and appropriateness of discharge planning to facilitate health decision-making at home. *Journal of Clinical Nursing*, 16(9), 1602–1609.

Purpose

The purpose of this study was to investigate how general surgery patients viewed their discharge planning in terms of adequacy and appropriateness. In an attempt to identify ways in which postsurgical patients could manage their care after discharge and promote continuity of care from hospital to home, the researchers hoped to gain insight about any aspects of discharge planning that could be improved.

Design

The researchers designed a qualitative, interpretive study that involved patient interviews at least 1 week after discharge from the hospital. They used purposive sampling to select 13 general surgical patients to be interviewed from one of three hospitals. The sample included six men and seven women who underwent the following procedures: spinal surgery, neurosurgery, cholecystectomy, bowel surgery, hernia repair, partial mastectomy, and prostate surgery. Researchers conducted unstructured interviews using questions they developed. They audiotaped the interviews and had them transcribed. Individual team members analyzed the transcripts using thematic analysis techniques. All members of the research team then analyzed the preliminary themes collectively in an attempt to reach a consensus about the patients' perspectives.

Results

Analysis of the data revealed four major themes: (1) information was provided in a "one-size-fits-all" manner, (2) advice provided by different health care professionals was often inconsistent or variable, (3) there was a lack of assessment of home and/or work conditions, and (4) there was a lack of follow-up to determine if patients had questions or needs that were not being met. The study participants reported that explanations given to them were often detailed but not tailored to their individual needs. Much of the information that they received was too general to be helpful. All of the subjects reported that a follow-up telephone call after discharge would have been appreciated.

Nursing Implications

It is important to recognize the discharge needs of individual patients. Discharge planning should include appropriate discharge assessment that focuses on the needs identified by the patient, specifically the needs of the patient within the home and the work environment. Information provided to patients should be specifically tailored to each patient's individual needs, and the various members of the health care team should provide the same discharge information. The best way to achieve this is to have a written plan that is distributed to the various members of the team. A follow-up telephone call to allow patients to ask questions and communicate their needs is particularly important to many patients.

Assessment and Diagnostic Findings

An upper GI x-ray series with small bowel follow-through using oral water-insoluble contrast with frequent and detailed x-rays to follow the contrast through the small bowel is the traditional approach to diagnosis. A more sensitive examination is an **enteroclysis**, in which a nasogastric tube is advanced into the small bowel to a position above the area in question; the area is then studied by single-contrast and double-contrast techniques. Abdominal CT is used to determine the extent of disease outside the lumen of the duodenum.

Management

Benign tumors of the duodenum include adenomas, lipomas, hemangiomas, and hamartomas (a focal malformation that resembles a neoplasm, but unlike a neoplasm does not result in compression of adjacent tissue). These tumors may be treated endoscopically by excision/resection or electrocautery if the patient is symptomatic. Routine monitoring is recommended to assess for malignant transformation.

The most common primary malignant tumor of the duodenum is adenocarcinoma; the second and third portions of the duodenum are most often involved. These tumors may present with bleeding or duodenal obstruction. If the tumor is located at the ampulla of Vater, obstructive jaundice is likely. Other rare malignant tumors of the duodenum include carcinoid tumors, lymphoma, and gastrointestinal stromal tumors. Abdominal surgery may be required to remove these rare tumors. Chemotherapy and radiation therapy may also be part of the treatment regimen.

The nursing process related to the care of the patient with a duodenal tumor is similar to that of the patient with gastric cancer. Each patient requires specialized care, astute assessment for complications, prompt interventions, and individualized teaching for self-care.

CRITICAL THINKING EXERCISES

1 You have been assigned to care for a 60-year-old man with a history of diabetes, esophageal reflux, peripheral neuropathy, and smoking. He is complaining of abdominal pain, nausea, and vomiting. What questions should you ask the patient? What signs should be noted during the physical examination? What diagnostic studies should you anticipate for this patient? Describe your nursing interventions, including teaching.

EBP 2 A 27-year-old morbidly obese woman is being evaluated for bariatric surgery. She has tried conservative measures, diets, behavior modification, exercise, and medications for obesity, and these weight loss measures have led to only limited success. Describe the criteria for bariatric surgery. What education would be appropriate for this patient preoperatively? What education and referrals would be appropriate for her postoperatively? What is the evidence base that supports the use of specific dietary modifications to meet her nutritional needs postoperatively? Describe the strength of this evidence and identify the criteria used to evaluate the

strength of the evidence that supports the appropriateness of the dietary modifications.

3 You are caring for a 61-year-old woman who was admitted for weight loss, decreased appetite, early satiety, and indigestion. Gastric cancer is the probable diagnosis. What questions should you ask this patient? What diagnostic studies and treatment plan would you anticipate for this patient? What nursing diagnoses, including knowledge deficit, would you anticipate for this patient?

4 A 55-year-old man is transferred to your unit from the intensive care unit following a head injury. During your admission assessment, he complains of a burning sensation in his midepigastric area. On examination, you note a distended abdomen with tenderness in the epigastric area. What questions would you ask the patient? What diagnostic tests would you anticipate and how would you prepare your patient for these? Describe your plan of nursing care for this patient.

chapter 38

Management of Patients With Intestinal and Rectal Disorders

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

- 1 Identify the health care learning needs of patients with constipation or diarrhea.
- 2 Compare the conditions of malabsorption with regard to their pathophysiology, clinical manifestations, and management.
- 3 Use the nursing process as a framework for care of patients with diverticular disease.
- 4 Compare Crohn's disease (regional enteritis) and ulcerative colitis with regard to their pathophysiology; clinical manifestations; diagnostic evaluation; and medical, surgical, and nursing management.
- 5 Use the nursing process as a framework for care of the patient with inflammatory bowel disease.
- 6 Describe the responsibilities of the nurse in meeting the needs of the patient with an intestinal diversion.
- 7 Describe the various types of intestinal obstructions and their management.
- 8 Use the nursing process as a framework for care of the patient with cancer of the colon or rectum.
- 9 Describe nursing management of the patient with an anorectal condition.

GLOSSARY

- abscess:** localized collection of purulent material surrounded by inflamed tissues, typically associated with signs of infection
- borborygmus:** rumbling noise caused by the movement of gas through the intestines
- colostomy:** surgical opening into the colon by means of a stoma to allow drainage of bowel contents; one type of fecal diversion
- constipation:** subjectively described infrequency or irregularity of defecation, with or without an abnormal hardening of feces that makes their passage difficult and sometimes painful, with or without a decrease in fecal volume
- diverticulitis:** inflammation of a diverticulum from obstruction (by fecal matter), resulting in abscess formation

GLOSSARY (Continued)

- diverticulosis:** presence of several diverticula in the intestine; common in middle age
- diverticulum:** saclike outpouching of the lining of the bowel protruding through the muscle of the intestinal wall, usually caused by high intraluminal pressure
- fecal incontinence:** involuntary passage of feces
- fissure:** normal or abnormal fold, groove, or crack in body tissue
- fistula:** anatomically abnormal tract that arises between two internal organs or between an internal organ and the body surface
- hemorrhoids:** dilated portions of the anal veins; can occur internal or external to the anal sphincter
- ileostomy:** surgical opening into the ileum by means of a stoma to allow drainage of bowel contents; one type of fecal diversion
- inflammatory bowel disease (IBD):** group of chronic disorders (most common are ulcerative colitis and Crohn's disease) that result in inflammation or ulceration (or both) of the bowel lining; associated with abdominal pain, diarrhea, fever, and weight loss
- irritable bowel syndrome (IBS):** functional disorder that affects frequency of defecation and consistency of stool; is associated with no specific structural or biochemical alterations; associated with crampy abdominal pain and bloating
- Kock pouch:** type of continent ileal reservoir created surgically by making an internal pouch with a portion of the ileum and placing a nipple valve flush with the stoma
- malabsorption:** impaired transport across the mucosa
- peritonitis:** inflammation of the lining of the abdominal cavity, usually as a result of a bacterial infection of an area in the gastrointestinal tract with leakage of contents into the abdominal cavity
- steatorrhea:** excess of fatty wastes in the feces or the urine
- tenesmus:** ineffective and sometimes painful straining to eliminate either feces or urine
- Valsalva maneuver:** forcible exhalation against a closed glottis followed by a rise in intrathoracic pressure and subsequent possible dramatic rise in arterial pressure; may occur during straining at stool
- wound-ostomy-continance (WOC) nurse:** nurse specially educated in the appropriate management of fecal and urinary diversions; guides patients, their families, surgeons, and nurses by recommending appropriate use of skin, wound, ostomy, and continence products; formerly called enterostomal therapist

The types of diseases and disorders that affect the lower gastrointestinal (GI) tract are many and varied. Between 60 and 70 million people in the United States are diagnosed with some type of disease of the GI tract. These diseases account for more than 45 million office visits and approximately 14 million hospital admissions annually. They cost the American public more than \$110 billion each year and account for approximately 9% of all deaths each year (National Institutes of Health [NIH], 2007).

In all age groups, a fast-paced lifestyle, high levels of stress, irregular eating habits, insufficient intake of fiber and water, and lack of daily exercise contribute to GI disorders. There is a growing understanding of the biopsychosocial implications of GI disease. Nurses can have an impact on these GI disorders by identifying behavior patterns that put patients at risk, by educating the public about prevention and management, and by helping those affected to improve their condition and prevent complications.

ABNORMALITIES OF FECAL ELIMINATION

Changes in patterns of fecal elimination are symptoms of functional disorders or diseases of the GI tract. The most common changes seen are constipation, diarrhea, and fecal incontinence. The nurse should be aware of the causes and therapeutic management of these disorders and of nursing management techniques. Education is important for patients with these conditions.

Constipation

Constipation is an abnormal infrequency or irregularity of defecation, abnormal hardening of stools that makes their passage difficult and sometimes painful, a decrease in stool volume, or retention of stool in the rectum for a prolonged period often with a sense of incomplete evacuation after defecation. Any variation from normal habits may be considered a problem. It is estimated that 4.5 million Americans are clinically constipated at any time, that between 12% and 19% of the American population may be affected periodically, and that women and adults older than 65 years are disproportionately constipated (Ginsberg, Phillips, Wallace, et al., 2007; Heitkemper & Wolf, 2007).

Constipation can be caused by certain medications (ie, tranquilizers, anticholinergics, antidepressants, antihypertensives, bile acid sequestrants, diuretics, opioids, aluminum-based antacids, iron preparations, selected antibiotics, and muscle relaxants); rectal or anal disorders (eg, hemorrhoids, fissures); obstruction (eg, bowel tumors); metabolic, neurologic, and neuromuscular conditions (eg, Hirschsprung's disease, Parkinson's disease, multiple sclerosis); endocrine disorders (eg, hypothyroidism, pheochromocytoma); lead poisoning; and connective tissue disorders (eg, scleroderma, systemic lupus erythematosus). Constipation is a major issue for patients taking opioids for pain. Diseases of the colon commonly associated with constipation include irritable bowel syndrome and diverticular disease. Constipation can also occur with an acute disease process in the abdomen (eg, appendicitis).

Other causes of constipation may include weakness, immobility, debility, fatigue, and an inability to increase intra-abdominal pressure to facilitate the passage of stools, as may occur in patients with emphysema or spinal cord injury, for instance. Many people develop constipation because they do not take the time to defecate or they ignore the urge to defecate. Constipation is also a result of dietary habits (ie, low consumption of fiber and inadequate fluid intake), lack of regular exercise, and a stress-filled life. Fiber is particularly important to bowel health as it increases the bulk of stool, generally easing the passage. More importantly, it also promotes optimal fermentation, providing good bowel wall health (Rose, DeMeo, Keshavarzian, et al., 2007).

Perceived constipation can also be an issue. This subjective problem occurs when a person's bowel elimination pattern is not consistent with what he or she considers normal. Chronic laxative use may contribute to this problem and is a major health issue in the United States. "Normal" bowel function varies substantially from three bowel movements a day to three times per week (Bisanz, 2007).

Pathophysiology

The pathophysiology of constipation is poorly understood, but it is thought to include interference with one of three major functions of the colon: mucosal transport (ie, mucosal secretions facilitate the movement of colon contents), myoelectric activity (ie, mixing of the rectal mass and propulsive actions), or the processes of defecation (eg, pelvic floor dysfunction). Any of the causative factors previously identified can interfere with any of these three processes.

The urge to defecate is stimulated normally by rectal distention that initiates a series of four actions: stimulation of the inhibitory rectoanal reflex, relaxation of the internal sphincter muscle, relaxation of the external sphincter muscle and muscles in the pelvic region, and increased intra-abdominal pressure. Interference with any of these processes can lead to constipation.

If all organic causes are eliminated, idiopathic constipation is diagnosed. When the urge to defecate is ignored, the rectal mucous membrane and musculature become insensitive to the presence of fecal masses, and consequently a stronger stimulus is required to produce the necessary peristaltic rush for defecation. The initial effect of fecal retention is to produce irritability of the colon, which at this stage frequently goes into spasm, especially after meals, giving rise to colicky midabdominal or low abdominal pains. After several years of this process, the colon loses muscular tone and becomes essentially unresponsive to normal stimuli (similar to an overstretched balloon). Atony or decreased muscle tone occurs with aging. This also leads to constipation because the stool is retained for longer periods.

Clinical Manifestations

Clinical manifestations of constipation include fewer than three bowel movements per week; abdominal distention; pain and pressure; decreased appetite; headache; fatigue; indigestion; a sensation of incomplete evacuation; straining at stool; and the elimination of small-volume, lumpy, hard, dry stools. To make diagnosis more efficient, an international committee developed the Rome criteria. To be considered true chronic constipation, the previously mentioned

manifestations must be present for at least 12 weeks of the preceding 12 months (Bharucha, 2007; Bisanz, 2007).

Assessment and Diagnostic Findings

Chronic constipation is usually considered idiopathic, but secondary causes should be excluded. In patients with severe, intractable constipation, further diagnostic testing is needed (Heitkemper & Wolf, 2007). The diagnosis of constipation is based on the patient's history, physical examination, possibly the results of a barium enema or sigmoidoscopy, and stool testing for occult blood. These tests are used to determine whether this symptom results from spasm or narrowing of the bowel. Anorectal manometry (ie, pressure studies such as a balloon expulsion test) may be performed to assess malfunction of the sphincter. Defecography and colonic transit studies can also assist in the diagnosis because they permit assessment of active anorectal function (see Chapter 34). Newer tests such as pelvic floor magnetic resonance imaging (MRI) may identify occult pelvic floor defects (Ginsberg, et al., 2007).

Complications

Complications of constipation include hypertension, fecal impaction, **hemorrhoids** (dilated portions of anal veins), **fissures** (tissue folds), and megacolon. Increased arterial pressure can occur with defecation. Straining at stool, which results in the **Valsalva maneuver** (ie, forcibly exhaling with the glottis closed), has a striking effect on arterial blood pressure. During active straining, the flow of venous blood in the chest is temporarily impeded because of increased intrathoracic pressure. This pressure tends to collapse the large veins in the chest. The atria and the ventricles receive less blood, and consequently less blood is ejected by the left ventricle. Cardiac output is decreased, and there is a transient drop in arterial pressure. Almost immediately after this period of hypotension, an increase in arterial pressure occurs; the pressure is elevated momentarily to a point far exceeding the original level (ie, rebound phenomenon). In patients with hypertension, this compensatory reaction may be exaggerated greatly, and the peak pressure attained may be dangerously high—sufficient to rupture a major artery in the brain or elsewhere.

Fecal impaction occurs when an accumulated mass of dry feces cannot be expelled. The mass may be palpable on digital examination, may produce pressure on the colonic mucosa that results in ulcer formation, and frequently causes seepage of liquid stools.

Hemorrhoids and anal fissures can develop as a result of constipation. Hemorrhoids develop as a result of perianal vascular congestion caused by straining. Anal fissures may result from the passage of the hard stool through the anus, tearing the lining of the anal canal.

Megacolon is a dilated and atonic colon caused by a fecal mass that obstructs the passage of colon contents. Symptoms include constipation, liquid fecal incontinence, and abdominal distention. Megacolon can lead to perforation of the bowel.

Gerontologic Considerations

Physician visits for treatment of constipation are most common in people 65 years and older (Ginsberg, et al., 2007).

The most common complaint they voice is the need to strain at stool. People who have loose-fitting dentures or have lost their teeth have difficulty chewing and frequently choose soft, processed foods that are low in fiber. Older adults tend to have decreased food intake, reduced mobility, and weak abdominal and pelvic muscles, and they are more likely to have multiple chronic illnesses requiring multiple medications (polypharmacy) that often cause constipation (Ginsberg, et al., 2007). Low-fiber convenience foods are widely used by people who have lost interest in eating. Some older people reduce their fluid intake if they are not eating regular meals. Depression, weakness, and prolonged bed rest also contribute to constipation by decreasing intestinal motility and anal sphincter tone. Nerve impulses are dulled, and there is a decreased urge to defecate. Many older people overuse laxatives in an attempt to have a daily bowel movement and become dependent on them.

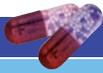

Medical Management

Treatment targets the underlying cause of constipation and aims to prevent recurrence. It includes education, bowel habit training, increased fiber and fluid intake, and judicious use of laxatives. Management may also include discontinuing laxative abuse. Routine exercise to strengthen abdominal muscles is encouraged. Biofeedback is a technique that can be used to help patients learn to relax the sphincter mechanism to expel stool (Bharucha, 2007; Heitkemper & Wolf, 2007). Daily dietary intake of 25 to 30 g/day of fiber (soluble and bulk-forming) is recommended, especially for the treatment of constipation in the elderly. If laxative use is necessary, one of the following may be prescribed: bulk-forming agents, saline and osmotic agents, lubricants, stimulants, or fecal softeners. The physiologic action and patient education information related to these laxatives are presented in Table 38-1. Enemas and rectal suppositories are generally not recommended for treating constipation; they should be reserved for the treatment of impaction. Treatment for impaction removal can be embarrassing and painful because it usually also requires digital dislodgement with enema administration. If long-term laxative use is necessary, a bulk-forming agent may be prescribed in combination with an osmotic laxative.

Specific medications may be prescribed to enhance colonic transit by increasing propulsive motor activity. These may include cholinergic agents (eg, bethanechol [Urecholine]), cholinesterase inhibitors (eg, neostigmine [Prostigmin]), or prokinetic agents (eg, metoclopramide [Reglan]). Newer prokinetic agents include serotonin receptors such as tegaserod (Zelnorm) and prostones such as lubiprostone (Amitiza). They should be used only for patients with unremitting constipation (Bharucha, 2007; Ginsberg, et al., 2007).

Nursing Management

The nurse elicits information about the onset and duration of constipation, current and past elimination patterns, the patient's expectation of normal bowel elimination, and lifestyle information (eg, exercise and activity level, occupation, food and fluid intake, and stress level) during the health history interview. Past medical and surgical history, current medications, and laxative and enema use are

**Table 38-1 LAXATIVE MEDICATIONS**

Medications (Classification and Sample Drugs)	Action	Patient Education
Bulk Forming		
Psyllium hydrophilic mucilloid (Metamucil) Methylcellulose (Citrucel) Saline agent	Polysaccharides and cellulose derivatives mix with intestinal fluids, swell, and stimulate peristalsis.	Take with 8 oz water and follow with 8 oz water; do not take dry. Report abdominal distention or unusual amount of flatulence.
Magnesium hydroxide (Milk of Magnesia)	Nonabsorbable magnesium ions alter stool consistency by drawing water into the intestines by osmosis; peristalsis is stimulated. Action occurs within 2 h.	The liquid preparation is more effective than the tablet form. Only short-term use is recommended because of toxicity (CNS or neuromuscular depression, electrolyte imbalance). Magnesium laxatives should not be taken by patients with renal insufficiency.
Lubricant		
Mineral oil Glycerin suppository	Nonabsorbable hydrocarbons soften fecal matter by lubricating the intestinal mucosa; the passage of stool is facilitated. Action occurs within 6–8 h for mineral oil and within 30 minutes for glycerin suppository.	Do not take mineral oil with meals because it can impair the absorption of fat-soluble vitamins and delay gastric emptying. Swallow carefully, because drops of oil that gain access to the pharynx can produce a lipid pneumonia. Glycerin suppositories must be inserted fully and retained.
Stimulant		
Bisacodyl (Dulcolax) Senna (Senokot)	Irritates the colonic epithelium by stimulating sensory nerve endings and increasing mucosal secretions. Action occurs within 6–8 h.	Catharsis may cause fluid and electrolyte imbalance, especially in the elderly. Tablets should be swallowed, not crushed or chewed. Avoid milk or antacids within 1 hour of taking medication, because the enteric coating may dissolve prematurely. Stimulant laxatives are not indicated for long-term use.
Fecal Softener		
Docusate (Colace)	Hydrates the stool by its surfactant action on the colonic epithelium (increases the wetting efficiency of intestinal water); aqueous and fatty substances are mixed. Does not exert a laxative action.	Can be used safely by patients who should avoid straining (cardiac patients, patients with anorectal disorders).
Osmotic Agent		
Polyethylene glycol and electrolytes (Colyte)	Cleanses colon rapidly and induces diarrhea.	This is a large-volume product. It takes time to consume it safely. It can cause considerable nausea and bloating.

important, as is information about the sensation of rectal pressure or fullness, abdominal pain, excessive straining at defecation, and flatulence.

Patient education and health promotion are important functions of the nurse (Chart 38-1). After the health history is obtained, the nurse sets specific goals for teaching. Goals for the patient include restoring or maintaining a regular pattern of elimination by responding to the urge to defecate, ensuring adequate intake of fluids and high-fiber foods, learning about methods to avoid constipation, relieving anxiety about bowel elimination patterns, and avoiding complications.

Diarrhea

Diarrhea is an increased frequency of bowel movements (more than three per day), an increased amount of stool (more than 200 g/day), and altered consistency (ie, increased liquidity) of stool. It is usually associated with ur-

gency, perianal discomfort, incontinence, or a combination of these factors. Any condition that causes increased intestinal secretions, decreased mucosal absorption, or altered motility can produce diarrhea. Irritable bowel syndrome, inflammatory bowel disease, and lactose intolerance are frequently the underlying disease processes that cause diarrhea.

Diarrhea can be acute or chronic. Acute diarrhea is most often associated with infection and is usually self-limiting, lasting up to 7 to 14 days; chronic diarrhea persists for more than 2 to 3 weeks and may return sporadically. Diarrhea can be caused by certain medications (eg, thyroid hormone replacement, stool softeners and laxatives, prokinetic agents, antibiotics, chemotherapy, antiarrhythmics, antihypertensives, magnesium-based antacids), certain tube-feeding formulas, metabolic and endocrine disorders (eg, diabetes, Addison's disease, thyrotoxicosis), and viral or bacterial infectious processes (eg, dysentery, shigellosis, food poisoning, Norwalk virus). Other disease processes associated with diarrhea include nutritional and malabsorptive disorders

CHART
38-1

HEALTH PROMOTION Preventing Constipation

- Emphasize the importance of responding to the urge to defecate.
- Teach how to establish a bowel routine, and explain that having a regular time for defecation (eg, best time is after a meal) may aid in initiating the reflex.
- Provide dietary information; suggest eating high-residue, high-fiber foods, (eg, fruits, vegetables) adding bran daily (must be introduced gradually), and increasing fluid intake (unless contraindicated).
- Explain how an exercise regimen, increased ambulation, and abdominal muscle toning will increase muscle strength and help propel colon contents.
- Describe abdominal toning exercises (contracting abdominal muscles 4 times daily and leg-to-chest lifts 10 to 20 times each day).
- Explain that the normal position (semisquatting) maximizes use of abdominal muscles and force of gravity.
- Avoid overuse or long-term use of stimulant laxatives (eg, bisacodyl) because they can weaken colonic function.

(eg, celiac disease), anal sphincter defect, Zollinger-Ellison syndrome, paralytic ileus, intestinal obstruction, and acquired immunodeficiency syndrome (AIDS) (Sabol & Carlson, 2007).

Pathophysiology

Types of diarrhea include secretory, osmotic, malabsorptive, infectious, and exudative. Secretory diarrhea is usually high-volume diarrhea. Often associated with bacterial toxins and neoplasms, it is caused by increased production and secretion of water and electrolytes by the intestinal mucosa into the intestinal lumen. Osmotic diarrhea occurs when water is pulled into the intestines by the osmotic pressure of unabsorbed particles, slowing the reabsorption of water. It can be caused by lactase deficiency, pancreatic dysfunction, or intestinal hemorrhage. Malabsorptive diarrhea combines mechanical and biochemical actions, inhibiting effective absorption of nutrients manifested by markers of malnutrition that include hypoalbuminemia. Low serum albumin levels lead to intestinal mucosa swelling and liquid stool. Infectious diarrhea results from infectious agents invading the intestinal mucosa. *Clostridium difficile* is the most commonly identified agent in antibiotic-associated diarrhea in the hospital. The pathophysiology of diarrhea related to infection is discussed in Chapter 70. Exudative diarrhea is caused by changes in mucosal integrity, epithelial loss, or tissue destruction by radiation or chemotherapy (Sabol & Carlson, 2007).

Notably, other causes of diarrhea also include laxative misuse.

Clinical Manifestations

In addition to the increased frequency and fluid content of stools, the patient usually has abdominal cramps, distention, intestinal rumbling (ie, **borborygmus**), anorexia, and thirst. Painful spasmodic contractions of the anus and

ineffective straining (ie, **tenesmus**) may occur with defecation. Other symptoms depend on the cause and severity of the diarrhea but are related to dehydration and to fluid and electrolyte imbalances.

Watery stools are characteristic of disorders of the small bowel, whereas loose, semisolid stools are associated more often with disorders of the large bowel. Voluminous, greasy stools suggest intestinal malabsorption, and the presence of blood, mucus, and pus in the stools suggests inflammatory enteritis or colitis. Oil droplets on the toilet water are almost always diagnostic of pancreatic insufficiency. Nocturnal diarrhea may be a manifestation of diabetic neuropathy. The possibility of *C. difficile* infection should be considered in all patients with unexplained diarrhea who are taking or have recently taken antibiotics (Sabol & Carlson, 2007).

Assessment and Diagnostic Findings

When the cause of the diarrhea is not obvious, the following diagnostic tests may be performed: complete blood cell count; serum chemistries; urinalysis; routine stool examination; and stool examinations for infectious or parasitic organisms, bacterial toxins, blood, fat, electrolytes, and white blood cells. Endoscopy or barium enema may assist in identifying the cause.

Complications

Complications of diarrhea include the potential for cardiac dysrhythmias because of significant fluid and electrolyte loss (especially loss of potassium). Urinary output of less than 30 mL per hour for 2 to 3 consecutive hours, muscle weakness, paresthesia, hypotension, anorexia, and drowsiness with a potassium level of less than 3.5 mEq/L (3.5 mmol/L) must be reported. Chronic diarrhea can also result in skin care issues related to irritant dermatitis, which can be prevented by cleansing with a wet wipe, drying the skin, and then applying barrier cream (Metcalf, 2007; Sabol & Carlson, 2007).

Gerontologic Considerations

Elderly patients can become dehydrated quickly and develop low potassium levels (ie, hypokalemia) as a result of diarrhea. The nurse observes for clinical manifestations of muscle weakness, dysrhythmias, or decreased peristaltic motility that may lead to paralytic ileus. The older patient taking digitalis (eg, digoxin [Lanoxin]) must be aware of how quickly dehydration and hypokalemia can occur with diarrhea. The nurse teaches the patient to recognize the symptoms of hypokalemia because low levels of potassium potentiate the action of digitalis, leading to digitalis toxicity.

Medical Management

Primary management is directed at controlling symptoms, preventing complications, and eliminating or treating the underlying disease. Certain medications (eg, antibiotics, anti-inflammatory agents) and antidiarrheals (eg, loperamide [Imodium], diphenoxylate [Lomotil]) may be used to reduce the severity of the diarrhea and treat the underlying disease (Sabol & Carlson, 2007). In most cases, loperamide is the medication of choice because it has fewer side effects than diphenoxylate (Sabol & Carlson, 2007).

Nursing Management

The nurse's role includes assessing and monitoring the characteristics and pattern of diarrhea. A health history should address the patient's medication therapy, medical and surgical history, and dietary patterns and intake. Reports of recent exposure to an acute illness or recent travel to another geographic area are important. Assessment includes abdominal auscultation and palpation for tenderness. Inspection of the abdomen, mucous membranes, and skin is important to determine hydration status. Stool samples are obtained for testing. It is also necessary to assess the perianal area.

During an episode of acute diarrhea, the nurse encourages bed rest and intake of liquids and foods low in bulk until the acute attack subsides. When the patient is able to tolerate food intake, the nurse recommends a bland diet of semisolid and solid foods. The patient should avoid caffeine, carbonated beverages, and very hot and very cold foods, because they stimulate intestinal motility. It may be necessary to restrict milk products, fat, whole-grain products, fresh fruits, and vegetables for several days. The nurse administers antidiarrheal medications such as diphenoxylate or loperamide as prescribed. Intravenous (IV) fluid therapy may be necessary for rapid rehydration in some patients, especially in elderly patients and in patients with preexisting GI conditions (eg, inflammatory bowel disease). It is important to monitor serum electrolyte levels closely. The nurse immediately reports evidence of dysrhythmias or a change in a patient's level of consciousness.

The perianal area may become excoriated because diarrheal stool contains digestive enzymes that can irritate the skin. The patient should follow a perianal skin care routine to decrease irritation and excoriation (see Chapter 56). The skin of an older person is very sensitive because of decreased turgor and reduced subcutaneous fat layers.

Fecal Incontinence

Fecal incontinence describes the involuntary passage of stool from the rectum. Factors that influence fecal continence include the ability of the rectum to sense and accommodate stool, the amount and consistency of stool, the integrity of the anal sphincters and musculature, and rectal motility. It is an embarrassing and socially incapacitating problem that requires a many-tiered approach to treatment and much adaptation on the patient's part.

Pathophysiology

Fecal incontinence has many causes and risk factors. In general, it results from conditions that interrupt or disrupt the structure or function of the anorectal unit (Beitz, 2006). Causes include trauma (eg, after surgical procedures involving the rectum), neurologic disorders (eg, stroke, multiple sclerosis, diabetic neuropathy, dementia), inflammation, infection, chemotherapy, radiation treatment, fecal impaction, pelvic floor relaxation, laxative abuse, medications, or advancing age (ie, weakness or loss of anal or rectal muscle tone).

Clinical Manifestations

Patients may have minor soiling, occasional urgency and loss of control, or complete incontinence. Patients may also experience poor control of flatus, diarrhea, or constipation.

Assessment and Diagnostic Findings

Diagnostic studies are necessary because the treatment of fecal incontinence depends on the cause. A rectal examination and endoscopic examinations such as a flexible sigmoidoscopy are performed to rule out tumors, inflammation, or fissures. X-ray studies such as barium enema, computed tomography (CT), anorectal manometry, and transit studies may be helpful in identifying alterations in intestinal mucosa and muscle tone or in detecting other structural or functional problems.

Medical Management

Although there is no known cure for fecal incontinence, specific management techniques can help the patient achieve a better quality of life. If fecal incontinence is related to diarrhea, the incontinence may disappear when diarrhea is successfully treated. Fecal incontinence is frequently a symptom of a fecal impaction. After the impaction is removed and the rectum is cleansed, normal functioning of the anorectal area can resume. If the fecal incontinence is related to a more permanent condition, other treatments are initiated. Biofeedback therapy with pelvic floor muscle training can be of assistance if the problem is decreased sensory awareness or sphincter control. Bowel training programs can also be effective. Surgical procedures include surgical reconstruction, artificial sphincter implantation, sphincter repair, or fecal diversion.

Nursing Management

The nurse obtains a thorough health history, including information about previous surgical procedures, chronic illnesses, dietary patterns, bowel habits and problems, and current medication regimen. The nurse also completes an examination of the rectal area. If a fecal impaction is noted, it must be removed before instituting any preventive therapies.

The nurse initiates a bowel-training program that involves setting a schedule to establish bowel regularity. The goal is to help the patient achieve fecal continence. If this is not possible, the goal should be to manage the problem so the patient can have predictable, planned elimination. Sometimes it is necessary to use suppositories to stimulate the anal reflex. After the patient has achieved a regular schedule, the suppository can be discontinued. Biofeedback can be used in conjunction with these therapies to help the patient improve sphincter contractility and rectal sensitivity. Bowel regulation also involves the therapeutic use of diet and fiber. Foods that thicken stool (eg, applesauce) and fiber products (eg, psyllium) help improve continence.

Fecal incontinence can also cause problems with perineal skin integrity. Maintaining skin integrity is a priority, especially in the debilitated or elderly patient. Incontinence briefs or adult diapers, although helpful in containing the fecal material, permit increased skin contact with feces and may cause skin excoriation. In general, incontinence briefs are to be used only for brief periods of time. The nurse

Figure 38-1 Flexi-Seal Fecal Management System (Courtesy of Convatec, Inc., © Skillman, NJ).

encourages and teaches meticulous skin hygiene and uses perineal skin cleansers and skin protection products to protect perineal skin (Beitz, 2006).

Continence sometimes cannot be achieved, and the nurse assists the patient and family to accept and cope with this chronic situation. The patient can use fecal incontinence devices, which include external collection devices and internal drainage systems. External devices are special rectal pouches, called fecal incontinence collectors, which are drainable. They are attached to a synthetic adhesive skin barrier specially designed to conform to the buttocks. Internal drainage systems can be used to eliminate fecal skin contact and are especially useful when there is extensive excoriation or skin breakdown. New fecal and bowel management systems (eg, Flexi-Seal Fecal Management System) are available. These systems, which consist of a tube with a low-pressure balloon that conforms to the internal rectal area, may be used for up to 29 consecutive days (Fig. 38-1). Compared with rectal catheters, the newer bowel management systems are associated with improved patient safety; therefore, the former are now generally contraindicated (Beitz, 2006).

Irritable Bowel Syndrome

Irritable bowel syndrome (IBS) is one of the most common GI conditions. Approximately 12% of adults in the United States report classic symptoms of IBS (Hadley & Gardner, 2005). IBS accounts for 3.5 million office visits and is a leading cause of workforce absenteeism (Harmon, 2007). It occurs more commonly in women than in men, and the cause remains unknown (Hasler, 2007). Although no anatomic or biochemical abnormalities have been found that account for its common symptoms, various factors are associated with the syndrome: heredity, psychological stress or conditions such as depression and anxiety, a diet high in fat and stimulating or irritating foods, alcohol consumption, and smoking. The diagnosis is made only after tests confirm the absence of structural or other disorders (Hasler, 2007).

Pathophysiology

IBS results from a functional disorder of intestinal motility. The change in motility may be related to neuroendocrine dysregulation, especially if there are changes in serotonin signaling, which regulates intestinal motility. Changes in intestinal motility may also result from infections or other inflammatory disorders or vascular or metabolic distur-

bances. The peristaltic waves are affected at specific segments of the intestine and in the intensity with which they propel the fecal matter forward. There is no evidence of inflammation or tissue changes in the intestinal mucosa (Costedio, Hyman & Mawe, 2006; Hasler, 2007).

Clinical Manifestations

There is a wide variability in symptom presentation. Symptoms range in intensity and duration from mild and infrequent to severe and continuous. The primary symptom is an alteration in bowel patterns: constipation, diarrhea, or a combination of both. Pain, bloating, and abdominal distention often accompany changes in bowel pattern. The abdominal pain is sometimes precipitated by eating and is frequently relieved by defecation.

Assessment and Diagnostic Findings

Specific diagnostic criteria established through international consensus conferences have led to improved diagnosis of IBS. Criteria include recurrent abdominal pain or discomfort for at least 3 days a month in the past 3 months, including two or more of the following: (1) improvement with defecation; (2) onset associated with change in frequency of stool; and (3) onset associated with change in appearance (form) of stool (Laine & Goldman, 2007; Spiller, 2007).

A definite diagnosis requires tests that confirm the absence of structural or other disorders. Stool studies, contrast x-ray studies, and proctoscopy may be performed to rule out other colon diseases. Barium enema and colonoscopy may reveal spasm, distention, or mucus accumulation in the intestine (Fig. 38-2). Manometry and electromyography (EMG) are used to study intraluminal pressure changes generated by spasticity.

Medical Management

The goals of treatment are relieving abdominal pain, controlling the diarrhea or constipation, and reducing stress. Restriction and then gradual reintroduction of foods that are possibly irritating may help determine what types of food are acting as irritants (eg, beans, caffeinated products, corn, wheat, dairy lactose, fried foods, alcohol, spicy foods,

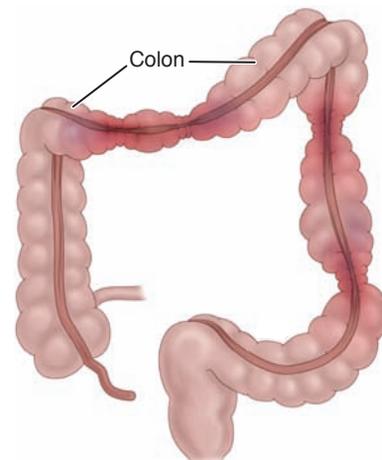

Figure 38-2 In irritable bowel syndrome (IBS), the spastic contractions of the bowel can be seen on x-ray contrast studies.

aspartame). A high-fiber diet is prescribed to help control the diarrhea and constipation. Exercise can assist in reducing anxiety and increasing intestinal motility. Patients often find it helpful to participate in a stress reduction or behavior modification program. Hydrophilic colloids (ie, bulk) and antidiarrheal agents (eg, loperamide) may be given to control the diarrhea and fecal urgency. Antidepressants can assist in treating underlying anxiety and depression but also have secondary benefits. They may affect serotonin levels, thus slowing intestinal transit time and improving diarrhea and abdominal comfort. Anticholinergics or antispasmodics (eg, propantheline [Pro-Banthine]) may be prescribed to decrease smooth muscle spasm, decreasing cramping and constipation.

Tegaserod was previously prescribed to treat women with IBS whose chief complaint was chronic constipation. Tegaserod was stopped for IBS treatment because it was associated with increased risks of myocardial infarction and stroke (Harmon, 2007; Laine & Goldman, 2007). Other alternatives for IBS management include probiotics and alternative medicines. Probiotics are bacteria that include *Lactobacillus* and *Bifidobacterium* that can be administered to help decrease abdominal bloating and gas. Complementary medicine approaches to treatment of IBS include artichoke leaf extract, peppermint oil, and caraway oil. They reputedly diminish IBS symptoms; however, formal studies are needed to examine their effectiveness (Harmon, 2007; Laine & Goldman, 2007).

Nursing Management

The nurse's role is to provide patient and family education. Teaching and reinforcement of good dietary habits (eg, avoidance of food triggers) are emphasized. A good method for identifying problem foods involves keeping a symptom and food diary for 1 to 2 weeks. Patients are encouraged to eat at regular times and to chew food slowly and thoroughly. They should understand that although adequate fluid intake is necessary, fluid should not be taken with meals because this results in abdominal distention. Alcohol use and cigarette smoking are discouraged. Stress management via relaxation techniques, yoga, or exercise can be recommended (Harmon, 2007).

Conditions of Malabsorption

Malabsorption is the inability of the digestive system to absorb one or more of the major vitamins (especially A and B₁₂), minerals (ie, iron and calcium), and nutrients (ie, carbohydrates, fats, and proteins). Interruptions in the complex digestive process may occur anywhere in the digestive system and cause decreased absorption. Diseases of the small intestine are the most common cause of malabsorption.

Pathophysiology

The conditions that cause malabsorption can be grouped into the following categories:

- Mucosal (transport) disorders causing generalized malabsorption (eg, celiac sprue, regional enteritis, radiation enteritis)

- Infectious diseases causing generalized malabsorption (eg, small bowel bacterial overgrowth, tropical sprue, Whipple's disease)
- Luminal disorders causing malabsorption (eg, bile acid deficiency, Zollinger-Ellison syndrome, pancreatic insufficiency)
- Postoperative malabsorption (eg, after gastric or intestinal resection)
- Disorders that cause malabsorption of specific nutrients (eg, disaccharidase deficiency leading to lactose intolerance)

Table 38-2 lists the clinical and pathologic aspects of malabsorptive diseases.

Clinical Manifestations

The hallmarks of malabsorption syndrome from any cause are diarrhea or frequent, loose, bulky, foul-smelling stools that have increased fat content and are often grayish. Patients often have associated abdominal distention, pain, increased flatus, weakness, weight loss, and a decreased sense of well-being. The chief result of malabsorption is malnutrition, manifested by weight loss and other signs of vitamin and mineral deficiency (eg, easy bruising, osteoporosis, anemia). Patients with a malabsorption syndrome, if untreated, become weak and emaciated because of starvation and dehydration. Failure to absorb the fat-soluble vitamins A, D, and K causes a corresponding avitaminosis.

Assessment and Diagnostic Findings

Several diagnostic tests may be prescribed, including stool studies for quantitative and qualitative fat analysis, lactose tolerance tests, D-xylose absorption tests, and Schilling tests. The hydrogen breath test that is used to evaluate carbohydrate absorption (see Chapter 34) is performed if carbohydrate malabsorption is suspected. Endoscopy with biopsy of the mucosa is the best diagnostic tool. Biopsy of the small intestine is performed to assay enzyme activity or to identify infection or destruction of mucosa. Ultrasound studies, CT scans, and x-ray findings can reveal pancreatic or intestinal tumors that may be the cause. A complete blood cell count is used to detect anemia. Pancreatic function tests can assist in the diagnosis of specific disorders.

Medical Management

Intervention is aimed at avoiding dietary substances that aggravate malabsorption and at supplementing nutrients that have been lost. Common supplements are water-soluble vitamins (eg, B₁₂, folic acid), fat-soluble vitamins (ie, A, D, and K), and minerals (eg, calcium, iron). Primary disease states may be managed surgically or nonsurgically. Dietary therapy is aimed at reducing gluten intake in patients with celiac sprue. Folic acid supplements are prescribed for patients with tropical sprue. Antibiotics (eg, tetracycline [Tetracylin], ampicillin [Polycillin]) are sometimes needed in the treatment of tropical sprue and bacterial overgrowth syndromes. Antidiarrheal agents may be used to decrease intestinal spasms. Parenteral fluids may be necessary to treat dehydration.

Table 38-2 CHARACTERISTICS OF DISEASES OF MALABSORPTION

Diseases/Disorders	Pathophysiology	Clinical Features
Gastric resection with gastrojejunostomy	Decreased pancreatic stimulation because of duodenal bypass; poor mixing of food, bile, pancreatic enzymes; decreased intrinsic factor	Weight loss, moderate steatorrhea, anemia (combination of iron deficiency, vitamin B ₁₂ malabsorption, folate deficiency)
Pancreatic insufficiency (chronic pancreatitis, pancreatic carcinoma, pancreatic resection, cystic fibrosis)	Reduced intraluminal pancreatic enzyme activity, with maldigestion of lipids and proteins	History of abdominal pain followed by weight loss; marked steatorrhea, azotorrhea (excess of nitrogenous matter in the feces or urine); also frequent glucose intolerance (70% in pancreatic insufficiency)
Ileal dysfunction (resection or disease)	Loss of ileal absorbing surface leads to reduced bile-salt pool size and reduced vitamin B ₁₂ absorption; bile in colon inhibits fluid absorption	Diarrhea, weight loss with steatorrhea, especially when greater than 100 cm resection, decreased vitamin B ₁₂ absorption
Stasis syndromes (surgical strictures, blind loops, enteric fistulas, multiple jejunal diverticula, scleroderma)	Overgrowth of intraluminal intestinal bacteria, especially anaerobic organisms, to greater than 10 ⁶ /mL results in deconjugation of bile salts, leading to decreased effective bile-salt pool size, also bacterial utilization of vitamin B ₁₂	Weight loss, steatorrhea; low vitamin B ₁₂ absorption; may have low D-xylose absorption
Zollinger-Ellison syndrome	Hyperacidity in duodenum inactivates pancreatic enzymes	Ulcer diathesis, steatorrhea
Lactose intolerance	Deficiency of intestinal lactase results in high concentration of intraluminal lactose with osmotic diarrhea	Varied degrees of diarrhea and cramps after ingestion of lactose-containing foods; positive lactose intolerance test, decreased intestinal lactase
Celiac disease (gluten-sensitive enteropathy)	Toxic response to a gluten fraction gliadin by surface epithelium results in destruction of absorbing surface of intestine	Weight loss, diarrhea, bloating, anemia (low iron, folate), osteomalacia, steatorrhea, azotorrhea, low D-xylose absorption; folate and iron malabsorption
Tropical sprue	Unknown toxic factor results in mucosal inflammation, partial villous atrophy	Weight loss, diarrhea, anemia (low folate, vitamin B ₁₂); steatorrhea; low D-xylose absorption, low vitamin B ₁₂ absorption
Whipple's disease	Bacterial invasion of intestinal mucosa	Arthritis, hyperpigmentation, lymphadenopathy, serous effusions, fever, weight loss, steatorrhea, azotorrhea
Certain parasitic diseases (giardiasis, strongyloidiasis, coccidiosis, capillariasis)	Damage to or invasion of surface mucosa	Diarrhea, weight loss; steatorrhea; organism may be seen on jejunal biopsy or recovered in stool
Immunoglobulinopathy	Decreased local intestinal defenses, lymphoid hyperplasia, lymphopenia	Frequent association with <i>Giardia</i> : hypogammaglobulinemia or isolated IgA deficiency

Gerontologic Considerations

The older patient may have more subtle symptoms of malabsorption that may be extraintestinal, including fatigue and confusion. Medical management may include the administration of corticosteroids, which may cause a host of adverse effects such as hypertension, hypokalemia, and mood changes. Antibiotics may reduce vitamin K-producing intestinal flora, resulting in a prolonged prothrombin time (PT) and international normalized ratio (INR) if the patient is concurrently taking warfarin (Coumadin). Urinary retention, altered mental status, or glaucoma may occur as adverse effects of anticholinergic drug therapy in older people.

Nursing Management

The nurse provides patient and family education regarding diet and the use of nutritional supplements (Chart 38-2). It is important to monitor patients with diarrhea for fluid and electrolyte imbalances. The nurse conducts ongoing assessments to determine whether the clinical manifestations related to the nutritional deficits have abated. Patient education includes information about the risk of osteoporosis related to malabsorption of calcium.

ACUTE INFLAMMATORY INTESTINAL DISORDERS

Any part of the lower GI tract is susceptible to acute inflammation caused by bacterial, viral, or fungal infection. Two such conditions are appendicitis and diverticulitis, both of which may lead to **peritonitis**, an inflammation of the lining of the abdominal cavity.

Appendicitis

The appendix is a small, fingerlike appendage about 10 cm (4 in) long that is attached to the cecum just below the ileocecal valve. The appendix fills with food and empties regularly into the cecum. Because it empties inefficiently and its lumen is small, the appendix is prone to obstruction and is particularly vulnerable to infection (ie, appendicitis).

Appendicitis, the most common cause of acute surgical abdomen in the United States, is the most common reason for emergency abdominal surgery. Although it can occur at any age, it more commonly occurs between the ages of 10 and 30 years (NIH, 2007).

CHART
38-2

PATIENT EDUCATION

Managing Lactose Intolerance

- Deficiency of lactase, a digestive enzyme essential for the digestion and absorption of lactose (“milk sugar”) from the intestines, results in an intolerance to milk.
- Elimination of milk and milk substances can prevent symptoms.
- Many processed foods have fillers, such as dried milk, added to them.
- Pretreatment of foods with lactase preparations (eg, LactAid drops) before ingestion can reduce symptoms.
- Ingestion of lactase enzyme tablets with the first bite of food can reduce symptoms.
- Most people can tolerate 1 to 2 cups of milk or milk products daily without major problems; they are best tolerated if ingested in small amounts during the day.
- Lactase activity of yogurt with “active cultures” helps the digestion of lactose within the intestine better than lactase preparations do.
- Milk and milk products are rich sources of calcium and vitamin D; elimination of milk from the diet may result in calcium and vitamin D deficiencies; decreased intake without supplements can lead to osteoporosis.

Pathophysiology

The appendix becomes inflamed and edematous as a result of becoming kinked or occluded by a fecalith (ie, hardened mass of stool), tumor, or foreign body. The inflammatory process increases intraluminal pressure, initiating a progressively severe, generalized, or periumbilical pain that becomes localized to the right lower quadrant of the abdomen within a few hours. Eventually, the inflamed appendix fills with pus.

Clinical Manifestations

Vague epigastric or periumbilical pain (ie, visceral pain that is dull and poorly localized) progresses to right lower quadrant pain (ie, parietal pain that is sharp, discrete, and well localized) and is usually accompanied by a low-grade fever and nausea and sometimes by vomiting. Loss of appetite is common. In up to 50% of presenting cases, local tenderness is elicited at McBurney’s point when pressure is applied (Fig. 38-3). Rebound tenderness (ie, production or intensification of pain when pressure is released) may be present. The extent of tenderness and muscle spasm and the existence of constipation or diarrhea depend not so much on the severity of the appendiceal infection as on the location of the appendix. If the appendix curls around behind the cecum, pain and tenderness may be felt in the lumbar region. If its tip is in the pelvis, these signs may be elicited only on rectal examination. Pain on defecation suggests that the tip of the appendix is resting against the rectum; pain on urination suggests that the tip is near the bladder or impinges on the ureter. Some rigidity of the lower portion of the right rectus muscle may occur. Rovsing’s sign may be elicited by palpating the left lower quadrant; this paradoxically causes pain to be felt in the right lower quadrant (see Fig. 38-3). If the appendix has ruptured, the pain becomes more diffuse;

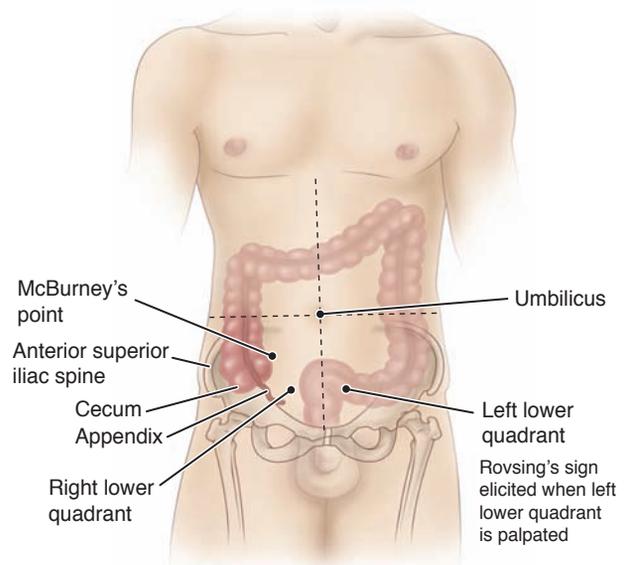

Figure 38-3 When the appendix is inflamed, tenderness can be noted in the right lower quadrant at McBurney’s point, which is between the umbilicus and the anterior superior iliac spine. Rovsing’s sign is pain felt in the right lower quadrant after the left lower quadrant has been palpated.

abdominal distention develops as a result of paralytic ileus, and the patient’s condition worsens.

Constipation can also occur with appendicitis. Laxatives administered in this instance may result in perforation of the inflamed appendix. In general, a laxative or cathartic should never be given when a person has fever, nausea, and abdominal pain.

Assessment and Diagnostic Findings

Diagnosis is based on results of a complete physical examination and on laboratory findings and imaging studies. The complete blood cell count demonstrates an elevated white blood cell count with an elevation of the neutrophils. Abdominal x-ray films, ultrasound studies, and CT scans may reveal a right lower quadrant density or localized distention of the bowel. A pregnancy test may be performed for women of childbearing age to rule out ectopic pregnancy and before x-rays are obtained. A diagnostic laparoscopy may be used to rule out acute appendicitis in equivocal cases.

Complications

The major complication of appendicitis is perforation of the appendix, which can lead to peritonitis, abscess formation (collection of purulent material), or portal pylephlebitis, which is septic thrombosis of the portal vein caused by vegetative emboli that arise from septic intestines. Perforation generally occurs 24 hours after the onset of pain. Symptoms include a fever of 37.7°C (100°F) or greater, a toxic appearance, and continued abdominal pain or tenderness.

Gerontologic Considerations

Acute appendicitis is uncommon in the elderly population. When it does occur, classic signs and symptoms are altered and may vary greatly. Pain may be absent or minimal.

Symptoms may be vague, suggesting bowel obstruction or another process. Fever and leukocytosis may not be present. As a result, diagnosis and prompt treatment may be delayed, causing complications and mortality. The patient may have no symptoms until the appendix ruptures. The incidence of perforated appendix is higher in the elderly population because many of these patients do not seek health care as quickly as younger patients.

Medical Management

Immediate surgery is typically indicated if appendicitis is diagnosed. To correct or prevent fluid and electrolyte imbalance, dehydration, and sepsis, antibiotics and IV fluids are administered until surgery is performed. Appendectomy (ie, surgical removal of the appendix) is performed as soon as possible to decrease the risk of perforation. It may be performed using general or spinal anesthesia with a low abdominal incision (laparotomy) or by laparoscopy. Both laparotomy and laparoscopy are safe and effective in the treatment of appendicitis with perforation. However, recovery after laparoscopic surgery is generally quicker. Consequently, laparoscopic appendectomy is more common.

When perforation of the appendix occurs, an abscess may form. If this occurs, the patient may be initially treated with antibiotics, and the surgeon may place a drain in the abscess. After the abscess is drained and there is no further evidence of infection, an appendectomy is then typically performed.

Nursing Management

Goals include relieving pain, preventing fluid volume deficit, reducing anxiety, eliminating infection due to the potential or actual disruption of the GI tract, maintaining skin integrity, and attaining optimal nutrition.

The nurse prepares the patient for surgery, which includes an IV infusion to replace fluid loss and promote adequate renal function and antibiotic therapy to prevent infection. If there is evidence or likelihood of paralytic ileus, a nasogastric tube is inserted. An enema is not administered because it can lead to perforation.

After surgery, the nurse places the patient in a high-Fowler's position. This position reduces the tension on the

incision and abdominal organs, helping to reduce pain. An opioid, usually morphine sulfate, is prescribed to relieve pain. When tolerated, oral fluids are administered. Any patient who was dehydrated before surgery receives IV fluids. Food is provided as desired and tolerated on the day of surgery when normal bowel sounds are present.

The patient may be discharged on the day of surgery if the temperature is within normal limits, there is no undue discomfort in the operative area, and the appendectomy was uncomplicated. Discharge teaching for the patient and family is imperative. The nurse instructs the patient to make an appointment to have the surgeon remove the sutures between the 5th and 7th days after surgery. Incision care and activity guidelines are discussed; heavy lifting is to be avoided postoperatively, although normal activity can usually be resumed within 2 to 4 weeks.

If there is a possibility of peritonitis, a drain is left in place at the area of the incision. Patients at risk for this complication may be kept in the hospital for several days and are monitored carefully for signs of intestinal obstruction or secondary hemorrhage. Secondary abscesses may form in the pelvis, under the diaphragm, or in the liver, causing elevation of the temperature, pulse rate, and white blood cell count.

When the patient is ready for discharge, the patient and family are taught to care for the incision and perform dressing changes and irrigations as prescribed. A home care nurse may be needed to assist with this care and to monitor the patient for complications and wound healing. Other complications of appendectomy are listed in Table 38-3.

Diverticular Disease

A **diverticulum** is a saclike herniation of the lining of the bowel that extends through a defect in the muscle layer. Diverticula may occur anywhere in the small intestine or colon but most commonly occur in the sigmoid colon (at least 95%) (Beitz, 2004). However, persons of Asian heritage tend to develop diverticula in the right colon, probably because of genetic differences.

Table 38-3 POTENTIAL COMPLICATIONS AND NURSING INTERVENTIONS AFTER APPENDECTOMY

Complication	Nursing Interventions
Peritonitis	Monitor for abdominal tenderness, fever, vomiting, abdominal rigidity, and tachycardia. Employ constant nasogastric suction. Correct dehydration as prescribed. Administer antibiotic agents as prescribed.
Pelvic abscess	Evaluate for anorexia, chills, fever, and diaphoresis. Observe for diarrhea, which may indicate pelvic abscess. Prepare patient for rectal examination. Prepare patient for surgical drainage procedure.
Subphrenic abscess (abscess under the diaphragm)	Assess patient for chills, fever, and diaphoresis. Prepare for x-ray examination. Prepare for surgical drainage of abscess.
Ileus (paralytic and mechanical)	Assess for bowel sounds. Employ nasogastric intubation and suction. Replace fluids and electrolytes by intravenous route as prescribed. Prepare for surgery, if diagnosis of mechanical ileus is established.

Diverticulosis exists when multiple diverticula are present without inflammation or symptoms. Diverticular disease of the colon is very common in developed countries, and its prevalence increases with age: More than 50% of Americans older than 80 years have diverticulosis (Beitz, 2004). A low intake of dietary fiber is considered a predisposing factor, but the exact cause has not been identified. Most patients with diverticular disease are asymptomatic, so its exact prevalence is unknown.

Diverticulitis results when food and bacteria retained in a diverticulum produce infection and inflammation that can impede drainage and lead to perforation or abscess formation. At least 10% of patients with diverticulosis have diverticulitis at some point. A congenital predisposition is suspected when the disorder occurs in those younger than 40 years. Diverticulitis may occur as an acute attack or may persist as a continuing, smoldering infection. The symptoms manifested generally result from complications: abscess, **fistula** (abnormal tract) formation, obstruction, perforation, peritonitis, and hemorrhage.

Pathophysiology

Diverticula form when the mucosa and submucosal layers of the colon herniate through the muscular wall because of high intraluminal pressure, low volume in the colon (ie, fiber-deficient contents), and decreased muscle strength in the colon wall (ie, muscular hypertrophy from hardened fecal masses). Bowel contents can accumulate in the diverticulum and decompose, causing inflammation and infection. The diverticulum can also become obstructed and then inflamed if the obstruction continues. The inflammation of the weakened colonic wall of the diverticulum can cause it to perforate, giving rise to irritability and spasticity of the colon (ie, diverticulitis). In addition, abscesses develop and may eventually perforate, leading to peritonitis and erosion of the arterial blood vessels, resulting in bleeding. When symptoms of diverticulitis have developed, microperforation of the colon has occurred (Beitz, 2004).

Clinical Manifestations

Chronic constipation often precedes the development of diverticulosis by many years. Frequently, no problematic symptoms occur with diverticulosis. Signs and symptoms of diverticulosis are relatively mild and include bowel irregularity with intervals of diarrhea, nausea and anorexia, and bloating or abdominal distention. With repeated local inflammation of the diverticula, the large bowel may narrow with fibrotic strictures, leading to cramps, narrow stools, and increased constipation or at times intestinal obstruction. Weakness, fatigue, and anorexia are common symptoms. With diverticulitis, the patient reports an acute onset of mild to severe pain in the left lower quadrant, accompanied by nausea, vomiting, fever, chills, and leukocytosis. The condition, if untreated, can lead to peritonitis and septicemia.

Assessment and Diagnostic Findings

Diverticulosis is typically diagnosed by colonoscopy, which permits visualization of the extent of diverticular disease and allows the physician to biopsy tissue to rule out other diseases. Until recently, barium enema had been the preferred diagnostic test, but it is now used less frequently than

colonoscopy. If there are symptoms of peritoneal irritation when the diagnosis is diverticulitis, barium enema is contraindicated because of the potential for perforation.

CT with contrast agent is the diagnostic test of choice if the suspected diagnosis is diverticulitis; it can also reveal abscesses. Abdominal x-rays may demonstrate free air under the diaphragm if a perforation has occurred from the diverticulitis. Laboratory tests that assist in diagnosis include a complete blood cell count, revealing an elevated white blood cell count, and elevated erythrocyte sedimentation rate (ESR).

Complications

Complications of diverticulitis include peritonitis, abscess formation, fistulas, and bleeding. If an abscess develops, the associated findings are tenderness, a palpable mass, fever, and leukocytosis. An inflamed diverticulum that perforates results in abdominal pain localized over the involved segment, usually the sigmoid; local abscess or peritonitis follows. Abdominal pain, a rigid boardlike abdomen, loss of bowel sounds, and signs and symptoms of shock occur with peritonitis. On occasion, the diverticular inflammation creates an abnormal passage between body structures such as a colovesical fistula (between bowel and bladder). Noninflamed or slightly inflamed diverticula may erode areas adjacent to arterial branches, causing massive rectal bleeding.

Gerontologic Considerations

The incidence of diverticular disease increases with age because of degeneration and structural changes in the circular muscle layers of the colon and because of cellular hypertrophy. The symptoms are less pronounced in the elderly than in other adults. The elderly may not have abdominal pain until infection occurs. They may delay reporting symptoms because they fear surgery or are afraid that they may have cancer. Blood in the stool is overlooked frequently, especially in the elderly, because of a failure to examine the stool or the inability to see changes if vision is impaired.

Medical Management

Dietary and Pharmacologic Management

Diverticulitis can usually be treated on an outpatient basis with diet and medication. When symptoms occur, rest, analgesics, and antispasmodics are recommended. Initially, a clear liquid diet is consumed until the inflammation subsides; then a high-fiber, low-fat diet is recommended. This type of diet helps increase stool volume, decrease colonic transit time, and reduce intraluminal pressure. Antibiotics are prescribed for 7 to 10 days. A bulk-forming laxative is also prescribed.

In acute cases of diverticulitis with significant symptoms, hospitalization is required. Hospitalization is often indicated for those who are elderly, immunocompromised, or taking corticosteroids. Withholding oral intake, administering IV fluids, and instituting nasogastric suctioning if vomiting or distention occurs are used to rest the bowel. Broad-spectrum antibiotics are prescribed for 7 to 10 days. An opioid (eg, meperidine [Demerol]) is prescribed for pain relief. Morphine is contraindicated because it can increase intraluminal pressure in the colon, exacerbating symptoms (Beitz, 2008). Oral intake is increased as symptoms subside.

A low-fiber diet may be necessary until signs of infection decrease.

Antispasmodics such as propantheline bromide and oxyphenyclimine (Daricon) may be prescribed. Often it is not possible for patients to consume the 20 to 30 g of daily fiber that is recommended. Normal stools can be achieved by supplementing dietary fiber by using bulk preparations (psyllium) or stool softeners (docusate), by instilling warm oil into the rectum, or by inserting an evacuant suppository (bisacodyl). Such a prophylactic plan can reduce the bacterial flora of the bowel, diminish the bulk of the stool, and soften the fecal mass so that it moves more easily through the area of inflammatory obstruction.

Surgical Management

Although acute diverticulitis usually subsides with medical management, immediate surgical intervention is necessary if complications (eg, perforation, peritonitis, hemorrhage, obstruction) occur. In cases of abscess formation without peritonitis, hemorrhage, or obstruction, CT-guided percutaneous drainage may be performed to drain the abscess, and IV antibiotics are administered. After the abscess is drained and the acute episode of inflammation has subsided (after approximately 6 weeks), surgery may be recommended to prevent repeated episodes. Two types of surgery are typically considered either to treat acute complications or prevent further episodes of inflammation:

- One-stage resection, in which the inflamed area is removed and a primary end-to-end anastomosis is completed
- Multiple-stage procedures for complications such as obstruction or perforation (Fig. 38-4)

The type of surgery performed depends on the extent of complications found during surgery. When possible, the area of diverticulitis is resected and the remaining bowel is

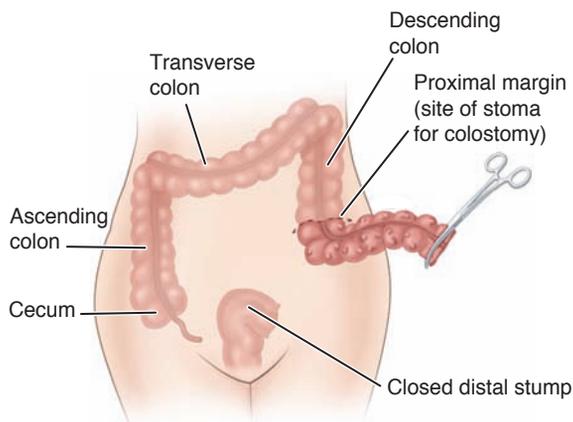

Figure 38-4 The Hartmann's procedure for diverticulitis: primary resection for diverticulitis of the colon. The affected segment (*clamp attached*) has been divided at its distal end. In a primary anastomosis, the proximal margin (*dotted line*) is transected and the bowel attached end to end. In a two-stage procedure, a colostomy is constructed at the proximal margin with the distal stump oversewn (Hartmann procedure, as shown) and the stump is left in the pelvis. The distal stump may be brought to the surface as a mucous fistula if there is concern about blood supply. The second stage consists of colostomy takedown and anastomosis.

joined end-to-end (ie, primary resection and end-to-end anastomosis). This is performed using traditional surgical or laparoscopically assisted colectomy. More primary anastomoses are completed because surgeons are now able to perform intraoperative colonic lavage to decrease intestinal bacterial load. A two-stage resection may be performed in which the diseased colon is resected (as in a one-stage procedure) but no anastomosis is performed. In this procedure, one end of the bowel is brought out to the abdominal wall and the distal end is closed over and left in the abdomen (Hartmann's procedure) or if the blood supply to the distal colon is questionable, both ends of the bowel are brought out to the abdominal wall (double-barrel) (Beitz, 2004). Both Hartmann's and double-barrel colostomies are usually reanastomosed at a later time. Fecal diversion procedures are discussed later in this chapter.

NURSING PROCESS

THE PATIENT WITH DIVERTICULITIS

Assessment

When obtaining the health history, the nurse asks the patient about the onset and duration of pain and about past and present elimination patterns. The nurse reviews dietary habits to determine fiber intake and asks the patient about straining at stool, history of constipation with periods of diarrhea, tenesmus, abdominal bloating, and distention.

Assessment includes auscultation for the presence and character of bowel sounds and palpation for left lower quadrant pain, tenderness, or firm mass. The stool is inspected for pus, mucus, or blood. Temperature, pulse, and blood pressure are monitored for abnormal variations.

Diagnosis

Nursing Diagnoses

Based on the assessment data, the nursing diagnoses may include the following:

- Constipation related to narrowing of the colon from thickened muscular segments and strictures
- Acute pain related to inflammation and infection

Collaborative Problems/Potential Complications

Potential complications that may develop include the following:

- Peritonitis
- Abscess formation
- Bleeding

Planning and Goals

The major goals for the patient may include attainment and maintenance of normal elimination patterns, pain relief, and absence of complications.

Nursing Interventions

Maintaining Normal Elimination Patterns

The nurse recommends a fluid intake of 2 L per day (within limits of the patient's cardiac and renal reserve) and suggests foods that are soft but have increased fiber, such as prepared

cereals or soft-cooked vegetables, to increase the bulk of the stool and facilitate peristalsis, thereby promoting defecation. An individualized exercise program is encouraged to improve abdominal muscle tone. It is important to review the patient's daily routine to establish a schedule for meals and a set time for defecation and to assist in identifying habits that may have suppressed the urge to defecate. The nurse encourages daily intake of bulk laxatives such as psyllium, which helps propel feces through the colon. Stool softeners are administered as prescribed to decrease straining at stool, which decreases intestinal pressure. Oil retention enemas may be prescribed to soften the stool, making it easier to pass. Some people with diverticulosis may have food triggers such as nuts and popcorn that bring on an attack of diverticulitis. Patients should be urged to identify these triggers and avoid them.

Relieving Pain

Opioid analgesics (eg, meperidine) to relieve the pain of diverticulitis and antispasmodic agents to decrease intestinal spasm are administered as prescribed (Beitz, 2008). The nurse records the intensity, duration, and location of pain to determine whether the inflammatory process worsens or subsides.

Monitoring and Managing Potential Complications

The major nursing focus is to prevent complications by identifying patients at risk and managing their symptoms as needed. The nurse assesses for the following signs and symptoms of perforation: increased abdominal pain and tenderness accompanied by abdominal rigidity, elevated white blood cell count, elevated ESR, increased temperature, tachycardia, and hypotension. Perforation is a surgical emergency. The clinical manifestations of perforation and peritonitis and the care of the patient with peritonitis are presented in the next section. The nurse monitors vital signs and urine output and administers IV fluids to replace volume loss as needed.

Promoting Home and Community-Based Care

Because patients and their family members and health care providers tend to focus on the most obvious needs and issues, the nurse reminds the patient and family about the importance of continuing health promotion and screening practices. The nurse educates patients who have not been involved in these practices in the past about their importance and refers the patients to appropriate health care providers.

Evaluation

Expected Patient Outcomes

Expected patient outcomes may include the following:

1. Attains a normal pattern of elimination
 - a. Reports less abdominal cramping and pain
 - b. Reports the passage of soft, formed stool without pain
 - c. Adds unprocessed bran to foods
 - d. Drinks at least 10 glasses of fluid each day (if fluid intake is tolerated)
 - e. Exercises daily
2. Reports decreased pain
 - a. Requests analgesics as needed
 - b. Adheres to a low-fiber diet during acute episodes

3. Recovers without complications
 - a. Is afebrile
 - b. Has normal blood pressure
 - c. Has a soft, nontender abdomen with normal bowel sounds
 - d. Maintains adequate urine output
 - e. Has no blood in the stool

Peritonitis

Peritonitis is inflammation of the peritoneum, the serous membrane lining the abdominal cavity and covering the viscera. Usually, it is a result of bacterial infection; the organisms come from diseases of the GI tract or, in women, from the internal reproductive organs (eg, fallopian tube). Peritonitis can also result from external sources such as injury or trauma (eg, gunshot wound, stab wound) or an inflammation that extends from an organ outside the peritoneal area, such as the kidney. Other common causes of peritonitis are appendicitis, perforated ulcer, diverticulitis, and bowel perforation (Fig. 38-5). Peritonitis may also be associated with abdominal surgical procedures and peritoneal dialysis. The most common bacteria implicated are *Escherichia coli*, *Klebsiella*, *Proteus*, *Pseudomonas*, and *Streptococcus* (Peralta & Genuit, 2006). Inflammation and paralytic ileus are the direct effects of the infection.

Pathophysiology

Peritonitis is caused by leakage of contents from abdominal organs into the abdominal cavity, usually as a result of inflammation, infection, ischemia, trauma, or tumor perforation. Bacterial proliferation occurs. Edema of the tissues results, and exudation of fluid develops in a short time. Fluid in the peritoneal cavity becomes turbid with increasing amounts of protein, white blood cells, cellular debris,

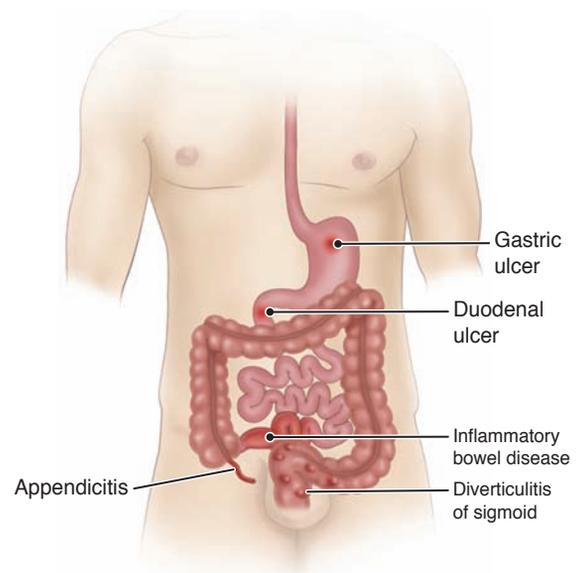

Figure 38-5 Common gastrointestinal causes of peritonitis.

and blood. The immediate response of the intestinal tract is hypermotility, soon followed by paralytic ileus with an accumulation of air and fluid in the bowel.

Clinical Manifestations

Symptoms depend on the location and extent of the inflammation. At first, there is diffuse pain, which tends to become constant, localized, and more intense over the site of the pathologic process (site of maximal peritoneal irritation). Movement usually aggravates it. The affected area of the abdomen becomes extremely tender and distended, and the muscles become rigid. Rebound tenderness and paralytic ileus may be present. Diminished perception of pain in peritonitis can occur in people receiving corticosteroids or analgesics. Patients with diabetes who have advanced neuropathy and patients with cirrhosis who have ascites may not experience pain during an acute bacterial infectious process. Usually, anorexia, nausea, and vomiting occur and peristalsis is diminished. A temperature of 37.8°C to 38.3°C (100°F to 101°F) can be expected, along with an increased pulse rate. With progression of the condition, patients may become hypotensive.

Assessment and Diagnostic Findings

The white blood cell count is almost always elevated. Serum electrolyte studies may reveal altered levels of potassium, sodium, and chloride.

An abdominal x-ray may show air and fluid levels as well as distended bowel loops. Abdominal ultrasound may reveal abscesses and fluid collections, and ultrasound-guided aspiration may assist in easier placement of drains. A CT scan of the abdomen may show abscess formation. MRI may be used for diagnosis of intra-abdominal abscesses (Peralta & Genuit, 2006). Peritoneal aspiration and culture and sensitivity studies of the aspirated fluid may reveal infection and identify the causative organisms.

Complications

The inflammation is most commonly not localized, and the entire abdominal cavity shows evidence of widespread infection. Sepsis is the major cause of death from peritonitis. Shock may result from septicemia or hypovolemia. The inflammatory process may cause intestinal obstruction, primarily from the development of bowel adhesions.

Medical Management

Fluid, colloid, and electrolyte replacement is the major focus of medical management. The administration of several liters of an isotonic solution is prescribed. Hypovolemia occurs because massive amounts of fluid and electrolytes move from the intestinal lumen into the peritoneal cavity and deplete the fluid in the vascular space.

Analgesics are prescribed for pain. Antiemetics are administered as prescribed for nausea and vomiting. Intestinal intubation and suction assist in relieving abdominal distention and in promoting intestinal function. Fluid in the abdominal cavity can cause pressure that restricts expansion of the lungs and causes respiratory distress. Oxygen therapy by nasal cannula or mask generally promotes adequate oxygenation, but airway intubation and ventilatory assistance may be required if peritonitis leads to septic shock (refer to Chapter 15 for further discussion).

Antibiotic therapy is initiated early in the treatment of peritonitis. Large doses of a broad-spectrum antibiotic are administered intravenously until the specific organism causing the infection is identified and appropriate antibiotic therapy can be initiated.

Surgical objectives include removing the infected material and correcting the cause. Surgical treatment is directed toward excision (ie, appendix), resection with or without anastomosis (ie, intestine), repair (ie, perforation), and drainage (ie, abscess). With extensive sepsis, a fecal diversion may need to be created. In selected instances, ultrasound-guided and CT-guided peritoneal drainage of abdominal and extraperitoneal abscesses has allowed for avoidance or delay of surgical therapy until the acute septic process has subsided (Peralta & Genuit, 2006).

The two most common postoperative complications are wound evisceration and abscess formation. Any suggestion from the patient that an area of the abdomen is tender or painful or “feels as if something just gave way” must be reported. The sudden occurrence of serosanguineous wound drainage strongly suggests wound dehiscence (see Chapter 20).

Nursing Management

Intensive care is often needed. The patient's blood pressure is monitored by arterial line if shock is present. The central venous pressure or pulmonary artery wedge pressure and urine output are monitored frequently. In addition, ongoing assessment of pain, GI function, and fluid and electrolyte balance is important. The nurse reports the nature of the pain, its location in the abdomen, and any changes in location. Administering analgesic medication and positioning the patient for comfort are helpful in decreasing pain. The patient is placed on the side with knees flexed; this position decreases tension on the abdominal organs. Accurate recording of all intake and output and central venous pressures and pulmonary artery pressures assist in calculating fluid replacement. The nurse administers and closely monitors IV fluids. Nasogastric intubation may be necessary.

Signs that indicate that peritonitis is subsiding include a decrease in temperature and pulse rate, softening of the abdomen, return of peristaltic sounds, passing of flatus, and bowel movements. The nurse increases fluid and food intake gradually and reduces parenteral fluids as prescribed. A worsening clinical condition may indicate a complication, and the nurse must prepare the patient for emergency surgery.

Drains are frequently inserted during the surgical procedure, and the nurse must monitor and record the character of the drainage postoperatively. Care must be taken when moving and turning the patient to prevent the drains from being dislodged. It is also important for the nurse to prepare the patient and family for discharge by teaching the patient to care for the incision and drains if the patient will be sent home with the drains still in place. Referral for home care may be indicated for further monitoring and patient and family teaching.

INFLAMMATORY BOWEL DISEASE

Inflammatory bowel disease (IBD) refers to two chronic inflammatory GI disorders: Crohn's disease (ie, regional enteritis) and ulcerative colitis. Both disorders have striking

Table 38-4 COMPARISON OF CROHN'S DISEASE AND ULCERATIVE COLITIS

Factor	Crohn's Disease	Ulcerative Colitis
Course	Prolonged, variable	Exacerbations, remissions
Pathology		
Early	Transmural thickening	Mucosal ulceration
Late	Deep, penetrating granulomas	Minute, mucosal ulcerations
Clinical Manifestations		
Location	Ileum, ascending colon (usually)	Rectum, descending colon
Bleeding	Usually not, but if it occurs, tends to be mild	Common—severe
Perianal involvement	Common	Rare—mild
Fistulas	Common	Rare
Rectal involvement	About 20%	Almost 100%
Diarrhea	Less severe	Severe
Abdominal mass	Common	Rare
Diagnostic Study Findings		
Barium series	Regional, discontinuous skip lesions Narrowing of colon Thickening of bowel wall Mucosal edema Stenosis, fistulas	Diffuse involvement No narrowing of colon No mucosal edema Stenosis rare Shortening of colon
Sigmoidoscopy	May be unremarkable unless accompanied by perianal fistulas	Abnormal inflamed mucosa
Colonoscopy	Distinct ulcerations separated by relatively normal mucosa in ascending colon	Friable mucosa with pseudopolyps or ulcers in descending colon
Therapeutic Management	Corticosteroids, sulfonamides (sulfasalazine [Azulfidine]) Antibiotics Parenteral nutrition Partial or complete colectomy, with ileostomy or anastomosis Rectum can be preserved in some patients Recurrence common	Corticosteroids, sulfonamides; sulfasalazine useful in preventing recurrence Bulk hydrophilic agents Antibiotics Proctocolectomy, with ileostomy Rectum can be preserved in only a few patients “cured” by colectomy
Systemic Complications	Small bowel obstruction Right-sided hydronephrosis Nephrolithiasis Cholelithiasis Arthritis Retinitis, iritis Erythema nodosum	Toxic megacolon Perforation Hemorrhage Malignant neoplasms Pyelonephritis Nephrolithiasis Cholangiocarcinoma Arthritis Retinitis, iritis Erythema nodosum

similarities but also several differences, which are compared in Table 38-4.

The incidence of IBD in the United States has increased in the past century, and more than 30,000 new cases occur annually. People between 15 and 30 years of age are at the greatest risk of developing IBD, followed by people between 50 and 70 years of age. Women and men tend to be equally affected, and family history appears to predispose people to IBD, particularly if a first-degree relative has the disease. Some genetic linkage exists, and in fact, a positive family history is the largest independent risk factor for IBD. Crohn's disease and ulcerative colitis are more prevalent in Jewish people, especially North American Jews of eastern European descent, than in any other ethnic group (Baumgart & Carding, 2007). It was previously believed that psychological conditions such as anxiety or depression predisposed certain people to IBD; however, this theory has been discarded (NIH, 2007).

Despite extensive research, the cause of IBD is still unknown. Researchers theorize that it is triggered by environ-

mental agents such as pesticides, food additives, tobacco, and radiation (Green, Morris & Lin, 2005; NIH, 2007). Nonsteroidal anti-inflammatory drugs (NSAIDs) have been found to exacerbate IBD. Allergies and immune disorders have also been suggested as causes. Abnormal response to dietary or bacterial antigens has been studied extensively, and genetic factors also are being studied. There is a high prevalence of coexistent IBS, which complicates the overall symptom presentation.

Types of Inflammatory Bowel Disease

Crohn's Disease (Regional Enteritis)

Crohn's disease is usually first diagnosed in adolescents or young adults but can appear at any time of life. The incidence has risen over the past 30 years (NIH, 2007). Crohn's

disease is seen more often in smokers than in nonsmokers (Colwell, Goldberg & Carmel, 2004).

Pathophysiology

Crohn's disease is a subacute and chronic inflammation of the GI tract wall that extends through all layers (ie, transmural lesion). Although its characteristic histopathological changes can occur anywhere in the GI tract, it most commonly occurs in the distal ileum and, to a lesser degree, the ascending colon. It is characterized by periods of remission and exacerbation. The disease process begins with edema and thickening of the mucosa. Ulcers begin to appear on the inflamed mucosa. These lesions are not in continuous contact with one another and are separated by normal tissue. Hence, these clusters of ulcers tend to take on a classic "cobblestone" appearance. Fistulas, fissures, and abscesses form as the inflammation extends into the peritoneum. Granulomas occur in 50% of patients. As the disease advances, the bowel wall thickens and becomes fibrotic, and the intestinal lumen narrows. Diseased bowel loops sometimes adhere to other loops surrounding them.

Clinical Manifestations

The onset of symptoms is usually insidious in Crohn's disease, with prominent right lower quadrant abdominal pain and diarrhea unrelieved by defecation. Scar tissue and the formation of granulomas interfere with the ability of the intestine to transport products of upper intestinal digestion through the constricted lumen, resulting in crampy abdominal pains. There is abdominal tenderness and spasm. Because eating stimulates intestinal peristalsis, the crampy pains occur after meals. To avoid these bouts of crampy pain, the patient tends to limit food intake, reducing the amounts and types of food to such a degree that normal nutritional requirements are often not met. As a result, weight loss, malnutrition, and secondary anemia occur. Ulcers in the membranous lining of the intestine and other inflammatory changes result in a weeping, edematous intestine that continually empties an irritating discharge into the colon. Disrupted absorption causes chronic diarrhea and nutritional deficits. The result is a person who is thin and emaciated from inadequate food intake and constant fluid loss. In some patients, the inflamed intestine may perforate, leading to intra-abdominal and anal abscesses. Fever and leukocytosis occur. Chronic symptoms include diarrhea, abdominal pain, **steatorrhea** (ie, excessive fat in the feces), anorexia, weight loss, and nutritional deficiencies.

Abscesses, fistulas, and fissures are common. Manifestations may extend beyond the GI tract and can include joint disorders (eg, arthritis), skin lesions (eg, erythema nodosum), ocular disorders (eg, conjunctivitis), and oral ulcers. The clinical course and symptoms can vary; in some patients, periods of remission and exacerbation occur, but in others, the disease follows a fulminating course. When intestinal symptoms worsen, extraintestinal manifestations often worsen also. Both usually improve simultaneously (Baumgart & Carding, 2007).

Assessment and Diagnostic Findings

A proctosigmoidoscopy is usually performed initially to determine whether the rectosigmoid area is inflamed. A stool examination is also performed; the result may be positive for

occult blood and steatorrhea. The most conclusive diagnostic aid for Crohn's disease is a barium study of the upper GI tract that shows the classic "string sign" on an x-ray film of the terminal ileum, indicating the constriction of a segment of intestine. Endoscopy, colonoscopy, and intestinal biopsies may be used to confirm the diagnosis. A barium enema may show ulcerations (the cobblestone appearance described earlier), fissures, and fistulas. A CT scan may show bowel wall thickening and fistula formation.

A complete blood count is performed to assess hematocrit and hemoglobin levels (usually decreased) as well as the white blood cell count (may be elevated). The ESR is usually elevated. Albumin and protein levels may be decreased, indicating malnutrition.

Complications

Complications of Crohn's disease include intestinal obstruction or stricture formation, perianal disease, fluid and electrolyte imbalances, malnutrition from malabsorption, and fistula and abscess formation. The most common type of small bowel fistula caused by Crohn's disease is the enterocutaneous fistula (ie, an abnormal opening between the small bowel and the skin). Abscesses can be the result of an internal fistula that results in fluid accumulation and infection. Patients with Crohn's disease are also at increased risk of colon cancer.

Ulcerative Colitis

Ulcerative colitis is a recurrent ulcerative and inflammatory disease of the mucosal and submucosal layers of the colon and rectum. The prevalence of ulcerative colitis is highest in Caucasians and people of Jewish heritage (Baumgart & Carding, 2007; Cho & Abraham, 2007). It is typically accompanied by systemic complications and a high mortality rate. Approximately 5% of patients with ulcerative colitis develop colon cancer (NIH, 2007).

Pathophysiology

Ulcerative colitis affects the superficial mucosa of the colon and is characterized by multiple ulcerations, diffuse inflammations, and desquamation or shedding of the colonic epithelium. Bleeding occurs as a result of the ulcerations. The mucosa becomes edematous and inflamed. The lesions are contiguous, occurring one after the other. Abscesses form, and infiltrate is seen in the mucosa and submucosa, with clumps of neutrophils found in the lumens of the crypts (ie, crypt abscesses) that line the intestinal mucosa (Huether & McCance, 2008). The disease process usually begins in the rectum and spreads proximally to involve the entire colon. Eventually, the bowel narrows, shortens, and thickens because of muscular hypertrophy and fat deposits. Because the inflammatory process is not transmural (ie, it affects the inner lining only), fistulas, obstruction, and fissures are uncommon (Baumgart & Sandborn, 2007).

Clinical Manifestations

The clinical course is usually one of exacerbations and remissions. The predominant symptoms of ulcerative colitis include diarrhea, passage of mucus and pus, left lower quadrant abdominal pain, intermittent tenesmus, and rectal

bleeding. The bleeding may be mild or severe, and pallor, anemia, and fatigue result. The patient may have anorexia, weight loss, fever, vomiting, and dehydration, as well as cramping, the feeling of an urgent need to defecate, and the passage of 10 to 20 liquid stools each day. The disease is classified as mild, severe, or fulminant, depending on the severity of the symptoms. Hypocalcemia and anemia frequently develop. Rebound tenderness may occur in the right lower quadrant. Extraintestinal manifestations include skin lesions (eg, erythema nodosum), eye lesions (eg, uveitis), joint abnormalities (eg, arthritis), and liver disease.

Assessment and Diagnostic Findings

The patient should be assessed for tachycardia, hypotension, tachypnea, fever, and pallor. Other assessments address the level of hydration and nutritional status. The abdomen is examined for bowel sounds, distention, and tenderness. These findings assist in determining the severity of the disease.

The stool is positive for blood, and laboratory test results reveal low hematocrit and hemoglobin levels in addition to an elevated white blood cell count, low albumin levels, and an electrolyte imbalance. Elevated antineutrophil cytoplasmic antibody levels are common (Baumgart & Sandborn, 2007). Abdominal x-ray studies are useful for determining the cause of symptoms. Free air in the peritoneum and bowel dilation or obstruction should be excluded as a source of the presenting symptoms. Sigmoidoscopy or colonoscopy and barium enema are valuable in distinguishing ulcerative colitis from other diseases of the colon with similar symptoms. A barium enema may show mucosal irregularities, focal strictures or fistulas, shortening of the colon, and dilation of bowel loops. Colonoscopy may reveal friable, inflamed mucosa with exudate and ulcerations, and it assists in defining the extent and severity of the disease. CT scanning, MRI, and ultrasound studies can identify abscesses and perirectal involvement. Leukocyte tagging (see Chapter 34) is useful when severe colitis prohibits the use of colonoscopy to determine the extent of inflammation.

Careful stool examination for parasites and other microbes is performed to rule out dysentery caused by common intestinal organisms, especially *Entamoeba histolytica*, *C. difficile*, *Campylobacter*, *Salmonella*, *Shigella*, and *Cryptospora* (Baumgart & Sandborn, 2007).

Complications

Complications of ulcerative colitis include toxic megacolon, perforation, and bleeding as a result of ulceration, vascular engorgement, and highly vascular granulation tissue. In toxic megacolon, the inflammatory process extends into the muscularis, inhibiting its ability to contract and resulting in colonic distention. Symptoms include fever, abdominal pain and distention, vomiting, and fatigue. If the patient with toxic megacolon does not respond within 24 to 72 hours to medical management with nasogastric suction, IV fluids with electrolytes, corticosteroids, and antibiotics, surgery is required. Total colectomy is then indicated. For many patients, surgery becomes necessary to relieve the effects of the disease and to treat these serious complications; an ileostomy usually is performed. The surgical procedures involved and the care of patients with this type of fecal diversion are discussed later in this chapter.

Patients with IBD also have a significantly increased risk of osteoporotic fractures due to decreased bone mineral density. Corticosteroid therapy may also contribute to the diminished bone density.

Management of Chronic Inflammatory Bowel Disease

Medical treatment for both Crohn's disease and ulcerative colitis is aimed at reducing inflammation, suppressing inappropriate immune responses, providing rest for a diseased bowel so that healing may take place, improving quality of life, and preventing or minimizing complications. Most patients have long periods of well-being interspersed with short intervals of illness (Baumgart & Sandborn, 2007). Management depends on the disease location, severity, and complications.

Nutritional Therapy

Oral fluids and a low-residue, high-protein, high-calorie diet with supplemental vitamin therapy and iron replacement are prescribed to meet nutritional needs, reduce inflammation, and control pain and diarrhea. Fluid and electrolyte imbalances from dehydration caused by diarrhea are corrected by IV therapy as necessary if the patient is hospitalized or by oral fluids if the patient is managed at home. Any foods that exacerbate diarrhea are avoided. Milk may contribute to diarrhea in those with lactose intolerance. Cold foods and smoking are avoided because both increase intestinal motility. Parenteral nutrition may be indicated (see Chapter 36).

Pharmacologic Therapy

Sedatives and antidiarrheal and antiperistaltic medications are used to minimize peristalsis to rest the inflamed bowel. They are continued until the patient's stools approach normal frequency and consistency.

Aminosalicylates such as sulfasalazine (Azulfidine) are often effective for mild or moderate inflammation and are used to prevent or reduce recurrences in long-term maintenance regimens. Corticosteroids are used to treat severe and fulminant disease and can be administered orally (eg, prednisone [Deltasone]) in outpatient treatment or parenterally (eg, hydrocortisone [Solu-Cortef]) in hospitalized patients. Topical (ie, rectal administration) corticosteroids (eg, budesonide [Entocortec]) are also widely used in the treatment of distal colon disease. When the dosage of corticosteroids is reduced or stopped, the symptoms of disease may return. If corticosteroids are continued, numerous adverse sequelae may ensue; these are discussed in Chapter 42 and summarized in Table 42-6.

Immunomodulators (eg, azathioprine [Imuran], mercaptopurine [6-MP], methotrexate [MTX], cyclosporine [Neoral]) have been used to alter the immune response. The exact mechanism of action of these medications in treating IBD is unknown. They are used in patients with severe disease who have not responded favorably to other therapies—in maintenance regimens to prevent relapses. Among the newer biologic therapies using monoclonal antibodies are natalizumab (Tysabri) for Crohn's disease (Sandborn,

Colombel, Enns, et al., 2005) and infliximab (Remicade) for ulcerative colitis (Pizzaro & Cominelli, 2007; Rutgeerts, Sandborn, Feagan, et al., 2005). Clinical outcomes associated with the use of both biologic agents are promising (Rutgeerts, et al., 2005; Sandborn, et al., 2005), although adverse effects may seriously limit their usefulness. Other biologic therapies recently tested in Crohn's disease include anticytokine therapy using anti-interleukin type drugs (eg, anti-IL-12), which has thus far demonstrated a satisfactory safety profile (Pizarro & Cominelli, 2007).

A major issue associated with appropriate pharmacological treatment of IBD is noncompliance. Patients who are noncompliant may suffer a greater chance of disease relapse that can be severe (Turnbough & Wilson, 2007).

Surgical Management

When nonsurgical measures fail to relieve the severe symptoms of IBD, surgery may be necessary. Ultimately, 75% of patients with Crohn's disease undergo surgery within 10 years of diagnosis and between 25% and 60% require further repeat surgery within the same time frame (Byrne, Solomon, Young, et al., 2007). The most common indications for surgery are medically intractable disease, poor quality of life, or complications from the disease or its treatment. Recurrence of inflammation and disease after surgery in Crohn's disease is inevitable (Colwell, et al., 2004).

A common procedure performed for strictures of the small intestines is laparoscope-guided strictureplasty, in which the blocked or narrowed sections of the intestines are widened, leaving the intestines intact. In some cases, a small bowel resection is performed and diseased segments of the small intestines are resected and the remaining portions of the intestines are anastomosed. Surgical removal of up to 50% of the small bowel usually can be tolerated. In cases of severe Crohn's disease of the colon, a total colectomy and ileostomy may be the procedure of choice.

A newer surgical procedure developed for patients with severe Crohn's disease is intestinal transplant. This technique is now available to children and to young and middle-aged adults who have lost intestinal function from disease. It may provide improvement in quality of life for some patients. The associated technical and immunologic problems remain formidable, and the costs and mortality rates continue to be high. None of the surgical procedures for Crohn's disease are curative. Ultimately, achievement of remission depends on medical therapy (Byrne, et al., 2007).

At least 25% of patients with ulcerative colitis eventually have total colectomies (NIH, 2007). When the colon is surgically removed, the patient is considered "cured" in that extraintestinal manifestations subside and the disease process is otherwise limited to the colon. Indications for surgery include lack of improvement and continued deterioration, profuse bleeding, perforation, continued stricture formation, and cancer. Surgical excision usually improves quality of life. Proctocolectomy with ileostomy (ie, complete excision of colon, rectum, and anus) is recommended when the rectum is severely diseased. If the rectum can be preserved, restorative proctocolectomy with ileal pouch anal anastomosis (IPAA) is the procedure of choice. Although IPAA is not "perfect," it generally leads to a good to excellent quality of life (Beitz, 1999).

Other types of surgical procedures, known as fecal diversions, are discussed later in this chapter.

Total Colectomy With Ileostomy

An **ileostomy**, the surgical creation of an opening into the ileum or small intestine (usually by means of an ileal stoma on the abdominal wall), is commonly performed after a total colectomy (ie, excision of the entire colon). It allows for drainage of fecal matter (ie, effluent) from the ileum to the outside of the body. The drainage is liquid to unformed and occurs at frequent intervals. Nursing management of the patient with an ileostomy is discussed later in this chapter.

Continent Ileostomy

Another procedure involves the creation of a continent ileal reservoir (ie, **Kock pouch**) by diverting a portion of the distal ileum to the abdominal wall and creating a stoma. This procedure eliminates the need for an external fecal collection bag. Approximately 30 cm of the distal ileum is reconstructed to form a reservoir with a nipple valve that is created by pulling a portion of the terminal ileal loop back into the ileum. GI effluent can accumulate in the pouch for several hours and then be removed by means of a catheter inserted through the nipple valve. In many patients, a total colectomy is also performed with the Kock pouch. Possible indications for a total colectomy with Kock pouch placement (rather than a restorative proctocolectomy with IPAA) include a badly diseased rectum, lack of rectal sphincter tone, or inability to achieve fecal continence post-IPAA.

The major problem with the Kock pouch is malfunction of the nipple valve, which often requires additional corrective surgery. Research is currently focused on developing valves that may fail less frequently than the nipple valve.

Restorative Proctocolectomy With Ileal Pouch Anal Anastomosis

A restorative proctocolectomy with IPAA is the surgical procedure of choice in cases where the rectum can be preserved in that it eliminates the need for a permanent ileostomy. It establishes an ileal reservoir that functions as a "new" rectum, and anal sphincter control of elimination is retained. The procedure involves connecting the ileum to the anal pouch (made from a small intestine segment), and the surgeon connects the pouch to the anus in conjunction with removing the colon and the rectal mucosa (ie, total abdominal colectomy and mucosal proctectomy) (Fig. 38-6). A temporary diverting loop ileostomy that promotes healing of the surgical anastomoses is constructed at the time of surgery and closed about 3 months later.

With IPAA or restorative proctocolectomy, the diseased colon and rectum are removed, voluntary defecation is maintained, and anal continence is preserved. The ileal reservoir decreases the number of bowel movements by 50%, from approximately 14 to 20 per day to 7 to 10 per day. Nighttime elimination is gradually reduced to one bowel movement. Complications of ileoanal anastomosis include irritation of the perianal skin from leakage of fecal contents, stricture formation at the anastomosis site, small bowel obstruction, and "pouchitis" (inflammation of the ileoanal pouch due to altered microbial levels).

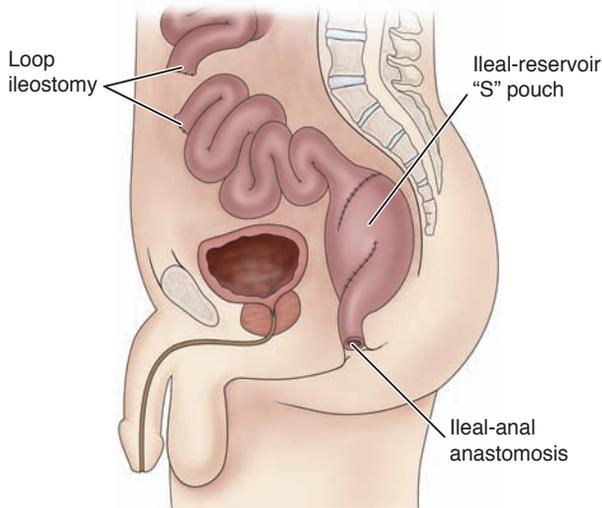

Figure 38-6 A mucosal proctectomy precedes anastomosis of the ileal reservoir. A temporary loop ileostomy diverts effluent for several months to allow healing.

NURSING PROCESS

MANAGEMENT OF THE PATIENT WITH CHRONIC INFLAMMATORY BOWEL DISEASE

Assessment

The nurse obtains a health history to identify the onset, duration, and characteristics of abdominal pain; the presence of diarrhea or fecal urgency, straining at stool (tenesmus), nausea, anorexia, or weight loss; and family history of IBD. It is important to discuss dietary patterns, including the amounts of alcohol, caffeine, and nicotine-containing products used daily and weekly. The nurse asks about patterns of bowel elimination, including character, frequency, and presence of blood, pus, fat, or mucus. It is important to note allergies and food intolerance, especially milk (lactose) intolerance. The patient may identify sleep disturbances if diarrhea or pain occurs at night.

Diagnosis

Nursing Diagnoses

Based on the assessment data, the nursing diagnoses may include the following:

- Diarrhea related to the inflammatory process
- Acute pain related to increased peristalsis and GI inflammation
- Deficient fluid volume related to anorexia, nausea, and diarrhea
- Imbalanced nutrition, less than body requirements, related to dietary restrictions, nausea, and malabsorption
- Activity intolerance related to generalized weakness
- Anxiety related to impending surgery
- Ineffective coping related to repeated episodes of diarrhea
- Risk for impaired skin integrity related to malnutrition and diarrhea

- Risk for ineffective therapeutic regimen management related to insufficient knowledge concerning the process and management of the disease

Collaborative Problems/Potential Complications

Potential complications that may develop include the following:

- Electrolyte imbalance
- Cardiac dysrhythmias related to electrolyte imbalances
- GI bleeding with fluid volume loss
- Perforation of the bowel

Planning and Goals

The major goals for the patient include attainment of normal bowel elimination patterns, relief of abdominal pain and cramping, prevention of fluid volume deficit, maintenance of optimal nutrition and weight, avoidance of fatigue, reduction of anxiety, promotion of effective coping, absence of skin breakdown, increased knowledge about the disease process and therapeutic regimen, and avoidance of complications.

Nursing Interventions

Maintaining Normal Elimination Patterns

The nurse provides ready access to a bathroom, commode, or bedpan and keeps the environment clean and odor-free. It is important to administer antidiarrheal medications as prescribed, to record the frequency and consistency of stools after therapy is initiated, and to encourage bed rest to decrease peristalsis.

Relieving Pain

The character of the pain is described as dull, burning, or crampy. It is important to ask about its onset. Does it occur before or after meals, during the night, or before elimination? Is the pattern constant or intermittent? Is it relieved with medications? The nurse administers anticholinergic medications 30 minutes before a meal as prescribed to decrease intestinal motility and administers analgesics as prescribed for pain. Position changes, local application of heat (as prescribed), diversional activities, and prevention of fatigue also are helpful for reducing pain.

Maintaining Fluid Intake

To detect fluid volume deficit, the nurse keeps an accurate record of oral and IV fluids and maintains a record of output (ie, urine, liquid stool, vomitus, wound or fistula drainage). The nurse monitors daily weights for fluid gains or losses and assesses the patient for signs of fluid volume deficit (ie, dry skin and mucous membranes, decreased skin turgor, oliguria, fatigue, decreased temperature, increased hematocrit, elevated urine specific gravity, and hypotension). It is important to encourage oral intake of fluids and to monitor the flow rate of any IV fluids. The nurse initiates measures to decrease diarrhea (eg, dietary restrictions, stress reduction, antidiarrheal agents).

Maintaining Optimal Nutrition

Parenteral nutrition is used when the symptoms of IBD are severe. With parenteral nutrition, the nurse maintains an accurate record of fluid intake and output as well as the

daily weight. The patient should gain 0.5 kg daily during parenteral nutrition therapy. Because parenteral nutrition is very high in glucose and can cause hyperglycemia, blood glucose levels are monitored every 6 hours. Once the symptoms of IBD exacerbation have diminished and the patient has gained or stabilized weight, parenteral nutrition is stopped and the patient is advanced on oral elemental feedings. Elemental feedings are high in protein and low in fat and residue. They are digested primarily in the jejunum, do not stimulate intestinal secretions, and allow the bowel to continue to rest. The nurse notes intolerance if the patient exhibits nausea, vomiting, diarrhea, or abdominal distention.

If oral foods are tolerated, small, frequent, low-residue feedings are given to avoid overdistending the stomach and stimulating peristalsis. It is important that the patient restrict activity to conserve energy, reduce peristalsis, and reduce caloric requirements.

Promoting Rest

The nurse recommends intermittent rest periods during the day and schedules or restricts activities to conserve energy and reduce the metabolic rate. It is important to encourage activity within the limits of the patient's capacity. The nurse suggests bed rest for a patient who is febrile, has frequent diarrheal stools, or is bleeding. However, the patient on bed rest should perform active exercises to maintain muscle tone and prevent thromboembolic complications. If the patient cannot perform these active exercises, the nurse performs passive exercises and joint range of motion. Activity restrictions are modified as needed on a day-to-day basis.

Reducing Anxiety

The patient may be emotionally labile because of the consequences of the disease and the uncertainty of exacerbations with complications. The nurse tailors information about possible impending surgery to the patient's level of understanding and desire for detail. If surgery is planned, pictures and illustrations help explain the surgical procedure and help the patient visualize what a stoma looks like.

Enhancing Coping Measures

Any patient suffering the discomforts of frequent bowel movements and rectal soreness is anxious, discouraged, and depressed. It is important to develop a relationship with the patient that supports all attempts to cope with these stressors. Stress reduction measures that may be used include relaxation techniques, visualization, breathing exercises, and biofeedback. Professional counseling may be needed to help the patient and family manage issues associated with chronic illness and resulting disability.

Preventing Skin Breakdown

The nurse examines the patient's skin frequently, especially the perianal skin. Perianal care, including the use of a skin barrier (eg, petroleum ointment [Vaseline]), is important after each bowel movement. The nurse gives immediate attention to reddened or irritated areas over bony prominences and uses pressure-relieving devices to prevent skin breakdown. Consultation with a **wound-ostomy-contenance nurse** (WOC nurse, or WOCN) (a nurse spe-

cially educated in the management of a variety of fecal and urinary diversions) is often helpful.

Monitoring and Managing Potential Complications

Serum electrolyte levels are monitored daily, and electrolyte replacements are administered as prescribed. It is important to report evidence of dysrhythmias or changes in level of consciousness immediately.

The nurse closely monitors rectal bleeding and administers blood component therapy and volume expanders as prescribed to prevent hypovolemia. It is important to monitor the blood pressure for hypotension and to obtain coagulation profiles and hemoglobin and hematocrit levels frequently. Vitamin K may be prescribed to increase clotting factors.

The nurse closely monitors the patient for indications of perforation (ie, acute increase in abdominal pain, rigid abdomen, vomiting, or hypotension) and obstruction and toxic megacolon (ie, abdominal distention, decreased or absent bowel sounds, change in mental status, fever, tachycardia, hypotension, dehydration, and electrolyte imbalances).

Promoting Home and Community-Based Care

TEACHING PATIENTS SELF-CARE. The nurse assesses the patient's understanding of the disease process and his or her need for additional information about medical management (eg, medications, diet) and surgical interventions. The nurse provides information about nutritional management; a bland, low-residue, high-protein, high-calorie, and high-vitamin diet relieves symptoms and decreases diarrhea. It is important to explain the rationale for the use of corticosteroids and anti-inflammatory, antibacterial, antidiarrheal, and antispasmodic medications. The nurse emphasizes the importance of taking medications as prescribed and not abruptly discontinuing them (especially corticosteroids) to avoid development of serious medical problems (Chart 38-3). The nurse reviews ileostomy care as necessary (see Nursing Management of the Patient Requiring an Ileostomy). Patient education information can be obtained from the Crohn's and Colitis Foundation of America (CCFA).

CONTINUING CARE. Patients with chronic IBD are managed at home with follow-up care by their physician or through an outpatient clinic. Those whose nutritional status is compromised and who are receiving parenteral nutrition need home care nursing to ensure that their nutritional requirements are being met and that they or their caregivers can follow through with the instructions for parenteral nutrition. Patients who are undergoing medical treatment need to understand that their disease can be controlled and that they can lead a healthy life between exacerbations. Control implies management based on an understanding of the disease and its treatment. Patients in the home setting need information about their medications (ie, name, dose, side effects, and frequency of administration) and need to take medications on schedule. Medication reminders such as containers that separate pills according to day and time or daily checklists are helpful.

During a flare-up, the nurse encourages the patient to rest as needed and to modify activities according to his or her energy level. Patients should limit tasks that impose strain on the lower abdominal muscles. They should sleep in a room close to the bathroom because of the frequent

CHART
38-3

HOME CARE CHECKLIST

Inflammatory Bowel Disease

At the completion of the home care instruction, the patient or caregiver will be able to:	PATIENT	CAREGIVER
• Verbalize an understanding of the disease process.	✓	✓
• Discuss nutritional management: bland, low-residue, high-protein, high-vitamin diet; identify foods to include and foods to be avoided.	✓	✓
• Describe medication regimen; identify medications by name, use, route, and frequency.	✓	✓
• Identify measures to be used to treat exacerbation of symptoms, to include rest, dietary modifications, and medications.	✓	✓
• Identify measures to be used to promote fluid and electrolyte balance during acute exacerbations.	✓	✓
• Demonstrate management of parenteral nutrition therapy, if applicable; identify possible complications and interventions.	✓	✓
• Incorporate stress reduction measures into lifestyle.	✓	

diarrhea (10 to 20 times per day); quick access to a toilet helps alleviate worry about having an “accident.” Room deodorizers help control odors.

Dietary modifications can control but do not cure the disease; the nurse recommends a low-residue, high-protein, high-calorie diet, especially during an acute phase. It is important to encourage the patient to keep a record of the foods that irritate the bowel and to avoid them and to drink at least eight glasses of water each day.

The prolonged nature of the disease has an impact on the patient and often strains his or her family life and financial resources. Family support is vital; however, some family members may be resentful, or feel guilty, tired, or unable to cope with the emotional demands of the illness and the physical demands of providing care. Some patients with IBD do not socialize for fear of being embarrassed. Many prefer to eat alone. Because they have lost control over elimination, they may fear losing control over other aspects of their lives. They need time to express their fears and frustrations. Individual and family counseling may be helpful.

Evaluation

Expected Patient Outcomes

Expected patient outcomes may include the following:

1. Reports a decrease in the frequency of diarrheal stools
 - a. Complies with dietary restrictions; maintains bed rest
 - b. Takes medications as prescribed
2. Has reduced pain
3. Maintains fluid volume balance
 - a. Drinks 1 to 2 L of oral fluids daily
 - b. Has normal body temperature
 - c. Displays adequate skin turgor and moist mucous membranes
4. Attains optimal nutrition; tolerates small, frequent feedings without diarrhea
5. Avoids fatigue
 - a. Rests periodically during the day
 - b. Adheres to activity restrictions

6. Is less anxious
7. Copes successfully with diagnosis
 - a. Verbalizes feelings freely
 - b. Uses appropriate stress reduction behaviors
8. Maintains skin integrity
 - a. Cleans perianal skin after defecation
 - b. Uses lotion or ointment as skin barrier
9. Acquires an understanding of the disease process
 - a. Modifies diet appropriately to decrease diarrhea
 - b. Adheres to medication regimen as prescribed
10. Recovers without complications
 - a. Electrolytes within normal ranges
 - b. Normal sinus or baseline cardiac rhythm
 - c. Maintains fluid balance
 - d. Experiences no perforation or rectal bleeding

Nursing Management of the Patient Requiring an Ileostomy

Some patients with IBD eventually require a permanent fecal diversion with creation of an ileostomy to manage symptoms and to treat or prevent complications. The Plan of Nursing Care summarizes care for the patient requiring an ostomy (Chart 38-4).

Providing Preoperative Care

A period of preparation with intensive replacement of fluid, blood, and protein is necessary prior to surgery. Antibiotics may be prescribed. If the patient has been taking corticosteroids, they will be continued during the surgical phase to prevent steroid-induced adrenal insufficiency. Usually, the patient is given a low-residue diet, provided in frequent, small feedings. All other preoperative measures are similar to those for general abdominal surgery. The patient must have a thorough understanding of the surgery to be performed and what to expect after surgery. Preoperative teaching includes management of drainage from the stoma; the nature of drainage; and the need for

CHART

PLAN OF NURSING CARE
The Patient Undergoing Ostomy Surgery

NURSING DIAGNOSIS: Deficient knowledge about the surgical procedure and preoperative preparation
GOAL: Understands the surgical process and the necessary preoperative preparations

Nursing Interventions	Rationale	Expected Outcomes
<p>Preoperative Care</p> <ol style="list-style-type: none"> 1. Ascertain whether the patient has had a previous surgical experience and ask for recollections of positive and negative impressions. 2. Determine what information the surgeon gave the patient and family and whether it was understood. Clarify and elaborate as necessary. Determine whether the stoma is permanent or temporary. Be aware of the patient's prognosis if carcinoma exists. 3. Use pictures or drawings to illustrate the location and appearance of the surgical wounds (abdominal, perineal) and the stoma if the patient is receptive. 4. Explain that oral/parenteral antimicrobials will be administered to cleanse the bowel preoperatively. Mechanical cleansing may also be required. 5. Assist the patient during nasogastric/nasoenteric intubation. Measure drainage from the tube. 	<ol style="list-style-type: none"> 1. Fear of a repeated negative experience increases anxiety. Talking about the experience with a nurse helps clarify misconceptions and helps the patient ventilate any repressed emotions. Positive experiences are reinforced. 2. Clarification prevents misunderstandings and alleviates anxiety. 3. Knowledge, for some, alleviates anxiety because fear of the unknown is decreased. Others choose not to know because it makes them more anxious. 4. Antimicrobials and mechanical cleansing (eg, laxatives, enemas) reduce intestinal bacterial flora. 5. Nasoenteral intubation is used for decompression and drainage of gastrointestinal contents before surgery. 	<ul style="list-style-type: none"> • Expresses anxieties and fears about the surgical process • Projects a positive attitude toward the surgical procedure • Repeats in own words information given by the surgeon • Identifies normal anatomy and physiology of gastrointestinal tract and how it will be altered; can point to expected location of abdominal wound and stoma; describes stoma appearance and size • Adheres to "bowel prep" regimen of antimicrobials or mechanical cleansing • Tolerates the presence of nasogastric/nasoenteric tube

NURSING DIAGNOSIS: Disturbed body image
GOAL: Attainment of a positive self-concept

Nursing Interventions	Rationale	Expected Outcomes
<ol style="list-style-type: none"> 1. Encourage the patient to verbalize feelings about the stoma. Offer to be present when the stoma is first viewed and touched. 2. Suggest that the spouse or significant other view the stoma. 3. Offer counseling, if desired. 4. Arrange for a visit or a phone call with another patient with a stoma. 	<ol style="list-style-type: none"> 1. Free expression of feelings allows the patient the opportunity to verbalize and identify concerns. Expressed concerns can be therapeutically addressed by health care team members. 2. Helps patient to overcome fears about partner's response. 3. Provides opportunity for additional support. 4. People with stomas can offer support and share mutual feelings and experiences. 	<ul style="list-style-type: none"> • Freely expresses concerns and fears • Accepts support • Seeks help as needed • States is willing to talk with another patient with a stoma

NURSING DIAGNOSIS: Anxiety related to the loss of bowel control
GOAL: Reduction of anxiety

Nursing Interventions	Rationale	Expected Outcomes
<p>Postoperative Care</p> <ol style="list-style-type: none"> 1. Provide information about expected bowel function: <ol style="list-style-type: none"> a. Characteristics of effluent b. Frequency of discharge. 	<ol style="list-style-type: none"> 1. Emotional adjustment is facilitated if adequate information is provided at the level of the learner. 	<ul style="list-style-type: none"> • Expresses interest in learning about altered bowel function • Handles equipment correctly • Changes the appliance unassisted • Irrigates colostomy successfully • Progresses toward a regular schedule of elimination

Continued on following page

 CHART
38-4

PLAN OF NURSING CARE
The Patient Undergoing Ostomy Surgery (Continued)

Nursing Interventions	Rationale	Expected Outcomes
2. Teach the patient how to prepare the appliance for an adequate fit. <ol style="list-style-type: none"> Choose the drainage appliance that will provide a secure fit around the stoma. Measure the stoma size with a measuring guide provided by the ostomy equipment manufacturer and compare with the opening on the pouch. The barrier opening should be sized to “hug” the stoma and cover the peristomal skin. Note: newer wafer barriers can be pulled or molded to the size of the stoma. Remove any plastic covering that protects the appliance adhesive. <i>Note:</i> The pouch is applied by pressing the adhesive for 30 seconds to the skin or skin barrier. 3. Demonstrate how to change the appliance or empty the pouch before leakage occurs. Be aware that the elderly person may have diminished vision and difficulty handling equipment. 4. When appropriate, demonstrate how to irrigate the colostomy (usually on the 4th or 5th day). Recommend that irrigation be performed at a consistent time, depending on the type of colostomy.	2. Adequate fit is necessary for successful use of the appliance. <ol style="list-style-type: none"> The appliance opening should be larger than the stoma for an adequate fit. Available brands come in different sizes to fit the stoma. Adjustments are made as necessary. The appliance is ready to apply directly to the skin or skin protector. 3. Manipulation of the appliance is a learned motor skill that requires practice and positive reinforcement. 4. Colostomy irrigation is used to regulate the passage of fecal material; alternatively the bowel can be allowed to evacuate naturally. Irrigation is not routinely indicated.	
NURSING DIAGNOSIS: Risk for impaired skin integrity related to irritation of the peristomal skin by the effluent GOAL: Maintenance of skin integrity		
Nursing Interventions <ol style="list-style-type: none"> Provide information about signs and symptoms of irritated or inflamed skin. Use pictures if possible. Teach patient how to cleanse the peristomal skin gently. Demonstrate how to apply a skin barrier (powder, gel, paste, wafer). Demonstrate how to remove the pouch. 	Rationale <ol style="list-style-type: none"> Peristomal skin should be slightly pink without abrasions and similar to that of the entire abdomen. Mild friction with warm water and a gentle soap cleanses the skin and minimizes irritation and possible abrasions. After rinsing the soap, patting the skin dry prevents tissue trauma. Skin barriers protect the peristomal skin from enzymes and bacteria. Gently separate adhesive from the skin to avoid irritation. Never pull! 	Expected Outcomes <ul style="list-style-type: none"> Describes appearance of healthy skin Correctly cleanses the skin Successfully applies a skin barrier Gently removes the drainage appliance without skin damage Demonstrates intact skin around the colostomy stoma
NURSING DIAGNOSIS: Potential imbalanced nutrition, less than body requirements, related to avoidance of foods that may cause GI discomfort GOAL: Achievement of an optimal nutritional intake		
Nursing Interventions <ol style="list-style-type: none"> Conduct a complete nutritional assessment to identify any foods that may increase peristalsis by irritating the bowel. 	Rationale <ol style="list-style-type: none"> Patients react differently to certain foods because of individual sensitivity. 	Expected Outcomes <ul style="list-style-type: none"> Modifies diet to avoid offensive foods yet maintains adequate nutritional intake

Continued

38-4

PLAN OF NURSING CARE
The Patient Undergoing Ostomy Surgery (Continued)

Nursing Interventions	Rationale	Expected Outcomes
<ol style="list-style-type: none"> 2. Advise the patient to avoid food products with a cellulose or hemicellulose base (nuts, seeds). 3. Recommend moderation in intake of certain irritating fruits such as prunes, grapes, and bananas. 	<ol style="list-style-type: none"> 2. Cellulose food products are the nondigestible residue of plant foods. They hold water, provide bulk, and stimulate elimination. 3. These fruits tend to increase the quantity of effluent. 	<ul style="list-style-type: none"> • Avoids cellulose-based foods such as peanuts • Modifies intake of certain fruits

NURSING DIAGNOSIS: Sexual dysfunction related to altered body image
GOAL: Attainment of satisfactory sexual performance

Nursing Interventions	Rationale	Expected Outcomes
<ol style="list-style-type: none"> 1. Encourage the patient to verbalize concerns and fears. The sexual partner is welcomed to participate in the discussion. 2. Recommend alternative sexual positions. 3. Seek assistance from a sexual therapist or wound-ostomy-continance (WOC) nurse. 	<ol style="list-style-type: none"> 1. Expressed needs help the therapist develop a plan of care. 2. Avoid patient embarrassment with the visual appearance of the stoma. Avoid peristomal skin irritation or stomal trauma secondary to friction. 3. Some patients need professional sexual counseling. 	<ul style="list-style-type: none"> • Expresses fears and concerns • Discusses alternative sexual positions • Accepts services of a professional counselor

NURSING DIAGNOSIS: Risk for deficient fluid volume related to anorexia and vomiting and increased loss of fluids and electrolytes from GI tract
GOAL: Attainment of fluid balance

Nursing Interventions	Rationale	Expected Outcomes
<ol style="list-style-type: none"> 1. Estimate fluid intake and output: <ol style="list-style-type: none"> a. Strict intake and output b. Daily weights 2. Assess serum and urinary values of sodium and potassium. 3. Observe and record skin turgor and the appearance of the tongue. 	<ol style="list-style-type: none"> 1. Provides indication of fluid balance. <ol style="list-style-type: none"> a. An early indicator of fluid imbalance is a daily, significant difference between intake and output. The average person ingests (food, fluids) and loses (urine, feces, lungs) about 2 L of fluid every 24 h. b. A gain/loss of 1 L of fluid is reflected in a body weight change of 2.2 lb. 2. Sodium is the major electrolyte regulating water balance. Vomiting results in decreased urinary and serum sodium levels. Urinary sodium values, in contrast to serum values, reflect early, sensitive changes in sodium balance. Sodium works in conjunction with potassium, which is also decreased with vomiting. A significant deficiency in potassium is associated with a decrease in intracellular potassium bicarbonate, which leads to acidosis and compensatory hyperventilation. 3. Adequate hydration is reflected by the skin's ability to return to its normal shape after being grasped between the fingers. <i>Note:</i> In the older person, it is normal for the return to be delayed. Changes in the mucous membrane covering the tongue are accurate and early indicators of hydration status. 	<ul style="list-style-type: none"> • Maintains fluid balance • Maintains normal serum and urinary values for sodium and potassium • Normal skin turgor • Surface of tongue is pink, with a moist mucous membrane

nasogastric intubation, parenteral fluids, and possibly perineal packing.

The abdomen is marked for the proper placement of the stoma by the surgeon or the WOC nurse. Care is taken to ensure that the stoma is conveniently placed—usually in the right lower quadrant about 2 inches below the waist, in an area away from previous scars, bony prominences, skin folds, or fistulas. It is essential that the stoma site be visible to the patient.

Providing Postoperative Care

General abdominal surgery wound care is required. The nurse observes the stoma for color and size. It should be pink to bright red and shiny. Typically, a temporary plastic bag (ie, appliance or pouch) with an adhesive facing is placed over the ileostomy in the operating room and firmly pressed onto the surrounding skin. The nurse monitors the ileostomy for fecal drainage, which should begin about 24 to 48 hours after surgery. The drainage is a continuous liquid from the small intestine because the stoma does not have a controlling sphincter. The contents drain into the pouch and are thus kept from coming into contact with the skin. They are collected, measured, and discarded when the pouch becomes full. If a continent ileal reservoir was created, as described for the Kock pouch, continuous drainage is provided by an indwelling reservoir catheter for 2 to 3 weeks after surgery. This allows the suture lines to heal.

Because these patients lose large fluid volumes in the early postoperative period, an accurate record of fluid intake, urinary output, and fecal discharge is necessary to help gauge the fluid needs of the patient. There may be 1000 to 2000 mL of fluid lost each day in addition to expected fluid loss through urine, perspiration, respiration, and other sources. With this loss, sodium and potassium are depleted. The nurse monitors laboratory values and administers electrolyte replacements as prescribed. Replacement fluids are administered intravenously for 4 to 5 days.

Nasogastric suction is also a part of the immediate postoperative care, with the tube requiring frequent irrigation, as prescribed. The purpose of nasogastric suction is to prevent a buildup of gastric contents while the intestines are not functioning. After the tube is removed, the nurse offers sips of clear liquids and gradually progresses the diet. It is important to report nausea and abdominal distention, which may indicate intestinal obstruction, immediately.

By the end of the first week, rectal packing is removed. Because this procedure may be uncomfortable, the nurse may administer an analgesic an hour before the removal. After the packing is removed, the perineum is irrigated two or three times daily until full healing takes place.

Providing Emotional Support

The patient may think that everyone is aware of the ileostomy and may view the stoma as a mutilation compared with other abdominal incisions that heal and are hidden. Concern about body image may lead to questions related to family relationships, sexual function, and, for women, the ability to become pregnant and to deliver a baby normally. The nurse can coordinate patient care needs, including needs for emotional support, through meetings attended by consultants such as the physician,

psychologist, psychiatrist, social worker, WOC nurse, and dietitian. The team approach is important in facilitating the often complex care of the patient.

Conversely, a surgical procedure to create an ileostomy can produce dramatic positive changes in patients who have suffered from IBD for several years. After the discomfort of the disease has decreased and the patient learns how to take care of the ileostomy, he or she often develops a more positive outlook. Until the patient progresses to this phase, an empathetic and tolerant approach by the nurse plays an important part in recovery. The sooner the patient masters the physical care of the ileostomy, the sooner he or she will psychologically accept it.

Support from other people with ostomies is also helpful. The United Ostomy Associations of America (UOAA) is dedicated to the rehabilitation of people with ostomies. This organization gives patients useful information about living with an ostomy through an educational program of literature, lectures, and exhibits. Local associations offer visiting services by qualified members who provide hope and rehabilitation services to patients with new ostomies.

Managing Skin and Stoma Care

The patient with a traditional ileostomy cannot establish regular bowel habits because the contents of the ileum are fluid and are discharged continuously. The patient must wear a pouch at all times. Stomal size and pouch size vary initially; the stoma should be rechecked 3 weeks after surgery, when the edema has subsided. The final size and type of appliance is selected in 3 months, after the patient's weight has stabilized and the stoma shrinks to a stable shape.

The location and length of the stoma are significant to the management of the ileostomy by the patient. The surgeon positions the stoma as close to the midline as possible and at a location where even an obese patient with a protruding abdomen can see it and can care for it easily. Usually, the ileostomy stoma is about 2.5 cm (1 in) long, which makes it convenient for the attachment of an appliance.

Skin excoriation around the stoma can be a persistent problem. Peristomal skin integrity may be compromised by several factors, such as an allergic reaction to the ostomy appliance, skin barrier, or paste; chemical irritation from the effluent; mechanical injury from the removal of the appliance; and infection. If irritation and yeast growth occur, nystatin powder (Mycostatin) is dusted lightly on the peristomal skin and a pouch with skin barrier is applied over the affected area.

Changing an Appliance

A regular schedule for changing the pouch before leakage occurs must be established for those with a traditional ileostomy. The patient can be taught to change the pouch in a manner similar to that described in Chart 38-5.

The amount of time a person can keep the appliance sealed to the body surface depends on the location of the stoma and on body structure. The usual wearing time, which also depends on the type of skin barrier, is 5 to 10 days. The appliance is emptied every 4 to 6 hours, or at the same time the patient empties the bladder. An emptying spout at the bottom of the appliance is closed with a special clip or Velcro closure.

CHART
38-5

Guidelines for Changing an Ostomy Appliance

Equipment Needed

- Mild soap
- Clean cloths or towels
- Skin barrier (stoma adhesive, Convatec)
- Cutting guide
- Appliance pouch

Optional Equipment

- Barrier powder
- Antifungal spray or powder
- Barrier washer

Implementation

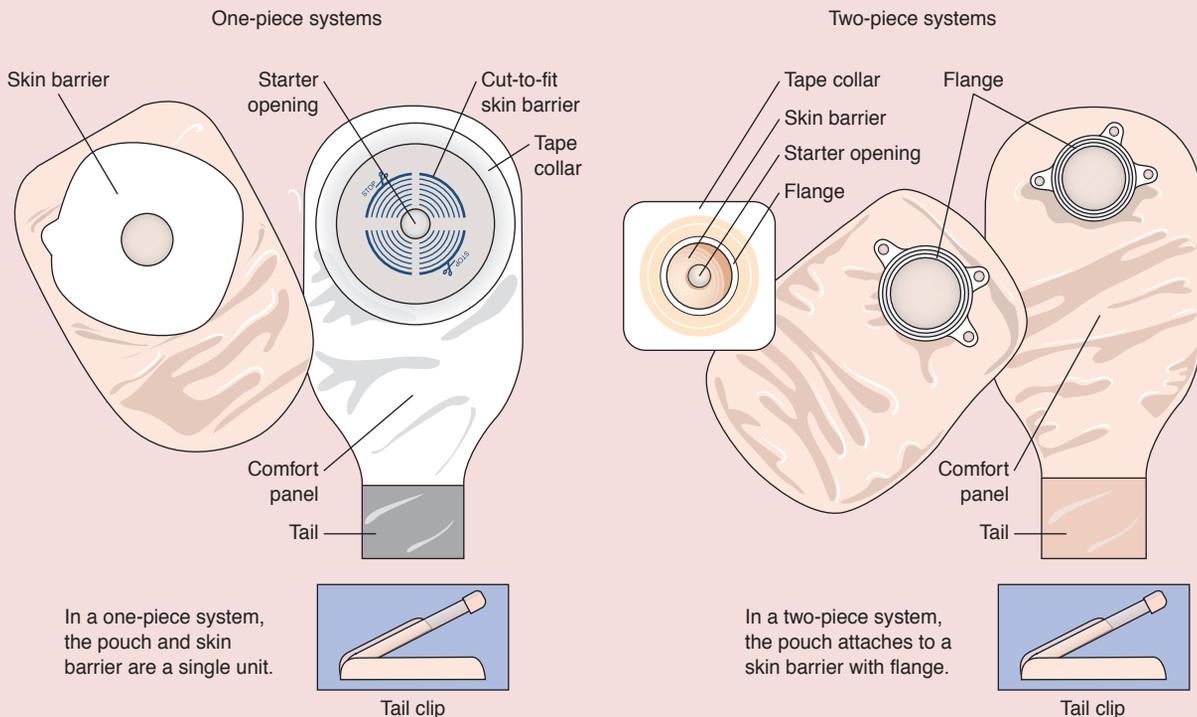

Nursing Action

1. Promote patient comfort and involvement in the procedure.
 - a. Have the patient assume a relaxed position.
 - b. Provide privacy.
 - c. Explain details of the procedure.
 - d. Expose the ileostomy area; remove the ileostomy belt (if worn)
2. Remove the appliance.
 - a. Have the patient sit on the toilet or on a chair facing the toilet. A patient who prefers to stand should face the toilet.
 - b. The appliance (pouch) can be removed by gently pushing the skin away from the adhesive.
3. Cleanse the skin:
 - a. Wash the skin gently with a soft cloth moistened with tepid water and mild soap; the patient may prefer to bathe before putting on a clean appliance.
 - b. Rinse the soap and dry the skin thoroughly after cleansing.

Rationale

1. Providing a relaxed atmosphere and adequate explanations help the patient to become an active participant in the procedure.
2. These positions facilitate disposal or drainage.
3. The patient may shower with or without the pouch.
 - a. Micropore or waterproof tape applied to the sides of the faceplate keeps it secure during bathing.
 - b. Moisture or soap residue interferes with appliance adhesion.

Pouching options

Continued on following page

 CHART
38-5

Guidelines for Changing an Ostomy Appliance (Continued)

Nursing Action

4. Apply appliance:
 - When there is *no* skin irritation:
 - a. An appropriate skin barrier is applied to the peristomal skin before the appliance is applied.
 - b. Remove cover from adherent surface of disk of disposable plastic appliance and apply directly to the skin.
 - c. Press firmly in place for 30 seconds to ensure adherence.
 - When there is skin irritation:
 - a. Cleanse the skin thoroughly but gently; pat dry. Apply barrier powder.
 - b. If more irritation developed, apply Kenalog spray; blot excess moisture with a cotton pledget and dust lightly with nystatin (Mycostatin) powder.
- OR
 - Apply as an alternative a wafer or barrier (Stomahesive, ConvaTec), which is commercially available. The stomal opening should be the same size as the stoma; use a cutting guide (supplied with appliance as indicated). The wafer is applied directly to the skin. Barrier powder can be used to dry irritated skin before barrier application.
 - c. Another alternative is to apply a special barrier washer (eg, Eakin's Seal). The special barrier adheres well to irritated skin.
 - d. The pouch is then applied to the treated skin.
5. Check the pouch bottom for closure; use clamp, Velcro closure, or clip provided.

Rationale

4. Many appliances have a built-in skin barrier. The skin should be thoroughly dried before applying the appliance.
 - a. Cleansing removes debris and protects irritated skin under wafer
 - b. The corticosteroid preparation (Kenalog) helps decrease inflammation. The antifungal agent (nystatin) treats those types of infections that are common around stomas. A prescription is required for either medication. A skin barrier is a substance that facilitates healing of excoriated skin. It adheres well even to moist, irritated skin.
 - c. A special barrier protects skin from effluent, promotes healing and helps with adherence.
 - d. This allows skin to heal while the appliance is in place.
5. Proper closure controls leakage.

Most pouches are disposable and odor-proof. Foods such as spinach and parsley act as deodorizers in the intestinal tract; foods that cause odors include asparagus, cabbage, onions, and fish. Bismuth subcarbonate tablets, which may be prescribed and taken orally three or four times each day, are effective in reducing odor. Oral diphenoxylate atropine (Lomotil) can be prescribed to diminish intestinal motility, thereby thickening the stool and assisting in odor control. Foods such as rice, mashed potatoes, and applesauce may also thicken stool.

Irrigating a Continent Ileostomy

For a continent ileostomy (ie, Kock pouch), the nurse teaches the patient to drain the pouch, as described in Chart 38-6. A catheter is inserted into the reservoir to drain the fluid. The length of time between drainage periods is gradually increased until the reservoir needs to be drained only every 4 to 6 hours and irrigated once each day. A pouch is not necessary; instead, most patients wear a small dressing over the opening.

When the fecal discharge is thick, water can be injected through the catheter to loosen and soften it. The consistency of the effluent is affected by food intake. At first, drainage is only 60 to 80 mL, but as time goes on, the amount increases significantly. The internal Kock pouch stretches, eventually accommodating 500 to 1000 mL. The patient learns to use the sensation of pressure in the pouch as a gauge to determine how often the pouch should be drained.

Managing Dietary and Fluid Needs

A low-residue diet is followed for the first 6 to 8 weeks. Strained fruits and vegetables are given. These foods are important sources of vitamins A and C. Later, there are few dietary restrictions, except for avoiding foods that are high in fiber or hard-to-digest kernels, such as celery, popcorn, corn, poppy seeds, caraway seeds, and coconut, which may result in a stomal obstruction (food blockage) for the person with an ileostomy. Foods are reintroduced one at a time. The nurse assesses the patient's tolerance for these foods and reminds him or her to chew food thoroughly.

Fluids may be a problem during the summer, when fluid lost through perspiration adds to the fluid loss through the ileostomy. Fluids such as Gatorade are helpful in maintaining electrolyte balance. If the fecal discharge is too watery, fibrous foods (eg, whole-grain cereals, fresh fruit skins, beans, corn, nuts) are restricted. If the effluent is excessively dry, salt intake is increased. Increased intake of water or fluid does not increase the effluent, because excess water is excreted in the urine.

Preventing Complications

Monitoring for complications is an ongoing activity for the patient with an ileostomy (Chart 38-7) Peristomal skin irritation, which results from leakage of effluent, is the most common complication of an ileostomy. A drainable pouching system that does not fit well is often the cause. Components

CHART
38-6

Guidelines for Draining a Continent Ileostomy (Kock Pouch)

A continent ileostomy is the surgical creation of a pouch of small intestine that can serve as an internal receptacle for fecal discharge; a nipple valve is constructed at the outlet. Postoperatively, a catheter extends from the stoma and is attached to a closed drainage suction system. To ensure patency of the catheter, 10 to 20 mL of normal saline is instilled gently into the pouch usually every 3 hours; return flow is not aspirated but is allowed to drain by gravity.

After approximately 2 weeks, when the healing process has progressed to the point at which the catheter is removed from the stoma, the patient is taught to drain the pouch.

The following procedure is used to drain the pouch; the patient is helped to participate in this procedure to learn to perform it unassisted.

Equipment

- Catheter
- Tissues
- Water-soluble lubricant
- Gauze squares
- Syringe
- Irrigating solution in a bowl
- Emesis or receiving basin

Implementation

Nursing Action

1. Lubricate the catheter and gently insert it about 5 cm (2 in), at which point some resistance may be felt at the valve or nipple.
2. If there is much resistance, fill a syringe with 20 mL of air or water and inject it through the catheter, while still exerting some pressure on the catheter.
3. Place the other end of the catheter in a drainage basin held below the level of the stoma. Later this process can be carried out at the toilet with drainage delivered into the toilet bowl.
4. After drainage, the catheter is removed and the area around the stoma is gently washed with warm water. Pat dry and apply an absorbent pad over the stoma. Fasten the pad with hypoallergenic tape.

Rationale

1. When gentle pressure is used, the catheter usually enters the pouch.
2. This permits the catheter to enter the pouch.
3. Gravity facilitates drainage. Drainage may include flatus as well as effluent.
4. The entire procedure requires about 5 to 10 min; at first it is performed every 3 h. The time between procedures is gradually lengthened to three times daily.

38-7

NURSING RESEARCH PROFILE

Validation of Stomal and Peristomal Complications

Colwell, J. & Beitz, J. (2007). Survey of wound, ostomy, continence nurse clinicians on stomal and peristomal complications: A content validation study. *Journal of WOCN*, 34(1), 57–69.

Purpose

The incidence and prevalence of stomal and peristomal complications are not known. Lack of validated and reliable stomal and peristomal complication definitions and interventions hampers effective research and nursing care. The objectives of this study were to establish content validation data for the proposed definitions of stomal and peristomal complications and their associated interventions, to obtain data related to nursing contact with patients who had stomal and peristomal complications, and to gain insight into the ostomy care process.

Design

The authors sent a researcher-designed survey to 2900 expert wound, ostomy, continence (WOC) nurses via a national mailing to a representative nonrandomized sample of clinicians who identified ostomy care as part of their practice. In total, 686 WOC nurses returned the survey (response rate 24%). The responses from the purposive sample quantified validity of definitions and interventions and also provided qualitative comments.

In addition they quantified WOC nurses' contact with patients who had experienced stomal and peristomal complications.

Findings

WOC nurses reported substantive contact with intestinal diversion patients who experienced stomal and peristomal complications. The WOC nurses supported the proposed definitions and interventions as generally valid (content validity index, 0.91). However, less consensus existed for interventions. The WOC nurses identified some complications and interventions not included in the survey. Nursing problems regarding the ostomy care process involved the art and versatility of ostomy care, clinical inexperience, and the lack of in-depth education regarding the variety of ostomy complications.

Nursing Implications

Findings from this study confirm that patients with intestinal diversions commonly experience selected stomal and peristomal complications. Researchers validated definitions for stomal and peristomal complications and pertinent interventions. Respondents identified additional complications and interventions not noted in the literature that demand future nursing research and scrutiny, so that ostomy nursing care can become more evidence based.

CHART
38-8HOME CARE CHECKLIST
Managing Ostomy Care

At the completion of the home care instruction, the patient or caregiver will be able to:	PATIENT	CAREGIVER
• Demonstrate ostomy care, including wound cleansing, irrigation, and appliance changing.	✓	✓
• Describe the importance of maintaining peristomal skin integrity.	✓	✓
• Identify sources for obtaining additional dressing and appliance supplies.	✓	✓
• Identify dietary restrictions (foods that can cause diarrhea and constipation).	✓	✓
• Identify measures to be used to promote fluid and electrolyte balance.	✓	✓
• Describe medication regimen: identify medications by name, use, route, and frequency.	✓	✓
• Describe potential complications and necessary actions to be taken if complications occur.	✓	✓
• Identify how to contact wound-ostomy-contenance or home health nurse.	✓	✓

of the drainable pouching system include the pouch, a solid skin barrier, and adhesive. The WOC nurse typically recommends the appropriate drainable pouching system. The solid skin barrier is the component of this system that is most important in ensuring healthy peristomal skin. Solid skin barriers are typically shaped as rectangular or elliptical wafers and are composed of polymers and hydrocolloids. They protect the skin around the stoma from effluent from the stoma and provide a stable interface between the stoma and the pouch. It is critical that the barrier be sized appropriately to “hug” the stoma (up to the stoma but not touching) and not expose peristomal skin.

Other common complications include diarrhea, stomal stenosis, urinary calculi, and cholelithiasis. Even in the presence of a properly fitted drainable pouching system, diarrhea can be problematic. Diarrhea, manifested by very irritating effluent that rapidly fills the pouch (every hour or sooner), can quickly lead to dehydration and electrolyte losses. Supplemental water, sodium, and potassium are administered to prevent hypovolemia and hypokalemia. Antidiarrheal agents are administered. Stenosis is caused by circular scar tissue that forms at the stoma site. The scar tissue must be surgically released. Urinary calculi may occur in patients with ileostomies and are at least partly attributed to dehydration from decreased fluid intake. Intense lower abdominal pain that radiates to the legs, hematuria, and signs of dehydration indicate that the urine should be strained. Fluid intake is encouraged. Sometimes, small stones are passed during urination; treatment that crushes or removes larger stones is necessary (see Chapter 45).

Cholelithiasis (ie, gallstones) occurs more commonly in patients with an ileostomy than in members of the general population because of changes in the absorption of bile acids that occur postoperatively. Spasm of the gallbladder causes severe upper right abdominal pain that can radiate to the back and right shoulder (see Chapter 40).

Promoting Home and Community-Based Care

Teaching Patients Self-Care. The partner and family should be familiar with the adjustments that will be necessary when the patient returns home. They need to know why it is necessary for the patient to occupy the bathroom

for 10 minutes or more at certain times of the day and why certain equipment is needed. Their understanding is necessary to reduce tension; a relaxed patient tends to have fewer problems. Visits from a WOC nurse may be arranged to ensure that the patient is progressing as expected and to provide additional guidance and teaching as needed.

Continuing Care. The patient needs to know the commercial name of the drainable pouching system to be used so that he or she can obtain a ready supply and should know how to obtain other supplies. The names and contact information of a local WOC nurse and local self-help groups are often helpful. Any restrictions on driving or working also need to be reviewed. The nurse teaches the patient about common postoperative complications and how to recognize and report them (Chart 38-8).

INTESTINAL OBSTRUCTION

Intestinal obstruction exists when blockage prevents the normal flow of intestinal contents through the intestinal tract. Two types of processes can impede this flow:

- **Mechanical obstruction:** An intraluminal obstruction or a mural obstruction from pressure on the intestinal wall occurs. Examples are intussusception, polypoid tumors and neoplasms, stenosis, strictures, adhesions, hernias, and abscesses.
- **Functional obstruction:** The intestinal musculature cannot propel the contents along the bowel. Examples are amyloidosis, muscular dystrophy, endocrine disorders such as diabetes mellitus, or neurologic disorders such as Parkinson’s disease. The blockage also can be temporary and the result of the manipulation of the bowel during surgery.

The obstruction can be partial or complete. Its severity depends on the region of bowel affected, the degree to which the lumen is occluded, and especially the degree to which the vascular supply to the bowel wall is disturbed.

Most bowel obstructions occur in the small intestine. Adhesions are the most common cause of small bowel obstruction, followed by hernias and neoplasms. Other causes

Table 38-5 MECHANICAL CAUSES OF INTESTINAL OBSTRUCTION

Cause	Course of Events	Result
Adhesions	Loops of intestine become adherent to areas that heal slowly or scar after abdominal surgery; occurs most commonly in small intestine.	After surgery, adhesions produce a kinking of an intestinal loop.
Intussusception	One part of the intestine slips into another part located below it (like a telescope shortening); occurs more commonly in infants than adults	The intestinal lumen becomes narrowed and blood supply becomes strangulated.
Volvulus	Bowel twists and turns on itself and occludes the blood supply.	Intestinal lumen becomes obstructed. Gas and fluid accumulate in the trapped bowel.
Hernia	Protrusion of intestine through a weakened area in the abdominal muscle or wall.	Intestinal flow may be completely obstructed. Blood flow to the area may be obstructed as well.
Tumor	A tumor that exists within the wall of the intestine extends into the intestinal lumen, or a tumor outside the intestine causes pressure on the wall of the intestine. Most common type is colorectal adenocarcinoma.	Intestinal lumen becomes partially obstructed; if the tumor is not removed, complete obstruction results.

include intussusception, volvulus (ie, twisting of the bowel), and paralytic ileus. Most obstructions in the large bowel occur in the sigmoid colon. The most common causes are carcinoma, diverticulitis, inflammatory bowel disorders, and benign tumors. Table 38-5 and Figure 38-7 list mechanical causes of obstruction and describe how they occur.

Small Bowel Obstruction

Pathophysiology

Intestinal contents, fluid, and gas accumulate above the intestinal obstruction. The abdominal distention and retention of fluid reduce the absorption of fluids and stimulate

more gastric secretion. With increasing distention, pressure within the intestinal lumen increases, causing a decrease in venous and arteriolar capillary pressure. This causes edema, congestion, necrosis, and eventual rupture or perforation of the intestinal wall, with resultant peritonitis.

Reflux vomiting may be caused by abdominal distention. Vomiting results in loss of hydrogen ions and potassium from the stomach, leading to reduction of chlorides and potassium in the blood and to metabolic alkalosis. Dehydration and acidosis develop from loss of water and sodium. With acute fluid losses, hypovolemic shock may occur.

Clinical Manifestations

The initial symptom is usually crampy pain that is wave-like and colicky. The patient may pass blood and mucus but no fecal matter and no flatus. Vomiting occurs. If the obstruction is complete, the peristaltic waves initially become extremely vigorous and eventually assume a reverse direction, with the intestinal contents propelled toward the mouth instead of toward the rectum. If the obstruction is in the ileum, fecal vomiting takes place. First, the patient vomits the stomach contents, then the bile-stained contents of the duodenum and the jejunum, and finally, with each paroxysm of pain, the darker, fecal-like contents of the ileum. The signs of dehydration become evident: intense thirst, drowsiness, generalized malaise, aching, and a parched tongue and mucous membranes. The abdomen becomes distended. The lower the obstruction is in the GI tract, the more marked the abdominal distention. If the obstruction continues uncorrected, hypovolemic shock occurs from dehydration and loss of plasma volume.

Assessment and Diagnostic Findings

Diagnosis is based on the symptoms described previously and on imaging studies. Abdominal x-ray and CT findings include abnormal quantities of gas, fluid, or both in the intestines. Laboratory studies (ie, electrolyte studies and a complete blood cell count) reveal a picture of dehydration, loss of plasma volume, and possible infection.

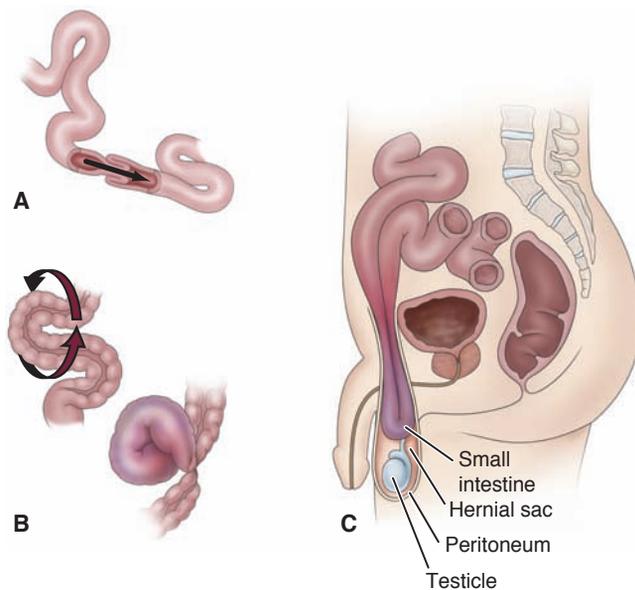

Figure 38-7 Three causes of intestinal obstruction. **A**, Intussusception; invagination or shortening of the colon caused by the movement of one segment of bowel into another. **B**, Volvulus of the sigmoid colon; the twist is counterclockwise in most cases. Note the edematous bowel. **C**, Hernia (inguinal). The sac of the hernia is a continuation of the peritoneum of the abdomen. The hernial contents are intestine, omentum, or other abdominal contents that pass through the hernial opening into the hernial sac.

Medical Management

Decompression of the bowel through a nasogastric tube (see Chapter 36) is successful in most cases. When the bowel is completely obstructed, the possibility of strangulation and tissue necrosis (ie, tissue death) warrants surgical intervention. Before surgery, IV fluids are necessary to replace the depleted water, sodium, chloride, and potassium.

The surgical treatment of intestinal obstruction depends on the cause of the obstruction. For the most common causes of obstruction, such as hernia and adhesions, the surgical procedure involves repairing the hernia or dividing the adhesion to which the intestine is attached. In some instances, the portion of affected bowel may be removed and an anastomosis performed. The complexity of the surgical procedure depends on the duration of the intestinal obstruction and the condition of the intestine.

Nursing Management

Nursing management of the nonsurgical patient with a small bowel obstruction includes maintaining the function of the nasogastric tube, assessing and measuring the nasogastric output, assessing for fluid and electrolyte imbalance, monitoring nutritional status, and assessing improvement (eg, return of normal bowel sounds, decreased abdominal distention, subjective improvement in abdominal pain and tenderness, passage of flatus or stool). The nurse reports discrepancies in intake and output, worsening of pain or abdominal distention, and increased nasogastric output. If the patient's condition does not improve, the nurse prepares him or her for surgery. Nursing care of the patient after surgical repair of a small bowel obstruction is similar to that for other abdominal surgeries (see Chapter 20).

Large Bowel Obstruction

Pathophysiology

As in small bowel obstruction, large bowel obstruction results in an accumulation of intestinal contents, fluid, and gas proximal to the obstruction. It can lead to severe distention and perforation unless some gas and fluid can flow back through the ileal valve. Large bowel obstruction, even if complete, may be undramatic if the blood supply to the colon is not disturbed. However, if the blood supply is cut off, intestinal strangulation and necrosis occur; this condition is life-threatening. In the large intestine, dehydration occurs more slowly than in the small intestine because the colon can absorb its fluid contents and can distend to a size considerably beyond its normal full capacity.

Adenocarcinoid tumors account for the majority of large bowel obstructions. Most tumors occur beyond the splenic flexure, making them accessible with a flexible sigmoidoscope.

Clinical Manifestations

Large bowel obstruction differs clinically from small bowel obstruction in that the symptoms develop and progress relatively slowly. In patients with obstruction in the sigmoid colon or the rectum, constipation may be the only symptom for months. The shape of the stool is altered as it passes the obstruction that is gradually increasing in size. Blood loss in the stool may result in iron deficiency anemia. The patient may experience weakness, weight loss, and anorexia. Eventually, the abdomen becomes markedly distended, loops of large bowel become visibly outlined through the abdominal wall, and the patient has crampy lower abdominal pain. Finally, fecal vomiting develops. Symptoms of shock may occur.

Assessment and Diagnostic Findings

Diagnosis is based on symptoms and on imaging studies. Abdominal x-ray and abdominal CT or MRI findings reveal a distended colon and pinpoint the site of the obstruction. Barium studies are contraindicated.

Medical Management

Restoration of intravascular volume, correction of electrolyte abnormalities, and nasogastric aspiration and decompression are instituted immediately. A colonoscopy may be performed to untwist and decompress the bowel. A cecostomy, in which a surgical opening is made into the cecum, may be performed in patients who are poor surgical risks and urgently need relief from the obstruction. The procedure provides an outlet for releasing gas and a small amount of drainage. A rectal tube may be used to decompress an area that is lower in the bowel. However, the usual treatment is surgical resection to remove the obstructing lesion. A temporary or permanent colostomy may be necessary. An ileoanal anastomosis may be performed if removal of the entire large bowel is necessary.

Nursing Management

The nurse's role is to monitor the patient for symptoms that indicate that the intestinal obstruction is worsening and to provide emotional support and comfort. The nurse administers IV fluids and electrolytes as prescribed. If the patient's condition does not respond to nonsurgical treatment, the nurse prepares the patient for surgery. This preparation includes preoperative teaching as the patient's condition indicates. After surgery, general abdominal wound care and routine postoperative nursing care are provided.

Colorectal Cancer

Tumors of the colon and rectum are relatively common; the colorectal area (the colon and rectum combined) is now the third most common site of new cancer cases in the United States. Colorectal cancer is a disease of Western cultures. In the United States, almost 150,000 new cases and 52,000 deaths from colorectal cancer occur annually (American Cancer Society [ACS], 2008). Colorectal cancer is the

second leading cause of cancer death in both men and women (Bazensky, Shoobridge-Moran & Yoder, 2007).

The lifetime risk of developing colorectal cancer is 1 in 17 (Gill, Blackstack & Goldberg, 2007). Incidence increases with age (the incidence is highest in people older than 85 years) and is higher in people with a family history of colon cancer and those with IBD or polyps. The exact cause of colon and rectal cancer is still unknown, but risk factors have been identified (Chart 38-9).

Improved screening strategies have helped reduce the number of deaths from colon cancer in recent years. Of the approximately 150,000 people diagnosed each year, fewer than half that number dies annually (ACS, 2008). Early diagnosis and prompt treatment could save almost three of every four people. If the disease is detected and treated at an early stage before the disease spreads, the 5-year survival rate is 90%; however, only 39% of colorectal cancers are detected at an early stage (ACS, 2008). Survival rates after late diagnosis are very low. Most people are asymptomatic for long periods and seek health care only when they notice a change in bowel habits or rectal bleeding. Prevention and early screening are key to detection and reduction of mortality rates (Bazensky, et al., 2007).

Hereditary colon cancer accounts for about 6% of all colon cancers. Early diagnosis helps target treatment and screening for clients and family members (Kelly, 2008). Genetic counselors are trained to help patients and their family members understand the significance of genetics information (Chan-Smutko, Patel, Shannon, et al., 2008). If patients are found to have a genetic susceptibility to cancer, they should be offered counseling and follow-up to ensure that care is consistent with current standards (Burke & Press, 2006).

Pathophysiology

Cancer of the colon and rectum is predominantly (95%) adenocarcinoma (ie, arising from the epithelial lining of the intestine) (ACS, 2008). It may start as a benign polyp but may become malignant, invade and destroy normal tissues, and extend into surrounding structures. Cancer cells may migrate away from the primary tumor and spread to other parts of the body (most often to the liver, peritoneum, and lungs) (Field & Lipton, 2007).

CHART
38-9

Risk Factors for Colorectal Cancer

- Increasing age
- Family history of colon cancer or polyps
- Previous colon cancer or adenomatous polyps
- High consumption of alcohol
- Cigarette smoking
- Obesity
- History of gastrectomy
- History of inflammatory bowel disease
- High-fat, high-protein (with high intake of beef), low-fiber diet
- Genital cancer (eg, endometrial cancer, ovarian cancer) or breast cancer (in women)

Clinical Manifestations

The symptoms are greatly determined by the location of the tumor, the stage of the disease, and the function of the affected intestinal segment. The most common presenting symptom is a change in bowel habits. The passage of blood in or on the stools is the second most common symptom. Symptoms may also include unexplained anemia, anorexia, weight loss, and fatigue.

The symptoms most commonly associated with right-sided lesions are dull abdominal pain and melena (ie, black, tarry stools). The symptoms most commonly associated with left-sided lesions are those associated with obstruction (ie, abdominal pain and cramping, narrowing stools, constipation, distention), as well as bright-red blood in the stool. Symptoms associated with rectal lesions are tenesmus (ie, ineffective, painful straining at stool), rectal pain, the feeling of incomplete evacuation after a bowel movement, alternating constipation and diarrhea, and bloody stool. In many instances, symptoms do not develop until colorectal cancer is at an advanced stage.

Assessment and Diagnostic Findings

Along with an abdominal and rectal examination, the most important diagnostic procedures for cancer of the colon are fecal occult blood testing, barium enema, proctosigmoidoscopy, and colonoscopy (see Chapter 34). The majority of colorectal cancer cases can be identified by colonoscopy with biopsy or cytology smears.

Carcinoembryonic antigen (CEA) studies may also be performed. Although CEA may not be a highly reliable indicator in diagnosing colon cancer because not all lesions secrete CEA, studies show that CEA levels are reliable prognostic predictors. With complete excision of the tumor, the elevated levels of CEA should return to normal within 48 hours. Elevations of CEA at a later date suggest recurrence.

Complications

Tumor growth may cause partial or complete bowel obstruction. Extension of the tumor and ulceration into the surrounding blood vessels result in hemorrhage. Perforation, abscess formation, peritonitis, sepsis, and shock may occur.

Gerontologic Considerations

The incidence of carcinoma of the colon and rectum increases with age. These cancers are considered common malignancies in advanced age. In men, only the incidence of prostate cancer and lung cancer exceeds that of colorectal cancer. In women, only the incidence of breast cancer exceeds that of colorectal cancer (ACS, 2008; Bazensky, et al., 2007). Symptoms are often insidious. Patients with colorectal cancer usually report fatigue, which is caused primarily by iron deficiency anemia. In early stages, minor changes in bowel patterns and occasional bleeding may occur. The later symptoms most commonly reported by the elderly are abdominal pain, obstruction, tenesmus, and rectal bleeding.

Colon cancer in the elderly has been closely associated with dietary carcinogens. Lack of fiber is a major causative factor because the passage of feces through the intestinal tract is prolonged, which extends exposure to possible carcinogens. Excess dietary fat, high alcohol consumption, and smoking all increase the incidence of colorectal tumors. Physical activity and dietary folate have protective effects (Bazensky, et al., 2007).

Medical Management

The patient with symptoms of intestinal obstruction is treated with IV fluids and nasogastric suction. If there has been significant bleeding, blood component therapy may be required.

Treatment for colorectal cancer depends on the stage of the disease (Chart 38-10) and consists of surgery to remove the tumor, supportive therapy, and adjuvant therapy. Patients who receive some form of adjuvant therapy, which may include chemotherapy, radiation therapy, immunotherapy, or multimodality therapy, typically demonstrate delays in tumor recurrence and increases in survival time (Field & Lipton, 2007; Gill, et al., 2007; Kosmider & Lipton, 2007).

Adjuvant Therapy

The standard adjuvant therapy administered to patients with Dukes' class C or non-metastasized colon cancer is the 5-fluorouracil (5-FU; Adrucil) plus leucovorin calcium (Wellcovorin) (Kosmider & Lipton, 2007). Other agents include oxaliplatin (Eloxatin) and capecitabine (Xeloda). Patients with Dukes' class B or C rectal cancer are given 5-FU and high doses of pelvic irradiation. Mitomycin is also used. Radiation therapy is used before, during, and after surgery to shrink the tumor; to achieve better results from surgery; and to reduce the risk of recurrence. For inoperable or unresectable tumors, radiation is used to provide

significant relief from symptoms. Intracavitary and implantable devices are used to deliver radiation to the site. The response to adjuvant therapy varies. Patients at risk of poor outcomes include those with higher Dukes' or tumor, node, metastasis (TNM) stage (see Chapter 16), elevated CEA levels, insufficient lymph node sampling, and presentation with colonic perforation or obstruction (Kosmider & Lipton, 2007).

Surgical Management

Surgery is the primary treatment for most colon and rectal cancers. It may be curative or palliative. Advances in surgical techniques can enable the patient with cancer to have sphincter-saving devices that restore continuity of the GI tract. The type of surgery recommended depends on the location and size of the tumor. Cancers limited to one site can be removed through the colonoscope. Laparoscopic colotomy with polypectomy minimizes the extent of

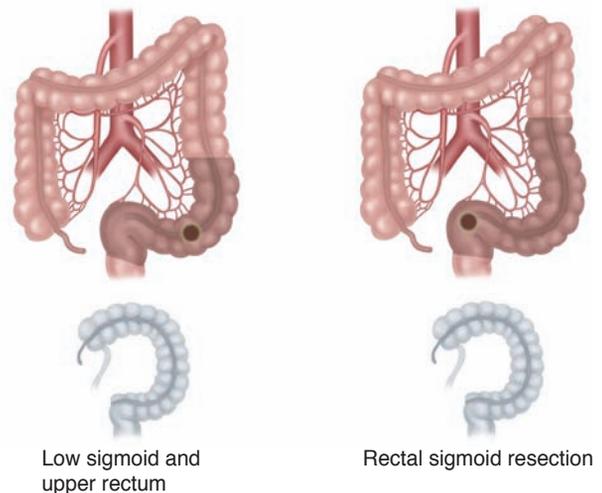

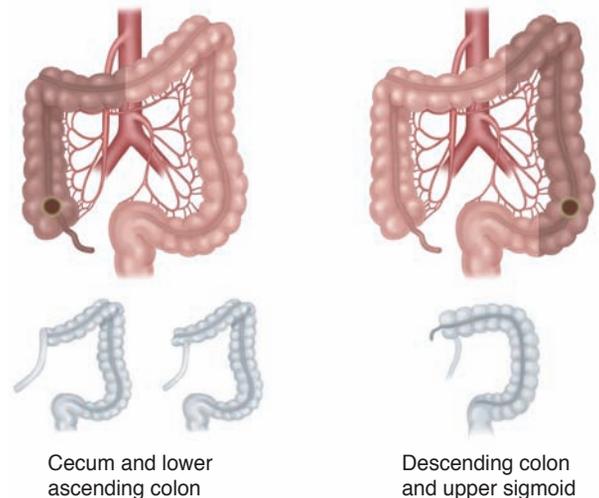

Chart 38-10 • Staging of Colorectal Cancer: Dukes' Classification–Modified Staging System

- Class A:** Tumor limited to muscular mucosa and submucosa
- Class B₁:** Tumor extends into mucosa
- Class B₂:** Tumor extends through entire bowel wall into serosa or pericolic fat, no nodal involvement
- Class C₁:** Positive nodes, tumor is limited to bowel wall
- Class C₂:** Positive nodes, tumor extends through entire bowel wall
- Class D:** Advanced and metastasis to liver, lung, or bone
- Another staging system, the TNM (tumor, nodal involvement, metastasis) classification, may be used to describe the anatomic extent of the primary tumor, depending on:
- Size, invasion depth, and surface spread
 - Extent of nodal involvement
 - Presence or absence of metastasis

The higher the score in each category, the worse the disease and prognosis.

Huether, S. E. & McCance, K. L. (2008). *Understanding pathophysiology*. St. Louis, MO: Mosby.

Figure 38-8 Examples of areas where cancer can occur, the area that is removed, and how the anastomosis is performed (*small diagrams*).

surgery needed in some cases. A laparoscope is used as a guide in making an incision into the colon; the tumor mass is then excised. Laparoscopic colectomy has also been shown to have equivalent surgical outcomes to open colectomy and is associated with decreased length of stay, decreased use of pain medications, and improved quality of life (Gill, et al., 2007). Use of the neodymium/yttrium-aluminum-garnet (Nd:YAG) laser is effective with some lesions as well. Bowel resection is indicated for most class A lesions and all class B and C lesions. Surgery is sometimes recommended for class D colon cancer, but the goal of surgery in this instance is palliative; if the tumor has spread and involves surrounding vital structures, it is considered nonresectable.

Possible surgical procedures include the following:

- Segmental resection with anastomosis (ie, removal of the tumor and portions of the bowel on either side of the growth, as well as the blood vessels and lymphatic nodes) (Fig. 38-8)
- Abdominoperineal resection with permanent sigmoid colostomy (ie, removal of the tumor and a portion of the sigmoid and all of the rectum and anal sphincter, also called Miles resection) (Fig. 38-9)
- Temporary colostomy followed by segmental resection and anastomosis and subsequent reanastomosis of the

colostomy, allowing initial bowel decompression and bowel preparation before resection

- Permanent colostomy or ileostomy for palliation of unresectable obstructing lesions
- Construction of a coloanal reservoir called a colonic J pouch, which is performed in two steps. A temporary loop ileostomy is constructed to divert intestinal flow, and the newly constructed J pouch (made from 6 to 10 cm of colon) is reattached to the anal stump. About 3 months after the initial stage, the ileostomy is reversed and intestinal continuity is restored. The anal sphincter and therefore continence are preserved.

A **colostomy** is the surgical creation of an opening (ie, stoma) into the colon. It can be created as a temporary or permanent fecal diversion. It allows the drainage or evacuation of colon contents to the outside of the body. The consistency of the drainage is related to the placement of the colostomy, which is dictated by the location of the tumor and the extent of invasion into surrounding tissues (Fig. 38-10). With improved surgical techniques that allow salvage of the anal sphincter, colostomies are performed in fewer than one third of patients with colorectal cancer. For patients with isolated metastases, newer, less invasive approaches have increased life expectancy. Management includes hepatic arterial infusion

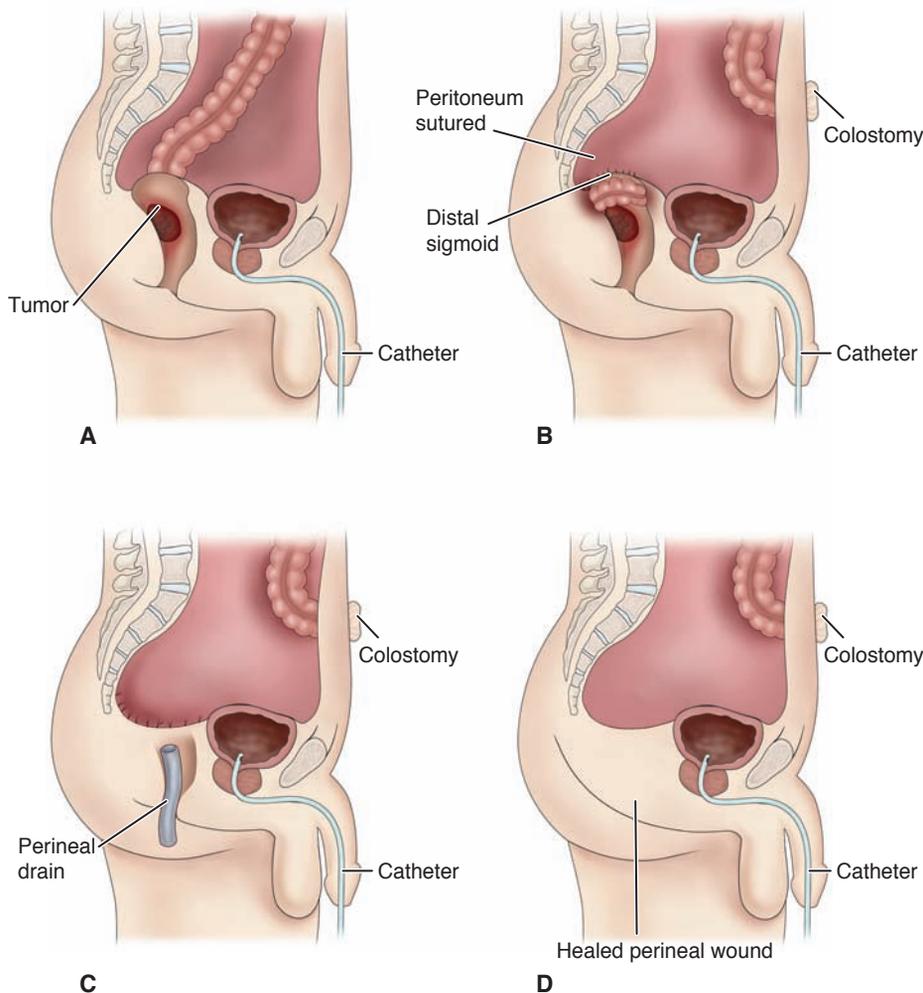

Figure 38-9 Abdominoperineal resection for carcinoma of the rectum. **A**, Prior to surgery. Note tumor in rectum. **B**, During surgery, the sigmoid is removed and the colostomy is established. The distal bowel is dissected free to a point below the pelvic peritoneum, which is sutured over the closed end of the distal sigmoid and rectum. **C**, Perineal resection includes removal of the rectum and free portion of the sigmoid from below. A perineal drain is inserted. **D**, The final result after healing. Note the healed perineal wound and the permanent colostomy.

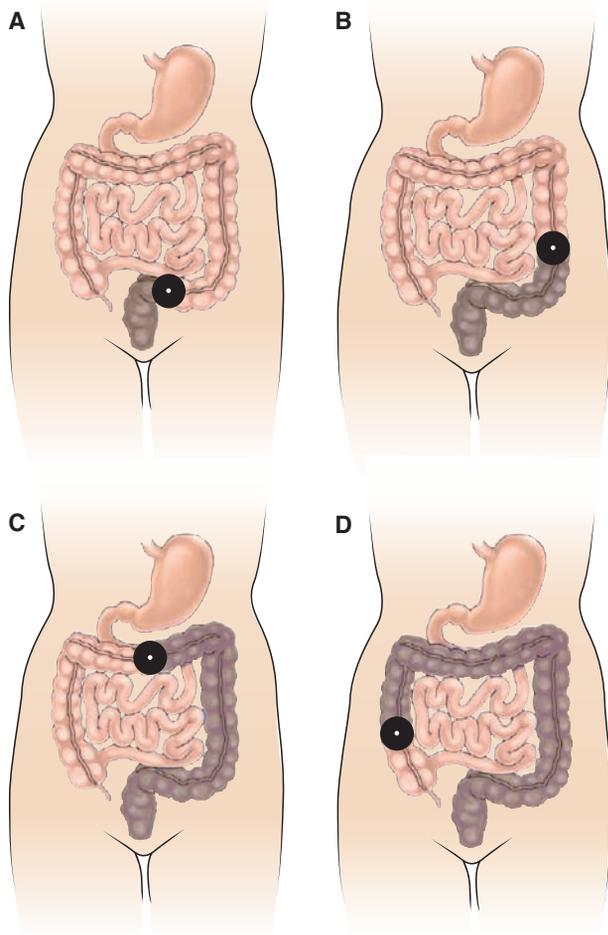

Figure 38-10 Placement of permanent colostomies. The nature of the discharge varies with the site. Shaded areas show sections of bowel removed. **A**, With a sigmoid colostomy, the feces are formed. **B**, With a descending colostomy, the feces are semi-formed. **C**, With a transverse colostomy, the feces are unformed. **D**, With an ascending colostomy, the feces are fluid.

chemotherapy, radiofrequency ablation, and selective internal radiation therapy (Field & Lipton, 2007).

Gerontologic Considerations

The elderly are at increased risk of complications after surgery and may have difficulty managing colostomy care. Some elderly patients may have decreased vision, impaired hearing, and difficulty with fine motor coordination. It may be helpful for patients to handle ostomy equipment and simulate cleaning the peristomal skin and irrigating the stoma before surgery. Skin care is a major concern in older patients with a colostomy because of the skin changes that occur with aging—the epithelial and subcutaneous fatty layers become thin, and the skin is irritated easily. To prevent skin breakdown, special attention is paid to skin cleansing and the proper fit of an appliance. Newer stoma skin barriers do not have to be cut but can be molded into shape around the stoma (eg, ConvaTec; Fig. 38-11). Arteriosclerosis may also be an issue; it causes decreased blood flow to the wound and stoma site. As a result, transport of nutrients is delayed and

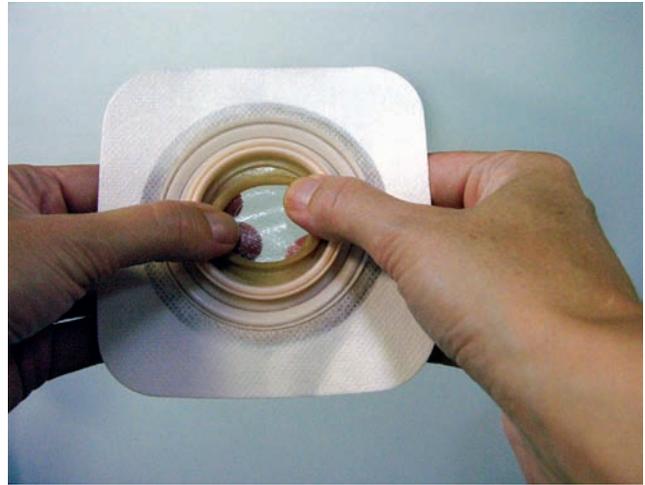

Figure 38-11 Moldable stoma skin barrier (Moldable Technology, Courtesy of ConvaTec, Inc., © Skillman, NJ).

healing time may be prolonged. Some patients have delayed elimination after irrigation because of decreased peristalsis and mucus production. Most patients require 6 months before they feel comfortable with their ostomy care.

NURSING PROCESS

THE PATIENT WITH COLORECTAL CANCER

Assessment

The nurse obtains a health history about the presence of fatigue, abdominal or rectal pain (eg, location, frequency, duration, association with eating or defecation), past and present elimination patterns, and characteristics of stool (eg, color, odor, consistency, presence of blood or mucus). Additional information includes a history of IBD or colorectal polyps, a family history of colorectal disease, and current medication therapy. The nurse assesses dietary patterns, including fat and fiber intake, as well as amounts of alcohol consumed and history of smoking. The nurse describes and documents a history of weight loss and feelings of weakness and fatigue.

Assessment includes auscultation of the abdomen for bowel sounds and palpation of the abdomen for areas of tenderness, distention, and solid masses. Stool specimens are inspected for character and presence of blood.

Diagnosis

Nursing Diagnoses

Based on the assessment data, the major nursing diagnoses may include the following:

- Imbalanced nutrition, less than body requirements, related to nausea and anorexia
- Risk for deficient fluid volume related to vomiting and dehydration
- Anxiety related to impending surgery and the diagnosis of cancer
- Risk for ineffective therapeutic regimen management related to knowledge deficit concerning the diagnosis, the surgical procedure, and self-care after discharge

- Impaired skin integrity related to the surgical incisions (abdominal and perianal), the formation of a stoma, and frequent fecal contamination of peristomal skin
- Disturbed body image related to colostomy
- Ineffective sexuality patterns related to presence of ostomy and changes in body image and self-concept

Collaborative Problems/Potential Complications

Potential complications that may develop include the following:

- Intraoperative infection
- Complete large bowel obstruction
- GI bleeding
- Bowel perforation
- Peritonitis, abscess, and sepsis

Planning and Goals

The major goals for the patient may include attainment of optimal level of nutrition; maintenance of fluid and electrolyte balance; reduction of anxiety; learning about the diagnosis, surgical procedure, and self-care after discharge; maintenance of optimal tissue healing; protection of peristomal skin; learning how to irrigate the colostomy (done only with sigmoid colostomies) and change the appliance; expressing feelings and concerns about the colostomy and the impact on self; and avoidance of complications.

Nursing Interventions

Preparing the Patient for Surgery

The patient awaiting surgery for colorectal cancer has many concerns, needs, and fears. He or she may be physically debilitated and emotionally distraught with concerns about lifestyle changes after surgery, prognosis, ability to perform in established roles, and finances. Priorities for nursing care include preparing the patient physically for surgery; providing information about postoperative care, including stoma care if a colostomy is to be created; and supporting the patient and family emotionally. Ideally, a WOC nurse or surgeon should identify the stoma site preoperatively to ensure that its placement is visible and accessible to the patient.

Physical preparation for surgery involves building the patient's stamina in the days preceding surgery and cleansing and sterilizing the bowel the day before surgery. If the patient's condition permits, the nurse recommends a diet high in calories, protein, and carbohydrates and low in residue for several days before surgery to provide adequate nutrition and minimize cramping by decreasing excessive peristalsis. A full liquid diet may be prescribed for 24 to 48 hours before surgery to decrease bulk. If the patient is hospitalized in the days preceding surgery, parenteral nutrition may be required to replace depleted nutrients, vitamins, and minerals. In some instances, parenteral nutrition is administered at home before surgery. Antibiotics such as kanamycin (Kantrex), neomycin (Mycifradin), and cephalixin (Keflex) are administered orally the day before surgery to reduce intestinal bacteria. The bowel is cleansed with laxatives, enemas, or colonic irrigations the evening before and the morning of surgery.

For the patient who is very ill and hospitalized, the nurse measures and records intake and output, including vomitus,

to provide an accurate record of fluid balance. The patient's intake of oral food and fluids may be restricted to prevent vomiting. The nurse administers antiemetics as prescribed. Full or clear liquids may be tolerated, or the patient may be allowed nothing by mouth. A nasogastric tube may be inserted to drain accumulated fluids and prevent abdominal distention. The nurse monitors the abdomen for increasing distention, loss of bowel sounds, and pain or rigidity, which may indicate obstruction or perforation. It also is important to monitor IV fluids and electrolytes. Monitoring serum electrolyte levels can detect the hypokalemia and hyponatremia that occur with GI fluid loss. The nurse observes for signs of hypovolemia (eg, tachycardia, hypotension, decreased pulse volume); assesses hydration status; and reports decreased skin turgor, dry mucous membranes, and concentrated urine.

The nurse assesses the patient's knowledge about the diagnosis, prognosis, surgical procedure, and expected level of functioning after surgery. It is important to include information about the physical preparation for surgery, the expected appearance and care of the wound, the technique of ostomy care (if applicable), dietary restrictions, pain control, and medication management in the teaching plan (see the Plan of Nursing Care in Chart 38-4). If the patient is admitted the day of surgery, the physician's office may arrange for the patient to be seen by a WOC nurse in the days preceding surgery. The WOC nurse helps determine the optimal site for the stoma and provides teaching about care. If the patient is hospitalized before the day of surgery, the WOC nurse is involved in the preoperative teaching. All procedures are explained in language the patient understands.

Providing Emotional Support

Patients anticipating bowel surgery for colorectal cancer may be very anxious. They may grieve about the diagnosis, the impending surgery, and possible permanent colostomy. Patients undergoing surgery for a temporary colostomy may express fears and concerns similar to those of a person with a permanent stoma. All members of the health care team, including the WOC nurse, should be available for assistance and support. The nurse's role is to assess the patient's anxiety level and coping mechanisms and suggest methods for reducing anxiety, such as deep-breathing exercises and visualizing a successful recovery from surgery and cancer. The nurse can arrange a meeting with a spiritual advisor if the patient desires or with the physician if the patient wishes to discuss the treatment or prognosis.

The patient undergoing a colostomy may find the anticipated changes in body image and lifestyle profoundly disturbing. Because the stoma is located on the abdomen, the patient may think that everyone will be aware of the ostomy. The nurse helps reduce this fear by presenting facts about the surgical procedure and the creation and management of the ostomy. If the patient is receptive, the nurse can use diagrams, photographs, and appliances to explain and clarify. Because the patient is experiencing emotional stress, the nurse will likely need to repeat some of the information. Consultation with a WOC nurse during the preoperative period can be extremely helpful, as can

speaking with a person who is successfully managing a colostomy. The UOAA provides visiting services by qualified members and rehabilitation services for patients with new ostomies.

Providing Postoperative Care

Postoperative nursing care for patients undergoing colon resection or colostomy is similar to nursing care for any abdominal surgery patient (see Chapter 20), including pain management during the immediate postoperative period. The nurse assesses the abdomen for returning peristalsis and assesses the initial stool characteristics. It is important to help patients with a colostomy out of bed on the first postoperative day and to encourage them to begin participating in managing the colostomy.

Maintaining Optimal Nutrition

The nurse teaches all patients undergoing surgery for colorectal cancer about the health benefits to be derived from consuming a healthy diet. The diet is individualized as long as it is nutritionally sound and does not cause diarrhea or constipation. The return to normal diet is rapid.

A complete nutritional assessment is important for the patient with a colostomy. The patient avoids foods that cause excessive odor and gas, including foods in the cabbage family, eggs, asparagus, fish, beans, and high-cellulose products such as peanuts. It is important to determine whether the elimination of specific foods is causing any nutritional deficiency. Nonirritating foods are substituted for those that are restricted so that deficiencies are corrected. The nurse advises the patient to experiment with an irritating food several times before restricting it, because an initial sensitivity may decrease with time. The nurse can help the patient identify any foods or fluids that may be causing diarrhea, such as fruits, high-fiber foods, soda, coffee, tea, or carbonated beverages. Diphenoxylate with atropine may be prescribed as needed to control the diarrhea. For constipation, prune or apple juice or a mild laxative is effective. The nurse suggests fluid intake of at least 2 L per day.

Providing Wound Care

The nurse frequently examines the abdominal dressing during the first 24 hours after surgery to detect signs of hemorrhage. It is important to help the patient splint the abdominal incision during coughing and deep breathing to lessen tension on the edges of the incision. The nurse monitors temperature, pulse, and respiratory rate for elevations that may indicate an infectious process. If the patient has a colostomy, the stoma is examined for swelling (slight edema from surgical manipulation is normal), color (a healthy stoma is pink or red), discharge (a small amount of oozing is normal), and bleeding (an abnormal sign if bright red or beyond trace amounts).

If the malignancy has been removed using the perineal route, the perineal wound is observed for signs of hemorrhage. This wound may contain a drain or packing that is removed gradually. Bits of tissue may slough off for a week. This process is hastened by mechanical irrigation of the wound or with sitz baths performed two or three times each

day initially. The condition of the perineal wound and any bleeding, infection, or necrosis is documented.

Monitoring and Managing Complications

The patient is observed for signs and symptoms of complications. It is important to frequently assess the abdomen, including bowel sounds and abdominal girth, to detect bowel obstruction. The nurse monitors vital signs for increased temperature, pulse, and respirations and for decreased blood pressure that may indicate an intra-abdominal infectious process. It is important to report rectal bleeding immediately because it indicates hemorrhage. The nurse monitors hemoglobin and hematocrit levels and administers blood component therapy as prescribed. Any abrupt change in abdominal pain is reported promptly. Elevated white blood cell counts and temperature or symptoms of shock are reported because they may indicate sepsis. The nurse administers antibiotics as prescribed.

Pulmonary complications are always a concern with abdominal surgery; patients older than 50 years are at risk, especially if they are or have been receiving sedatives or are being maintained on bed rest for a prolonged period. Two major pulmonary complications are pneumonia and atelectasis. Frequent activity (eg, turning the patient from side to side every 2 hours), deep breathing, coughing, and early ambulation can reduce the risk for these complications. Table 38-6 lists postoperative complications.

The incidence of complications related to the colostomy is usually less than that of an ileostomy. Some common complications are prolapse of the stoma, parastomal hernia, perforation (from improper stoma irrigation), stoma retraction, mucocutaneous separation, and skin irritation (Colwell & Beitz, 2007). Leakage from an anastomotic site can occur if the remaining bowel segments are diseased or weakened. Leakage from an intestinal anastomosis causes peritonitis with abdominal distention and rigidity, temperature elevation, and signs of shock. Surgical repair is necessary.

Removing and Applying the Colostomy Appliance

The colostomy begins to function 3 to 6 days after surgery. The nurse manages the colostomy and teaches the patient about its care until the patient can take over its management. The nurse teaches skin care and how to apply, empty, and remove the drainage pouch. Care of the peristomal skin is an ongoing concern because excoriation or ulceration can develop quickly. The presence of such irritation makes adhering the ostomy appliance difficult, and adhering the ostomy appliance to irritated skin can worsen the skin condition. The effluent discharge and the degree to which it is irritating vary with the type of ostomy. With a transverse colostomy, the stool is soft and unformed and irritating to the skin. With a descending or sigmoid colostomy, the stool is fairly solid and less irritating to the skin. Other skin problems include yeast infections and allergic dermatitis. If the patient wants to bathe or shower before putting on a clean appliance, micropore tape applied to the sides of the pouch keeps it secure during

Table 38-6 POTENTIAL COMPLICATIONS AND NURSING INTERVENTIONS AFTER INTESTINAL SURGERY

Complication	Nursing Interventions
General Complications	
Paralytic ileus	Initiate or continue nasogastric intubation as prescribed. Prepare patient for x-ray study. Ensure adequate fluid and electrolyte replacement.
Mechanical obstruction	Administer prescribed antibiotics if patient has symptoms of peritonitis. Assess patient for intermittent colicky pain, nausea, and vomiting.
Intra-abdominal Septic Conditions	
Peritonitis	Evaluate patient for nausea, hiccups, chills, spiking fever, tachycardia, boardlike abdomen. Administer antibiotics as prescribed. Prepare patient for drainage procedure. Administer parenteral fluid and electrolyte therapy as prescribed. Prepare patient for surgery if condition deteriorates.
Abscess formation	Administer antibiotics as prescribed. Apply warm compresses as prescribed. Prepare for surgical drainage.
Surgical Wound Complications	
Infection	Monitor temperature; report temperature elevation. Observe for redness, tenderness, hardening (induration), and pain around the surgical wound. Assist in establishing local drainage. Obtain specimen of drainage material for culture and sensitivity studies.
Wound disruption	Observe for sudden drainage of profuse serous fluid from wound. Cover wound area with sterile moist dressings supported with binder or similar method. Prepare patient immediately for surgery.
Intraperitoneal infection and abdominal wound infection	Monitor for evidence of constant or generalized abdominal pain, rapid pulse, and elevation of temperature. Prepare for tube decompression of bowel. Administer fluids and electrolytes by IV route as prescribed. Administer antibiotics as prescribed.
Anastomotic Complications	
Dehiscence of anastomosis	Prepare patient for surgery.
Fistulas	Prepare for tube decompression of bowel. Administer parenteral fluids as prescribed to correct fluid and electrolyte deficits.

bathing. Refer to Chart 38-5 for guidelines on changing an ostomy appliance.

Colostomy appliances are not always necessary for some patients who have end sigmoid colostomies and who irrigate them. As soon as the patient has learned a routine for evacuation, pouches may be dispensed with, and a closed ostomy appliance or a stoma cap is used to cover the stoma. Except for gas and a slight amount of mucus, nothing escapes from the colostomy opening between irrigations.

Irrigating the Colostomy

The purpose of irrigating a colostomy is to empty the colon of gas, mucus, and feces so that the patient can go about social and business activities without fear of fecal drainage. A stoma does not have voluntary muscular control and may empty at irregular intervals. Regulating the passage of fecal material is achieved by irrigating the colostomy or allowing the bowel to evacuate naturally without irrigations. This choice depends on the person and the type of the colostomy (ie, descending or sigmoid colostomies). By irrigating the stoma at a regular time, there is less gas and retention of the irrigant. The time for irrigating the colostomy should be consistent with the schedule the person will follow after leaving the hospital. Chart 38-11 describes the irrigating procedure.

Colostomy irrigation is not recommended for persons with extensive pelvic irradiation because it carries a risk of perforation (Colwell, et al., 2004).

Supporting a Positive Body Image

The patient is encouraged to verbalize feelings and concerns about altered body image and to discuss the surgery and the stoma (if one was created). If applicable, the patient must learn colostomy care and begin to plan for incorporating stoma care into daily life. The nurse helps the patient overcome aversion to the stoma or fear of self-injury by providing care and teaching in an open, accepting manner and by encouraging the patient to talk about his or her feelings about the stoma.

Discussing Sexuality Issues

The nurse encourages the patient to discuss feelings about sexuality and sexual function. The nurse can say, “Many people after surgery wonder how this will affect their role as a sexual partner. Do you have concerns about that?” (Junkin & Beitz, 2005). Some patients may initiate questions about sexual activity directly or give indirect clues about their fears. Some may view the surgery as mutilating and a threat to their sexuality; some fear impotence. Others may express worry about odor or leakage from the pouch during sexual activity.

Guidelines for Irrigating a Colostomy

Before the procedure, the patient sits on a chair in front of the toilet or on the toilet itself. An irrigating reservoir containing 500 to 1500 mL of lukewarm tap water is hung 45 to 50 cm (18 to 20 in) above the stoma (shoulder height when the patient is seated). The dressing or pouch is removed. The following procedure is used; the patient is helped to participate in the procedure so he or she can learn to perform it unassisted.

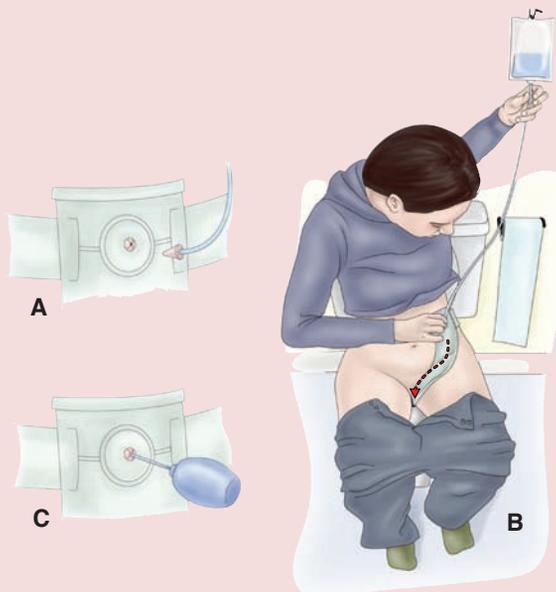

Equipment

- Irrigating sleeve or sheath
- Irrigating catheter or cone and tubing
- Lubricant
- Clamp
- Mild soap
- Cloth or towel
- New colostomy dressing or appliance

Implementation

Nursing Action

1. Apply an irrigating sleeve or sheath to the stoma. Place the end in the commode.
2. Allow some of the solution to flow through the tubing and catheter/cone.
3. Lubricate the irrigating cone and gently insert it into the stoma (Fig. A). Insert the cone into the stoma and hold it gently, but firmly, against the stoma to prevent backflow of water.
4. Allow water to flow slowly while advancing catheter (Fig. B).
5. Allow tepid fluid to enter the colon slowly. If cramping occurs, clamp off the tubing and allow the patient to rest before progressing. Water should flow in over a 5- to 10-minute period.

Rationale

1. This helps control odor and splashing and allows feces and water to flow directly into the commode.
2. Air bubbles in the setup are released so that air is not introduced into the colon, which would cause crampy pain.
3. Lubrication permits ease of insertion of the cone. A cone is used to prevent internal damage if a catheter is used.
4. A slow rate of flow helps to relax the bowel.
5. Painful cramps usually are caused by too rapid a flow or by too much solution; 300 mL of fluid may be all that is needed to stimulate evacuation. Volume may be increased with subsequent irrigations to 500, 1000, or 1500 mL as needed by the patient for effective results.

6. Hold the cone in place 10 seconds after the water has been instilled; then gently remove it.
7. Allow 10 to 15 minutes for most of the return; then dry the bottom of the sleeve/sheath and attach it to the top, or apply the appropriate clamp to the bottom of the sleeve.
8. Leave the sleeve/sheath in place for 30 to 45 minutes while the patient gets up and moves around.
9. Cleanse the area with a mild soap and water; pat the area dry.
10. Replace the colostomy dressing or appliance.

6. This minimizes or eliminates spillage of water.
7. Most of the water, feces, and flatus will be expelled in 10 to 15 minutes.
8. Ambulation stimulates peristalsis and completion of the irrigation return.
9. Cleanliness and dryness will provide the patient with hours of comfort.
10. The patient should use an appliance until the colostomy is sufficiently controlled. Then a dressing may be all that is needed.

Although the appliance presents no deterrent to sexual activity, some patients wear silk or cotton covers and smaller pouches during sex. Alternative sexual positions are recommended, as well as alternative methods of stimulation to satisfy sexual drives. The nurse assesses the patient's needs and attempts to identify specific concerns. If the nurse is uncomfortable with this or if the patient's concerns seem complex, the nurse may seek assistance from a WOC nurse, sex counselor or therapist, or advanced practice nurse (Junkin & Beitz, 2005).

Promoting Home and Community-Based Care

TEACHING PATIENTS SELF-CARE. Patient education and discharge planning require the combined efforts of the physician, nurse, WOC nurse, social worker, and dietitian. Patients are given specific information, individualized to their needs, about ostomy care and signs and symptoms of potential complications. Dietary instructions are essential to help patients identify and eliminate irritating foods that can cause diarrhea or constipation. It is important to teach patients about their prescribed medications (ie, action, purpose, and possible side and toxic effects).

The nurse reviews treatments (eg, irrigations, wound cleansing) and dressing changes and encourages the family to participate. Because the hospital stay is short, the patient may not become proficient in all stoma care techniques before discharge home. However, it is critical that the patient or family member learn how to empty and change the pouch before leaving the hospital. Many patients need referral to a home care agency and the telephone number of the local chapter of the American Cancer Society. The home care nurse provides further care and teaching and assesses the patient's and family's adjustment to the colostomy. The home environment is assessed for adequacy of resources that allow the patient to manage self-care activities. A family member may assume responsibility for purchasing the equipment and supplies needed at home.

Patients need very specific directions about when to call the physician. They need to know which complications require prompt attention (ie, bleeding, abdominal distention and rigidity, diarrhea, fever, wound drainage, and disruption of suture line). If radiation therapy is planned, the possible side effects (ie, anorexia, vomiting, diarrhea, fatigue) are reviewed.

CONTINUING CARE. Ongoing care of the patient with cancer and a colostomy often extends well beyond the initial hospital stay. Home care nurses manage ostomy follow-up care, manage the assessment and care of the debilitated patient, and coordinate adjuvant therapy. The home visits also provide an opportunity to assess the patient's physical and emotional status and the patient's and family's ability to carry out recommended care strategies. Visits from a WOC nurse are available to the patient and family as they learn to care for the ostomy and work through their feelings about it, the diagnosis of cancer, and the future. Some patients are interested in and can benefit from involvement in an ostomy support group (eg, the UOAA).

Evaluation

Expected Patient Outcomes

Expected patient outcomes may include the following:

1. Consumes a healthy diet
 - a. Avoids foods and fluids that cause diarrhea, constipation, and obstruction
 - b. Substitutes nonirritating foods and fluids for those that are restricted
2. Maintains fluid balance
 - a. Experiences no vomiting or diarrhea
 - b. Experiences no signs or symptoms of dehydration
3. Feels less anxious
 - a. Expresses concerns and fears freely
 - b. Uses coping measures to manage stress
4. Acquires information about diagnosis, surgical procedure, preoperative preparation, and self-care after discharge
 - a. Discusses the diagnosis, surgical procedure, and postoperative self-care
 - b. Demonstrates techniques of ostomy care
5. Maintains clean incision, stoma, and perineal wound
6. Expresses feelings and concerns about self
 - a. Gradually increases participation in stoma and peristomal skin care
 - b. Discusses feelings related to changed appearance
7. Discusses sexuality in relation to ostomy and to changes in body image
8. Recovers without complications
 - a. Is afebrile
 - b. Regains normal bowel activity
 - c. Exhibits no signs and symptoms of perforation or bleeding
 - d. Identifies signs and symptoms that should be reported to health care provider

Polyps of the Colon and Rectum

A polyp is a mass of tissue that protrudes into the lumen of the bowel. Polyps can occur anywhere in the intestinal tract and rectum. They can be classified as neoplastic (ie, adenomas and carcinomas) or non-neoplastic (ie, mucosal and hyperplastic). Non-neoplastic polyps, which are benign epithelial growths, are common in the Western world. They occur more commonly in the large intestine than in the small intestine. Although most polyps do not develop into invasive neoplasms, they must be identified and followed closely. Adenomatous polyps are more common in men. The proportion of these polyps arising in the proximal part of the colon increases with age (after 50 years of age). Prevalence rates vary from 25% to 60%, depending on age. Non-neoplastic polyps occur in 80% of the population, and their frequency increases with age. Up to two thirds of people older than 65 years are at risk for colonic adenomas (McPhee, Papadakis & Tierney, 2007).

Clinical manifestations depend on the size of the polyp and the amount of pressure it exerts on intestinal tissue. The most common symptom is rectal bleeding. Lower abdominal pain may also occur. If the polyp is large enough, symptoms of obstruction occur. The diagnosis is based on

history and digital rectal examination, barium enema studies, sigmoidoscopy, or colonoscopy.

After a polyp is identified, it should be removed. Several methods are used: colonoscopy with the use of special equipment (ie, biopsy forceps and snares), laparoscopy, or colonoscopic excision with laparoscopic visualization. The latter technique enables immediate detection of potential problems and allows laparoscopic resection and repair of the major complications of perforation and bleeding that may occur with polypectomy. Microscopic examination of the polyp then identifies the type of polyp and indicates what further surgery is required, if any.

DISEASES OF THE ANORECTUM

Anorectal disorders are common, and the majority of the population will experience one at some time during their lives. Patients with anorectal disorders seek medical care primarily because of pain, rectal bleeding, or change in bowel habits. Other common complaints are protrusion of hemorrhoids, anal discharge, perianal itching, swelling, anal tenderness, stenosis, and ulceration. Constipation results from delaying defecation because of anorectal pain.

There has been a steady increase in the prevalence of sexually transmitted diseases (STDs; also called sexually transmitted infections, or STIs) in recent decades, leading to the identification of new anorectal syndromes. The prevalence of these conditions is increasing. These syndromes include STIs such as syphilis, gonorrhea, herpes, chlamydia, and candidiasis, and they are most commonly seen in male homosexuals who practice anorectal intercourse.

Diseases

Anorectal Abscess

An anorectal abscess is caused by obstruction of an anal gland, resulting in retrograde infection. People with Crohn's disease or immunosuppressive conditions such as

AIDS are particularly susceptible to these infections. Many of these abscesses result in fistulas.

An abscess may occur in a variety of spaces in and around the rectum. It often contains a quantity of foul-smelling pus and is painful. If the abscess is superficial, swelling, redness, and tenderness are observed. A deeper abscess may result in severe lower abdominal pain and fever.

Palliative therapy consists of sitz baths and analgesics. However, prompt surgical treatment to incise and drain the abscess is the treatment of choice. When a deeper infection exists with the possibility of a fistula, the fistulous tract must be excised. If possible, the fistula is excised when the abscess is incised and drained, or a second procedure may be necessary to do so. The wound may be packed with an absorptive dressing (eg, calcium alginate or hydrofiber) and allowed to heal by granulation.

Anal Fistula

An anal fistula is a tiny, tubular, fibrous tract that extends into the anal canal from an opening located beside the anus in the perianal skin (Fig. 38-12A). Fistulas usually result from an infection. They may also develop from trauma, fissures, or Crohn's disease (up to 25% of patients with Crohn's disease develop a perianal fistula). Purulent drainage or stool may leak constantly from the cutaneous opening. Other symptoms may be the passage of flatus or feces from the vagina or bladder, depending on the location of the fistula tract. Untreated fistulas may cause systemic infection with related symptoms (Koutroubakis, 2007).

Medical therapy includes antibiotics or anti-inflammatory type agents (eg, azathioprine, infliximab, cyclosporine). Fistula recurrence is common (Koutroubakis, 2007). Surgery is recommended because few fistulas heal spontaneously. A fistulectomy (ie, excision of the fistulous tract) is the recommended surgical procedure. The lower bowel is evacuated thoroughly with several prescribed enemas. The fistula is dissected out or laid open by an incision from its rectal opening to its outlet. The wound is packed with gauze.

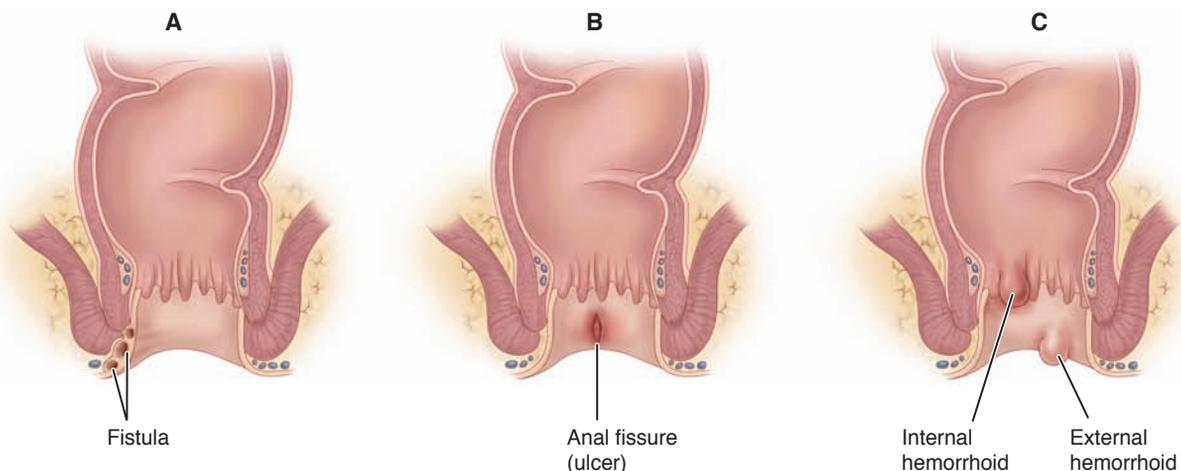

Figure 38-12 Various types of anal lesions. **A**, Fistula. **B**, Fissure. **C**, External and internal hemorrhoids.

Anal Fissure

An anal fissure is a longitudinal tear or ulceration in the lining of the anal canal (see Fig. 38-12B). Fissures are usually caused by the trauma of passing a large, firm stool or from persistent tightening of the anal canal because of stress and anxiety (leading to constipation). Other causes include childbirth, trauma, and overuse of laxatives.

Extremely painful defecation, burning, and bleeding characterize fissures. Bright-red blood may be seen on the toilet tissue after a bowel movement. Most of these fissures heal if treated by conservative measures that include dietary modification with addition of fiber supplements, stool softeners and bulk agents, an increase in water intake, sitz baths, and emollient suppositories. A suppository combining an anesthetic with a corticosteroid helps relieve the discomfort. Anal dilation under anesthesia may be required. A novel therapy, perianal or intra-anal application of nitroglycerin ointment, has increased the rate of healing and lowered pain levels in chronic anal fissures. The ointment is believed to increase blood supply to the wound and relax the anal sphincter (Azarnoff, Lee, Lee, et al., 2007; Brown, Dubreuil, Santora, et al., 2007).

If fissures do not respond to conservative treatment, surgery is indicated. Most surgeons consider the procedure of choice to be the lateral internal sphincterotomy with excision of the fissure (Brown, et al., 2007).

Hemorrhoids

Hemorrhoids are dilated portions of veins in the anal canal. They are very common; by 50 years of age, about 50% of people have hemorrhoids (NIH, 2007). Shearing of the mucosa during defecation results in the sliding of the structures in the wall of the anal canal, including the hemorrhoidal and vascular tissues. Increased pressure in the hemorrhoidal tissue due to pregnancy may initiate hemorrhoids or aggravate existing ones. Hemorrhoids are classified as one of two types: those above the internal sphincter are called internal hemorrhoids, and those appearing outside the external sphincter are called external hemorrhoids (see Fig. 38-12C).

Hemorrhoids cause itching and pain and are the most common cause of bright-red bleeding with defecation. External hemorrhoids are associated with severe pain from the inflammation and edema caused by thrombosis (ie, clotting of blood within the hemorrhoid). This may lead to ischemia of the area and eventual necrosis. Internal hemorrhoids are not usually painful until they bleed or prolapse when they become enlarged.

Hemorrhoid symptoms and discomfort can be relieved by good personal hygiene and by avoiding excessive straining during defecation. A high-residue diet that contains fruit and bran along with an increased fluid intake may be all the treatment that is necessary to promote the passage of soft, bulky stools to prevent straining. If this treatment is not successful, the addition of hydrophilic bulk-forming agents such as psyllium may help. Warm compresses, sitz baths, analgesic ointments and suppositories, astringents (eg, witch hazel), and bed rest reduce engorgement.

There are several types of nonsurgical treatments for hemorrhoids. Infrared photocoagulation, bipolar diathermy, and laser therapy are used to affix the mucosa to the underlying muscle. Injection of sclerosing agents is also effective for small, bleeding hemorrhoids. These procedures help prevent prolapse.

A conservative surgical treatment of internal hemorrhoids is the rubber-band ligation procedure. The hemorrhoid is visualized through the anoscope, and its proximal portion above the mucocutaneous lines is grasped with an instrument. A small rubber band is then slipped over the hemorrhoid. Tissue distal to the rubber band becomes necrotic after several days and sloughs off. Fibrosis occurs; the result is that the lower anal mucosa is drawn up and adheres to the underlying muscle. Although this treatment has been satisfactory for some patients, it has proven painful for others and may cause secondary hemorrhage. It has also been known to cause perianal infection.

Cryosurgical hemorrhoidectomy, another method for removing hemorrhoids, involves freezing the hemorrhoid for a sufficient time to cause necrosis. Although it is relatively painless, this procedure is not widely used because the discharge is foul-smelling and wound healing is prolonged. The Nd:YAG laser is useful in excising hemorrhoids, particularly external hemorrhoidal tags. The treatment is quick and relatively painless. Hemorrhage and abscess are rare postoperative complications.

The previously described methods of treating hemorrhoids are not effective for advanced thrombosed veins, which must be treated by more extensive surgery. Stapled hemorrhoidopexy, a newer procedure, uses surgical staples to treat prolapsing hemorrhoids and is associated with less postoperative pain and fewer complications (Goldstein, Meslin, Mazza, et al., 2007). If it is not successful, hemorrhoidectomy, or surgical excision, may be performed to remove all the redundant tissue involved in the process. During surgery, the rectal sphincter is usually dilated digitally, and the hemorrhoids are removed with a clamp and cautery or are ligated and then excised. After the surgical procedures are completed, a small tube may be inserted through the sphincter to permit the escape of flatus and blood; pieces of Gelfoam or Oxycel gauze may be placed over the anal wounds.

Sexually Transmitted Anorectal Diseases

Three infectious syndromes that are related to STDs have been identified: proctitis, proctocolitis, and enteritis. Proctitis involves the rectum. It is commonly associated with recent anal-receptive intercourse with an infected partner. Symptoms include mucopurulent discharge or bleeding, rectal pain, and diarrhea. The pathogens most frequently involved are *Neisseria gonorrhoeae*, *Chlamydia*, herpes simplex virus, and *Treponema pallidum*.

Proctocolitis involves the rectum and lowest portion of the descending colon. Symptoms are similar to proctitis but may also include watery or bloody diarrhea, cramps, pain, and bloating. Enteritis involves more of the descending

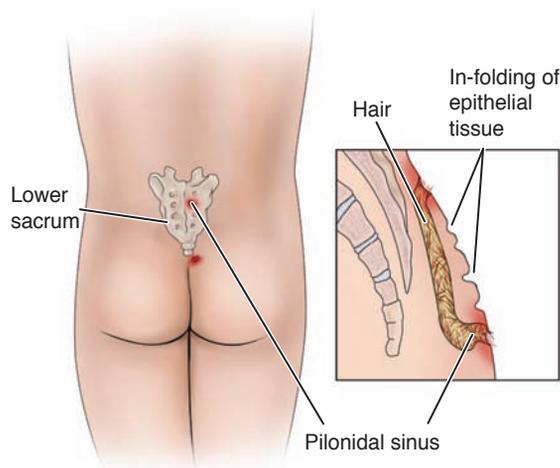

Figure 38-13 (Left) Pilonidal sinus on lower sacrum about 5 cm (2 in) above the anus in the intergluteal cleft. (Right) Hair particles emerge from the sinus tract, and localized indentations (pits) can appear on the skin near the sinus openings.

colon, and symptoms include watery, bloody diarrhea; abdominal pain; and weight loss. The most common pathogens causing enteritis are *E. histolytica*, *Giardia lamblia*, *Shigella*, and *Campylobacter*.

Sigmoidoscopy is performed to identify portions of the anorectum involved. Samples are taken with rectal swabs, and cultures are obtained to identify the pathogens involved. Antibiotics (ie, ceftriaxone [Rocephin] or cefixime [Suprax], doxycycline [Vibramycin], and penicillin G) are the treatment of choice for bacterial infections (CDC, 2007). Acyclovir [Zovirax] is given to patients with viral infections. Antiamebic therapy (ie, metronidazole [Flagyl]) is appropriate for infections with *E. histolytica* and *G. lamblia*. Ciprofloxacin (Cipro) is effective for *Shigella*. The antibiotics erythromycin (E-Mycin) and ciprofloxacin are the treatment of choice for *Campylobacter* infection (CDC, 2007).

Pilonidal Sinus or Cyst

A pilonidal sinus or cyst is found in the intergluteal cleft on the posterior surface of the lower sacrum (Fig. 38-13). Current theories suggest that it results from local trauma, causing penetration of hairs into the epithelium and subcutaneous tissue. It may also be formed congenitally by an infolding of epithelial tissue beneath the skin, which may communicate with the skin surface through one or several small sinus openings. Hair frequently is seen protruding from these openings, and this gives the cyst its name, *pilonidal* (ie, a nest of hair). The cysts rarely cause symptoms until adolescence or early adult life, when infection produces an irritating drainage or an abscess. Perspiration and friction easily irritate this area.

In the early stages of the inflammation, the infection may be controlled by antibiotic therapy, but after an abscess has formed, surgery is indicated. The abscess is incised and drained under local anesthesia. After the acute process resolves, further surgery is performed to excise the cyst and the secondary sinus tracts. The wound is allowed to heal by

granulation. Absorptive dressings are placed in the wound to keep its edges separated while healing occurs.

Nursing Management of Patients With Anorectal Conditions

Promoting Home and Community-Based Care

Teaching Patients Self-Care

Most patients with anorectal conditions are not hospitalized. Those who undergo surgical procedures to correct the condition often are discharged directly from the outpatient surgical center. If they are hospitalized, it is for a short time, usually only 24 hours. Patient teaching is essential to facilitate recovery at home.

The nurse instructs the patient to keep the perianal area as clean as possible by gently cleansing with warm water and then drying with absorbent cotton wipes. The patient should avoid rubbing the area with toilet tissue. Instructions are provided about how to take a sitz bath and how to test the temperature of the water.

During the first 24 hours after rectal surgery, painful spasms of the sphincter and perineal muscles may occur. The nurse instructs the patient that ice and analgesic ointments may decrease the pain. Warm compresses may promote circulation and soothe irritated tissues. Sitz baths taken three or four times each day can relieve soreness and pain by relaxing sphincter spasm. Twenty-four hours after surgery, topical anesthetic agents may be beneficial in relieving local irritation and soreness. Medications may include topical anesthetics (ie, suppositories), astringents, antiseptics, tranquilizers, and antiemetics. Patients are more compliant and less apprehensive if they are free of pain.

Wet dressings saturated with equal parts of cold water and witch hazel help relieve edema. When wet compresses are being used continuously, petrolatum is applied around the anal area to prevent skin maceration. The patient is instructed to assume a prone position at intervals because this position reduces edema of the tissue.

Continuing Care

Sitz baths may be given in the bathtub or plastic sitz bath unit three or four times each day. Sitz baths should follow each bowel movement for 1 to 2 weeks after surgery. The nurse encourages intake of at least 2 L of water daily to provide adequate hydration and recommends high-fiber foods to promote bulk in the stool and to make it easier to pass fecal matter through the rectum. Bulk laxatives such as psyllium may be recommended and stool softeners (eg, docusate) may be prescribed. The patient is advised to set aside a time for bowel movements and to heed the urge to defecate as promptly as possible. The nurse encourages the patient to respond quickly to the urge to defecate to prevent constipation. The diet is modified to increase fluids and fiber. Moderate exercise is encouraged, and the patient is taught about the prescribed diet, the significance of proper eating habits and exercise, and the laxatives that can be taken safely.

CRITICAL THINKING EXERCISES

1 A 92-year-old woman in a long-term care facility is a patient assigned to your care. With visible discomfort, she tells you that she has noticed blood in the toilet bowl with her last several bowel movements and she has had blood on her underwear. What other questions should you ask this woman to clarify potential causes of this problem? Explain how the patient's age might affect your focused assessment.

EBP 2 A fellow nursing student enrolled in your pharmacology class shares with you that she has been feeling poorly for the past 2 weeks. She has been tired, has lost 10 pounds recently, and has had recurrent abdominal pain. She appears pale to you. She is very worried about her success on the final examination that is scheduled for next week. This student casually mentions that she hopes that she does not develop ulcerative colitis like her sister. What further questions might you ask? What is the strength of the evidence that suggests she may be at risk for ulcerative colitis? What advice would you give to your classmate? What further workup do you think should be recommended?

3 A 40-year-old female teacher is admitted to the outpatient surgery clinic with complaints of anorectal swelling. You note in this patient's health history that her swelling has worsened over the past 2 weeks, and today there is purulent drainage from the anus. A surgeon examines the patient and schedules immediate surgery in the adjacent operating room suite. The patient asks you, "Why can't I just get an antibiotic?" Given the likely pathophysiology involved in her condition, explain to this patient why surgical intervention is indicated. Identify essential actions you must take before she is taken to the operating room. After your interventions, this patient decides to undergo surgery. Later that afternoon, she is prepared for discharge. Design a discharge plan for her for the next 2 weeks, and include the principles of care that you should teach her so that she may understand the reasons for her home care routine.

The Smeltzer suite offers these additional resources to enhance learning and facilitate understanding of this chapter:

Case Study • Applying Concepts From NANDA, NIC, and NOC

A Patient With Complications of Diabetes

Mr. Johansen is a 58-year-old man with type 2 diabetes, peripheral vascular disease, hyperlipidemia, and peripheral neuropathy. He is also 50 lb over his ideal body weight. He takes an oral antidiabetic agent twice daily and lovastatin for elevated cholesterol levels. Mr. Johansen comes to the clinic for treatment of an unrelated respiratory infection. While there, he tells the nurse that he has numbness and tingling of his feet and has burning pain in his legs if he stands for long periods of time. The nurse assesses his feet and notes decreased sensory function in both feet. Mr. Johansen states that he has not seen his doctor for more than 1 year and only comes to the clinic if he feels sick.

Visit thePoint to view a concept map that illustrates the relationships that exist between the nursing diagnoses, interventions, and outcomes for the patient's clinical problems.

Nursing Classifications and Languages

NANDA NURSING DIAGNOSES	NIC NURSING INTERVENTIONS	NOC NURSING OUTCOMES
		Return to functional baseline status, stabilization of, or improvement in:
INEFFECTIVE TISSUE PERFUSION (ALL TYPES) —Decrease in oxygen resulting in the failure to nourish tissues at the capillary level	CIRCULATORY CARE: ARTERIAL INSUFFICIENCY —Promotion of arterial circulation	CIRCULATION STATUS —Extent to which blood flows unobstructed, unidirectionally, and at an appropriate pressure through large vessels of the systemic and pulmonary circuits
DISTURBED TACTILE SENSORY PERCEPTION —Change in the amount or patterning of incoming stimuli accompanied by a diminished, exaggerated, distorted, or impaired response to such stimuli	CIRCULATORY PRECAUTIONS —Protection of localized area with limited perfusion	SENSORY FUNCTION: CUTANEOUS —Extent to which stimulation of the skin is correctly sensed
INEFFECTIVE THERAPEUTIC REGIMEN MANAGEMENT —Pattern of regulating and integrating into daily living a program for treatment of illness and the sequelae of illness that is unsatisfactory for meeting specific health goals	TEACHING: FOOT CARE —Preparing an at-risk patient and/or a significant other to provide preventive foot care	TISSUE INTEGRITY: SKIN AND MUCOUS MEMBRANES —Structural intactness and normal physiologic function of skin and mucous membranes
	SKIN SURVEILLANCE —Collection and analysis of patient data to maintain skin and mucous membrane integrity	KNOWLEDGE: DIABETES MANAGEMENT —Extent of understanding conveyed about diabetes mellitus and its control
	TEACHING: INDIVIDUAL —Planning, implementation, and evaluation of a teaching program designed to address a patient's particular needs

Assessment and Management of Patients With Hepatic Disorders

LEARNING OBJECTIVES

On completion of this chapter, the learner will be able to:

- 1 Identify the metabolic functions of the liver and the alterations in these functions that occur with liver disease.
- 2 Explain liver function tests and the clinical manifestations of liver dysfunction in relation to pathophysiologic alterations of the liver.
- 3 Relate jaundice, portal hypertension, ascites, varices, nutritional deficiencies, and hepatic coma to pathophysiologic alterations of the liver.
- 4 Describe the medical, surgical, and nursing management of patients with esophageal varices.
- 5 Compare the various types of hepatitis and their causes, prevention, clinical manifestations, management, prognosis, and home health care needs.
- 6 Use the nursing process as a framework for care of the patient with cirrhosis of the liver.
- 7 Compare the nonsurgical and surgical management of patients with cancer of the liver.
- 8 Describe the postoperative nursing care of the patient undergoing liver transplantation.

GLOSSARY

asterixis: involuntary flapping movements of the hands associated with metabolic liver dysfunction

balloon tamponade: use of balloons placed within the esophagus and proximal portion of the stomach and inflated to compress bleeding vessels (esophageal and gastric varices)

Budd-Chiari syndrome: hepatic vein thrombosis resulting in non-cirrhotic portal hypertension

cirrhosis: a chronic liver disease characterized by fibrotic changes and the formation of dense connective tissue within the liver, subsequent degenerative changes, and loss of functioning cells

constructional apraxia: inability to draw figures in two or three dimensions

fetor hepaticus: sweet, slightly fecal odor to the breath, presumed to be of intestinal origin; prevalent with the extensive collateral portal circulation in chronic liver disease

fulminant hepatic failure: sudden, severe onset of acute liver failure that occurs within 8 weeks after the first symptoms of jaundice

hepatic encephalopathy: central nervous system dysfunction resulting from liver disease; frequently associated with elevated ammonia levels that produce changes in mental status, altered level of consciousness, and coma

orthotopic liver transplantation (OLT): grafting of a donor liver into the normal anatomic location, with removal of the diseased native liver

portal hypertension: elevated pressure in the portal circulation resulting from obstruction of venous flow into and through the liver

sclerotherapy: the injection of substances into or around esophagogastric varices to cause constriction, thickening, and hardening of the vessel and thus to stop bleeding

variceal banding: procedure that involves the endoscopic placement of a rubber band-like device over esophageal varices to ligate the area and stop bleeding

xenograft: transplantation of organs from one species to another

Liver function is complex, and liver dysfunction affects all body systems. For this reason, the nurse must understand how the liver functions and must have expert clinical assessment and management skills to care for patients undergoing complex diagnostic and treatment procedures. The nurse also must understand technologic advances in the management of liver disorders. Liver disorders are common and may result from a virus, exposure to toxic substances such as alcohol, or tumors.

ASSESSMENT OF THE LIVER

Anatomic and Physiologic Overview

The liver, the largest gland of the body, can be considered a chemical factory that manufactures, stores, alters, and excretes a large number of substances involved in metabolism. The location of the liver is essential in this function because it receives nutrient-rich blood directly from the gastrointestinal (GI) tract and then either stores or transforms these nutrients into chemicals that are used elsewhere in the body for metabolic needs. The liver is especially important in the regulation of glucose and protein metabolism. The liver manufactures and secretes bile, which has a major role in the digestion and absorption of fats in the GI tract. The liver removes waste products from the bloodstream and secretes them into the bile. The bile produced by the liver is stored temporarily in the gallbladder until it is needed for digestion, at which time the gallbladder empties and bile enters the intestine (Fig. 39-1).

Anatomy of the Liver

The liver is a large, highly vascular organ located behind the ribs in the upper right portion of the abdominal cavity. It weighs between 1200 and 1500 g and is divided into four lobes. A thin layer of connective tissue surrounds each lobe, extending into the lobe itself and dividing the liver mass into small, functional units called lobules (Rodes, Benhamou, Blei, et al., 2007).

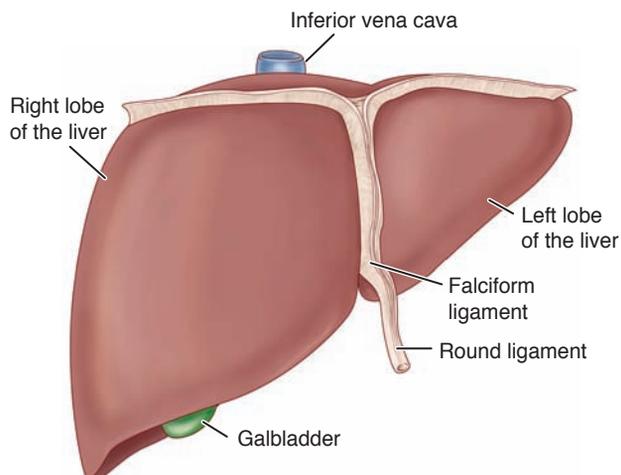

Figure 39-1 The liver and biliary system.

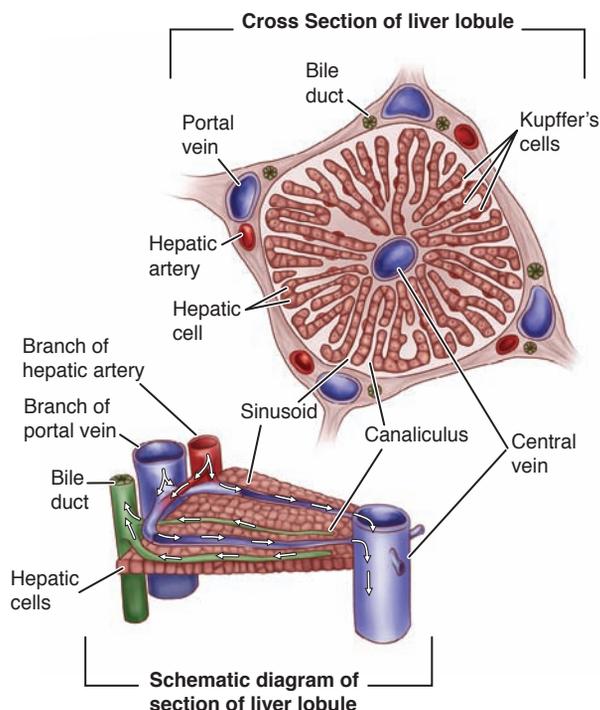

Figure 39-2 A section of liver lobule showing the location of hepatic veins, hepatic cells, liver sinusoids, and branches of the portal vein and hepatic artery.

The circulation of the blood into and out of the liver is of major importance to liver function. The blood that perfuses the liver comes from two sources. Approximately 80% of the blood supply comes from the portal vein, which drains the GI tract and is rich in nutrients but lacks oxygen. The remainder of the blood supply enters by way of the hepatic artery and is rich in oxygen. Terminal branches of these two blood vessels join to form common capillary beds, which constitute the sinusoids of the liver (Fig. 39-2). Thus, a mixture of venous and arterial blood bathes the liver cells (hepatocytes). The sinusoids empty into venules that occupy the center of each liver lobule and are called the central veins. The central veins join to form the hepatic vein, which constitutes the venous drainage from the liver and empties into the inferior vena cava, close to the diaphragm (Rodes, et al., 2007).

In addition to hepatocytes, phagocytic cells belonging to the reticuloendothelial system are present in the liver. Other organs that contain reticuloendothelial cells are the spleen, bone marrow, lymph nodes, and lungs. In the liver, these cells are called Kupffer cells. As the most common phagocyte in the human body, their main function is to engulf particulate matter (eg, bacteria) that enters the liver through the portal blood.

The smallest bile ducts, called canaliculi, are located between the lobules of the liver. The canaliculi receive secretions from the hepatocytes and carry them to larger bile ducts, which eventually form the hepatic duct. The hepatic duct from the liver and the cystic duct from the gallbladder join to form the common bile duct, which empties into the small intestine. The sphincter of Oddi, located at the

junction where the common bile duct enters the duodenum, controls the flow of bile into the intestine.

Functions of the Liver

Glucose Metabolism

The liver plays a major role in the metabolism of glucose and the regulation of blood glucose concentration. After a meal, glucose is taken up from the portal venous blood by the liver and converted into glycogen, which is stored in the hepatocytes. Subsequently, the glycogen is converted back to glucose (glycogenolysis) and released as needed into the bloodstream to maintain normal levels of blood glucose. However, this process provides a limited amount of glucose. Additional glucose can be synthesized by the liver through a process called gluconeogenesis. For this process, the liver uses amino acids from protein breakdown or lactate produced by exercising muscles. This process occurs in response to hypoglycemia (Shils, Shike, Ross, et al., 2006).

Ammonia Conversion

Use of amino acids from protein for gluconeogenesis results in the formation of ammonia as a byproduct. The liver converts this metabolically generated ammonia into urea. Ammonia produced by bacteria in the intestines is also removed from portal blood for urea synthesis. In this way, the liver converts ammonia, a potential toxin, into urea, a compound that is excreted in the urine (Porth & Matfin, 2009).

Protein Metabolism

The liver also plays an important role in protein metabolism. It synthesizes almost all of the plasma proteins (except gamma-globulin), including albumin, alpha-globulins and beta-globulins, blood clotting factors, specific transport proteins, and most of the plasma lipoproteins. Vitamin K is required by the liver for synthesis of prothrombin and some of the other clotting factors. Amino acids are used by the liver for protein synthesis (Porth & Matfin, 2009).

Fat Metabolism

The liver is also active in fat metabolism. Fatty acids can be broken down for the production of energy and ketone bodies (acetoacetic acid, beta-hydroxybutyric acid, and acetone). Ketone bodies are small compounds that can enter the bloodstream and provide a source of energy for muscles and other tissues. Breakdown of fatty acids into ketone bodies occurs primarily when the availability of glucose for metabolism is limited, as in starvation or in uncontrolled diabetes. Fatty acids and their metabolic products are also used for the synthesis of cholesterol, lecithin, lipoproteins, and other complex lipids (Porth & Matfin, 2009).

In some conditions, lipids may accumulate in the hepatocytes, resulting in the abnormal condition called fatty liver.

Vitamin and Iron Storage

Vitamins A, B, and D and several of the B-complex vitamins are stored in large amounts in the liver. Certain substances, such as iron and copper, are also stored in the liver. Because the liver is rich in these substances, liver extracts have been used for therapy for more than a century for a wide range of nutritional disorders; however, the U.S. Food

and Drug Administration (FDA) has urged caution regarding the use of any animal organ extract because of possible risk of exposure to pathogenic organisms.

Bile Formation

Bile is continuously formed by the hepatocytes and collected in the canaliculi and bile ducts. It is composed mainly of water and electrolytes such as sodium, potassium, calcium, chloride, and bicarbonate, and it also contains significant amounts of lecithin, fatty acids, cholesterol, bilirubin, and bile salts. Bile is collected and stored in the gallbladder and is emptied into the intestine when needed for digestion. The functions of bile are excretory, as in the excretion of bilirubin; bile also serves as an aid to digestion through the emulsification of fats by bile salts.

Bile salts are synthesized by the hepatocytes from cholesterol. After conjugation or binding with amino acids (taurine and glycine), bile salts are excreted into the bile. The bile salts, together with cholesterol and lecithin, are required for emulsification of fats in the intestine, which is necessary for efficient digestion and absorption. Bile salts are then reabsorbed, primarily in the distal ileum, into portal blood for return to the liver and are again excreted into the bile. This pathway from hepatocytes to bile to intestine and back to the hepatocytes is called the enterohepatic circulation. Because of the enterohepatic circulation, only a small fraction of the bile salts that enter the intestine are excreted in the feces. This decreases the need for active synthesis of bile salts by the liver cells (Porth & Matfin, 2009).

Bilirubin Excretion

Bilirubin is a pigment derived from the breakdown of hemoglobin by cells of the reticuloendothelial system, including the Kupffer cells of the liver. Hepatocytes remove bilirubin from the blood and chemically modify it through conjugation to glucuronic acid, which makes the bilirubin more soluble in aqueous solutions. The conjugated bilirubin is secreted by the hepatocytes into the adjacent bile canaliculi and is eventually carried in the bile into the duodenum.

In the small intestine, bilirubin is converted into urobilinogen, which is partially excreted in the feces and partially absorbed through the intestinal mucosa into the portal blood. Much of this reabsorbed urobilinogen is removed by the hepatocytes and secreted into the bile once again (enterohepatic circulation). Some of the urobilinogen enters the systemic circulation and is excreted by the kidneys in the urine. Elimination of bilirubin in the bile represents the major route of its excretion.

The bilirubin concentration in the blood may be increased in the presence of liver disease, if the flow of bile is impeded (eg, by gallstones in the bile ducts), or if there is excessive destruction of red blood cells. With bile duct obstruction, bilirubin does not enter the intestine; as a consequence, urobilinogen is absent from the urine and decreased in the stool (Porth & Matfin, 2009).

Drug Metabolism

The liver metabolizes many medications, such as barbiturates, opioids, sedatives, anesthetics, and amphetamines. Metabolism generally results in drug inactivation, although activation may also occur. One of the important pathways

for medication metabolism involves conjugation (binding) of the medication with a variety of compounds, such as glucuronic acid or acetic acid, to form more soluble substances. These substances may be excreted in the feces or urine, similar to bilirubin excretion. Bioavailability is the fraction of the administered medication that actually reaches the systemic circulation. The bioavailability of an oral medication (absorbed from the GI tract) can be decreased if the medication is metabolized to a great extent by the liver before it reaches the systemic circulation; this is known as first-pass effect. Some medications have such a large first-pass effect that their use is essentially limited to the parenteral route, or oral doses must be substantially larger than parenteral doses to achieve the same effect.

Gerontologic Considerations

Chart 39-1 summarizes age-related changes in the liver. In the elderly, the most common change in the liver is a decrease in size and weight, accompanied by a decrease in total hepatic blood flow. However, in general, these decreases are proportional to the decreases in body size and weight seen in normal aging. Results of liver function tests do not normally change in the elderly; abnormal results in elderly patients indicate abnormal liver function and are not a result of the aging process itself.

Metabolism of medications by the liver decreases in the elderly, but such changes are usually accompanied by changes in intestinal absorption, renal excretion, and altered body distribution of some medications secondary to changes in fat deposition. These alterations necessitate careful medication administration and monitoring; if appropriate, reduced dosages may be needed to prevent medication toxicity.

Assessment

Health History

If liver function test results are abnormal, the patient is evaluated for liver disease. In such cases, the health history focuses on previous exposure of the patient to hepatotoxic

substances or infectious agents. The patient's occupational, recreational, and travel history may assist in identifying exposure to hepatotoxins (eg, industrial chemicals, other toxins). The patient's history of alcohol and drug use, including but not limited to the use of intravenous (IV) or injection drugs, provides additional information about exposure to toxins and infectious agents. Many medications (including acetaminophen [Tylenol], ketoconazole [Nizoral], and valproic acid [Depakene]) are responsible for hepatic dysfunction and disease. A thorough medication history should address all current and past prescription medications, over-the-counter medications, herbal remedies, and dietary supplements.

Lifestyle behaviors that increase the risk for exposure to infectious agents are identified. IV or injection drug use, sexual practices, and foreign travel are all potential risk factors for liver disease. The amount and type of alcohol consumption are identified using screening tools (questionnaires) that have been developed for this purpose (see Chapter 5). Men who consume 60 to 80 g/day of alcohol (approximately four glasses of beer, wine, or mixed drinks) and women whose alcohol intake is 40 to 60 g/day are considered at high risk for cirrhosis.

The history also includes an evaluation of the patient's past medical history to identify risk factors for the development of liver disease. Current and past medical conditions, including those of a psychological or psychiatric nature, are identified. The family history includes questions about familial liver disorders that may have their origin in alcohol abuse or gallstone disease, as well as other familial or genetic diseases, such as hemochromatosis, Wilson's disease, or alpha₁-antitrypsin disease (see Chart 42-1).

The history also addresses symptoms that suggest liver disease. Symptoms that may have their origin in liver disease but are not specific to hepatic dysfunction include jaundice, malaise, weakness, fatigue, pruritus, abdominal pain, fever, anorexia, weight gain, edema, increasing abdominal girth, hematemesis, melena, hematochezia (passage of bloody stools), easy bruising, changes in mental acuity, personality changes, sleep disturbances, and decreased libido in men and secondary amenorrhea in women.

Physical Assessment

The nurse assesses the patient for physical signs that may occur with liver dysfunction, including the pallor often seen with chronic illness and jaundice. The skin, mucosa, and sclerae are inspected for jaundice, and the extremities are assessed for muscle atrophy, edema, and skin excoriation secondary to scratching. The nurse observes the skin for petechiae or ecchymotic areas (bruises), spider angiomas, and palmar erythema. The male patient is assessed for unilateral or bilateral gynecomastia and testicular atrophy due to hormonal changes. The patient's cognitive status (recall, memory, abstract thinking) and neurologic status are assessed. The nurse observes for general tremor, asterixis, weakness, and slurred speech. These symptoms are discussed later.

The nurse assesses for the presence of an abdominal fluid wave (discussed later). The abdomen is palpated to assess liver size and to detect any tenderness over the liver. The liver may be palpable in the right upper quadrant. A palpable liver presents as a firm, sharp ridge with a smooth surface

CHART
39-1

Age-Related Changes of the Hepatobiliary System

- Steady decrease in size and weight of the liver, particularly in women
- Decrease in blood flow
- Decrease in replacement/repair of liver cells after injury
- Reduced drug metabolism
- Slow clearance of hepatitis B surface antigen
- More rapid progression of hepatitis C infection and lower response rate to therapy
- Decline in drug clearance capability
- Increased prevalence of gallstones due to the increase in cholesterol secretion in bile
- Decreased gallbladder contraction after a meal
- Atypical clinical presentation of biliary disease
- More severe complications of biliary tract disease

Figure 39-3 Technique for palpating the liver. The examiner places one hand under the right lower rib cage and presses downward with light pressure with the other hand.

(Fig. 39-3). The nurse estimates the size of the liver by percussing its upper and lower borders. If the liver is not palpable but tenderness is suspected, tapping the lower right thorax briskly may elicit tenderness. For comparison, the nurse then performs a similar maneuver on the left lower thorax (Bickley, 2007).

If the liver is palpable, the examiner notes and records its size, its consistency, any tenderness, and whether its outline is regular or irregular. If the liver is enlarged, the degree to which it descends below the right costal margin is recorded to provide some indication of its size. The examiner determines whether the liver's edge is sharp and smooth or blunt and whether the enlarged liver is nodular or smooth. The liver of a patient with cirrhosis is small and hard; whereas the liver of a patient with acute hepatitis is soft, and the hand easily moves the edge.

Tenderness of the liver indicates recent acute enlargement with consequent stretching of the liver capsule. The absence of tenderness may imply that the enlargement is of long-standing duration. The liver of a patient with viral hepatitis is tender; whereas that of a patient with alcoholic hepatitis is not. Enlargement of the liver is an abnormal finding that requires evaluation (Bickley, 2007).

Diagnostic Evaluation

Liver Function Tests

More than 70% of the parenchyma of the liver may be damaged before liver function test results become abnormal. Function is generally measured in terms of serum enzyme activity (ie, serum aminotransferases, alkaline phosphatase, lactic dehydrogenase) and serum concentrations of proteins (albumin and globulins), bilirubin, ammonia, clotting factors, and lipids. Several of these tests may be helpful for as-

sessing patients with liver disease. However, the nature and extent of hepatic dysfunction cannot be determined by these tests alone, because other disorders can affect test results.

Serum aminotransferases (previously called transaminases) are sensitive indicators of injury to the liver cells and are useful in detecting acute liver disease such as hepatitis. Alanine aminotransferase (ALT), aspartate aminotransferase (AST), and gamma-glutamyl transferase (GGT) (also called G-glutamyl transpeptidase) are the most frequently used tests of liver damage. ALT levels increase primarily in liver disorders and may be used to monitor the course of hepatitis or cirrhosis or the effects of treatments that may be toxic to the liver. AST is present in tissues that have high metabolic activity; therefore, the level may be increased if there is damage to or death of tissues of organs such as the heart, liver, skeletal muscle, and kidney. Although not specific to liver disease, levels of AST may be increased in cirrhosis, hepatitis, and liver cancer. Increased GGT levels are associated with cholestasis but can also be due to alcoholic liver disease. Although the kidney has the highest level of the enzyme, the liver is considered the source of normal serum activity. The test determines liver cell dysfunction and is a sensitive indicator of cholestasis. Its main value in liver disease is confirming the hepatic origin of an elevated alkaline phosphatase level. Common liver function tests are summarized in Table 39-1.

Liver Biopsy

Liver biopsy is the removal of a small amount of liver tissue, usually through needle aspiration. It permits examination of liver cells. The most common indication is to evaluate diffuse disorders of the parenchyma and to diagnose space-occupying lesions. Liver biopsy is especially useful when clinical findings and laboratory tests are not diagnostic. Bleeding and bile peritonitis after liver biopsy are the major complications; therefore, coagulation studies are obtained, their values are noted, and abnormal results are treated before liver biopsy is performed. Other techniques for liver biopsy are preferred if ascites or coagulation abnormalities exist. A liver biopsy can be performed percutaneously with ultrasound guidance or transvenously through the right internal jugular vein to right hepatic vein under fluoroscopic control. Liver biopsy can also be performed laparoscopically. Nursing responsibilities related to percutaneous liver biopsy are summarized in Chart 39-2.

Other Diagnostic Tests

Ultrasonography, computed tomography (CT), and magnetic resonance imaging (MRI) are used to identify normal structures and abnormalities of the liver and biliary tree. A radioisotope liver scan may be performed to assess liver size and hepatic blood flow and obstruction.

Laparoscopy (insertion of a fiberoptic endoscope through a small abdominal incision) is used to examine the liver and other pelvic structures. It is also used to perform guided liver biopsy, to determine the cause of ascites, and to diagnose and stage tumors of the liver and other abdominal organs.

Table 39-1 COMMON LABORATORY TESTS TO ASSESS LIVER FUNCTION

Test	Normal	Clinical Functions
Pigment Studies		
Serum bilirubin, direct	0–0.3 mg/dL (0–5.1 μmol/L)	These studies measure the ability of the liver to conjugate and excrete bilirubin. Results are abnormal in liver and biliary tract disease and are associated with jaundice clinically.
Serum bilirubin, total	0–0.9 mg/dL (1.7–20.5 μmol/L)	
Urine bilirubin	0(0)	
Urine urobilinogen	(Urine urobilinogen) 0.05–2.5 mg/24 h (0.5–4.0 Ehrlich U/24 h)	
Fecal urobilinogen (infrequently used)	(Fecal urobilinogen) 50–300 mg/24 h (100–400 Ehrlich U/100 g)	
Protein Studies		
Total serum protein	7.0–7.5 g/dL (70–75 g/L)	Proteins are manufactured by the liver. Their levels may be affected in a variety of liver impairments: albumin is affected in cirrhosis, chronic hepatitis, edema and ascites, globulins are affected in cirrhosis, liver disease, chronic obstructive jaundice, and viral hepatitis.
Serum albumin	4.0–5.5 g/dL (40–55 g/L)	
Serum globulin	1.7–3.3 g/dL (17–33 g/L)	
Serum protein electrophoresis		
Albumin	4.0–5.5 g/dL (40–55 g/L)	
α ₁ -Globulin	0.15–0.25 g/dL (1.5–2.5 g/L)	
α ₂ -Globulin	0.43–0.75 g/dL (4.3–7.5 g/L)	
β-Globulin	0.5–1.0 g/dL (5–10 g/L)	
γ-Globulin	0.6–1.3 g/dL (6–13 g/L)	
Albumin/globulin (A/G) ratio	A > G or 1.5:1–2.5:1	
Prothrombin Time	100% or 12–16 seconds	Prothrombin time may be prolonged in liver disease. It will not return to normal with vitamin K in severe liver cell damage.
Serum Alkaline Phosphatase	Varies with method: 2–5 Bodansky units 30–50 U/L at 34°C (17–142 U/L at 30°C) (20–90 U/L at 30°C)	Serum alkaline phosphatase is manufactured in bones, liver, kidneys, and intestine and excreted through biliary tract. In the absence of bone disease, it is a sensitive measure of biliary tract obstruction.
Serum Aminotransferase Studies		
AST	10–40 units (4.8–19 U/L)	The studies are based on release of enzymes from damaged liver cells. These enzymes are elevated in liver cell damage.
ALT	5–35 units (2.4–17 U/L)	
GGT, GGTP	10–48 IU/L	Elevated in alcohol abuse. Marker for biliary cholestasis.
LDH	100–200 units (100–225 U/L)	
Ammonia (plasma)	15–45 μg/dL (11–32 μmol/L)	Liver converts ammonia to urea. Ammonia level rises in liver failure.
Cholesterol		
Ester	60% of total (fraction of total cholesterol: 0.60)	Cholesterol levels are elevated in biliary obstruction and decreased in parenchymal liver disease.
HDL (high-density lipoprotein)	HDL Male: 35–70 mg/dL, Female: 35–85 mg/dL	
LDL (low-density lipoprotein)	LDL <130 μg/dL	

MANIFESTATIONS OF HEPATIC DYSFUNCTION

Hepatic dysfunction results from damage to the liver's parenchymal cells, directly from primary liver diseases, or indirectly from either obstruction of bile flow or derangements of hepatic circulation. Liver dysfunction may be acute or chronic; the latter is far more common.

Chronic liver disease, including cirrhosis, is the 12th-leading cause of death in the United States among young and middle-aged adults (Mathews, McGuire & Estrada, 2006). At least 40% of those deaths are associated with alcohol use. The rate of chronic liver disease for men is twice that for women, and chronic liver disease is more common in Asian and African countries than it is in Europe and the United States. Compensated cirrhosis, in which the damaged liver is still able to perform normal functions, often goes undetected for extended periods, and as many as 1% of people may have subclinical cirrhosis (Schuppan & Afdhal, 2008).

Disease processes that lead to hepatocellular dysfunction may be caused by infectious agents such as bacteria and viruses and by anoxia, metabolic disorders, toxins and medications, nutritional deficiencies, and hypersensitivity states. The most common cause of parenchymal damage is malnutrition, especially that related to alcoholism.

The parenchymal cells respond to most noxious agents by replacing glycogen with lipids, producing fatty infiltration with or without cell death or necrosis. This is commonly associated with inflammatory cell infiltration and growth of fibrous tissue. Cell regeneration can occur if the disease process is not too toxic to the cells. The result of chronic parenchymal disease is the shrunken, fibrotic liver seen in cirrhosis.

Among the most common and significant manifestations of liver disease are jaundice, portal hypertension, ascites and varices, nutritional deficiencies (resulting from the inability of damaged liver cells to metabolize certain vitamins), and hepatic encephalopathy or coma. The consequences of

Guidelines for Assisting With Percutaneous Liver Biopsy

Equipment

- Liver biopsy tray (contains needles, scalpel, specimen tubes, etc.)
- Sterile gloves
- Antiseptic solution
- Local anesthetic
- Sterile dressing
- Sphygmomanometer to monitor BP

Implementation

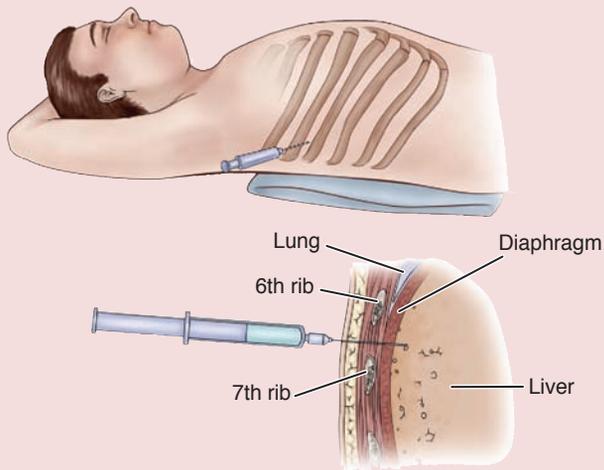

Nursing Interventions

Preprocedure

1. Ascertain that results of coagulation tests (prothrombin time, partial thromboplastin time, and platelet count) are available and that compatible donor blood is available.
2. Check for signed consent; confirm that informed consent has been provided.
3. Measure and record the patient's pulse, respirations, and blood pressure immediately before biopsy.
4. Describe to the patient in advance: steps of the procedure; sensations expected; after-effects anticipated; restrictions of activity and monitoring procedures to follow.

During Procedure

1. Support the patient during the procedure.
2. Expose the right side of the patient's upper abdomen (right hypochondriac).
3. Instruct the patient to inhale and exhale deeply several times, finally to exhale, and to hold breath at the end of expiration. The physician promptly introduces the biopsy needle by way of the transthoracic (intercostal) or transabdominal (subcostal) route, penetrates the liver, aspirates, and withdraws.
4. Instruct the patient to resume breathing.

Postprocedure

1. Immediately after the biopsy, assist the patient to turn on to the right side; place a pillow under the costal margin, and caution the patient to remain in this position, recumbent and immobile, for several hours. Instruct the patient to avoid coughing or straining.
2. Measure and record the patient's pulse, respiratory rate, and blood pressure at 10- to 15-minute intervals for the first hour, then every 30 minutes for the next 1 to 2 hours or until the patient's condition stabilizes.
3. If the patient is discharged after the procedure, instruct the patient to avoid heavy lifting and strenuous activity for 1 week.

Rationale

1. Many patients with liver disease have clotting defects and are at risk for bleeding.
 2. Ensures that the patient consents to this invasive procedure.
 3. Prebiopsy values provide a basis on which to compare the patient's vital signs and evaluate status after the procedure.
 4. Explanations allay fears and ensure cooperation.
-
1. Encouragement and support of the nurse enhance comfort and promote a sense of security.
 2. The skin at the site of penetration will be cleansed and a local anesthetic will be infiltrated.
 3. Holding the breath immobilizes the chest wall and the diaphragm; penetration of the diaphragm thereby is avoided, and the risk of lacerating the liver is minimized.
 4. The patient often continues holding his or her breath because of anxiety.

liver disease are numerous and varied. Their ultimate effects are often incapacitating or life-threatening, and their presence is ominous. Treatment often is difficult.

Jaundice

When the bilirubin concentration in the blood is abnormally elevated, all the body tissues, including the sclerae and the skin, become tinged yellow or greenish-yellow, a condition called jaundice. Jaundice becomes clinically evident when the serum bilirubin level exceeds 2.5 mg/dL (43 fmol/L). Increased serum bilirubin levels and jaundice may result from impairment of hepatic uptake, conjugation of bilirubin, or excretion of bilirubin into the biliary system. There are several types of jaundice: hemolytic, hepatocellular, and obstructive jaundice, and jaundice due to hereditary hyperbilirubinemia. Hepatocellular and obstructive jaundice are the two types commonly associated with liver disease.

Hemolytic Jaundice

Hemolytic jaundice is the result of an increased destruction of the red blood cells, the effect of which is to flood the plasma with bilirubin so rapidly that the liver, although functioning normally, cannot excrete the bilirubin as quickly as it is formed. This type of jaundice is encountered in patients with hemolytic transfusion reactions and other hemolytic disorders. In these patients, the bilirubin in the blood is predominantly unconjugated or free. Fecal and urine urobilinogen levels are increased, but the urine is free of bilirubin. Patients with this type of jaundice, unless their hyperbilirubinemia is extreme, do not experience symptoms or complications as a result of the jaundice per se. However, prolonged jaundice, even if mild, predisposes to the formation of pigment stones in the gallbladder, and extremely severe jaundice (levels of free bilirubin exceeding 20 to 25 mg/dL) poses a risk for brainstem damage.

Hepatocellular Jaundice

Hepatocellular jaundice is caused by the inability of damaged liver cells to clear normal amounts of bilirubin from the blood. The cellular damage may be caused by hepatitis viruses, other viruses that affect the liver (eg, yellow fever virus, Epstein-Barr virus), medications or chemical toxins (eg, carbon tetrachloride, chloroform, phosphorus, arsenicals, certain medications), or alcohol. Cirrhosis of the liver is a form of hepatocellular disease that may produce jaundice. It is usually associated with excessive alcohol intake, but it may also be a late result of liver cell necrosis caused by viral infection. In prolonged obstructive jaundice, cell damage eventually develops, so that both types of jaundice (ie, obstructive and hepatocellular jaundice) appear together.

Patients with hepatocellular jaundice may be mildly or severely ill, with lack of appetite, nausea, malaise, fatigue, weakness, and possible weight loss. In some cases of hepatocellular disease, jaundice may not be obvious. The serum bilirubin concentration and the urine urobilinogen level may be elevated. In addition, AST and ALT levels may be increased, indicating cellular necrosis. The patient may report headache, chills, and fever if the cause is infectious.

Depending on the cause and extent of the liver cell damage, hepatocellular jaundice may be completely reversible.

Obstructive Jaundice

Obstructive jaundice resulting from extrahepatic obstruction may be caused by occlusion of the bile duct from a gallstone, an inflammatory process, a tumor, or pressure from an enlarged organ (eg, liver, gallbladder). The obstruction may also involve the small bile ducts within the liver (ie, intrahepatic obstruction); this may be caused, for example, by pressure on these channels from inflammatory swelling of the liver or by an inflammatory exudate within the ducts themselves. Intrahepatic obstruction resulting from stasis and inspissation (thickening) of bile within the canaliculi may occur after the ingestion of certain medications, which are referred to as cholestatic agents. These agents include phenothiazines, antithyroid medications, sulfonylureas, tricyclic antidepressant agents, nitrofurantoin, androgens and estrogens, propylthiouracil, amoxicillin-clavulanic acid, and erythromycin estolate.

Regardless of whether the obstruction is intrahepatic or extrahepatic, and regardless of its cause, bile cannot flow normally into the intestine and becomes backed up into the liver substance. It is then reabsorbed into the blood and carried throughout the entire body, staining the skin, mucous membranes, and sclerae. It is excreted in the urine, which becomes deep orange and foamy. Because of the decreased amount of bile in the intestinal tract, the stools become light or clay-colored. The skin may itch intensely, requiring repeated soothing baths. Dyspepsia and intolerance to fatty foods may develop because of impaired fat digestion in the absence of intestinal bile. In general, AST, ALT, and GGT levels rise only moderately, but bilirubin and alkaline phosphatase levels are elevated.

Hereditary Hyperbilirubinemia

Increased serum bilirubin levels (hyperbilirubinemia), resulting from any of several inherited disorders, can also produce jaundice. Gilbert's syndrome is a familial disorder characterized by an increased level of unconjugated bilirubin that causes jaundice. Although serum bilirubin levels are increased, liver histology and liver function test results are normal, and there is no hemolysis. This syndrome affects 3% to 8% of the population, predominantly males (Hauser, Pardi & Poterucha, 2006).

Other conditions that are probably caused by inborn errors of biliary metabolism include Dubin-Johnson syndrome (chronic idiopathic jaundice, with pigment in the liver) and Rotor's syndrome (chronic familial conjugated hyperbilirubinemia, without pigment in the liver); the "benign" cholestatic jaundice of pregnancy, with retention of conjugated bilirubin, probably secondary to unusual sensitivity to the hormones of pregnancy; and benign recurrent intrahepatic cholestasis.

Portal Hypertension

Portal hypertension is the increased pressure throughout the portal venous system that results from obstruction of blood flow through the damaged liver. Commonly associated with

hepatic cirrhosis, it can also occur with non-cirrhotic liver disease. Although splenomegaly (enlarged spleen) with possible hypersplenism is a common manifestation of portal hypertension, the two major consequences of portal hypertension are ascites and varices.

Ascites

Pathophysiology

The mechanisms responsible for the development of ascites are not completely understood. Portal hypertension and the resulting increase in capillary pressure and obstruction of venous blood flow through the damaged liver are contributing factors. The vasodilation that occurs in the splanchnic circulation (the arterial supply and venous drainage of the GI system from the distal esophagus to the midrectum including the liver and spleen) is also a suspected causative factor. The failure of the liver to metabolize aldosterone increases sodium and water retention by the kidney. Sodium and water retention, increased intravascular fluid volume, increased lymphatic flow, and decreased synthesis of albumin by the damaged liver all contribute to the movement of fluid from the vascular system into the peritoneal space. The process becomes self-perpetuating; loss of fluid into the peritoneal space causes further sodium and water retention by the kidney in an effort to maintain the vascular fluid volume.

As a result of liver damage, large amounts of albumin-rich fluid, 15 L or more, may accumulate in the peritoneal cavity as ascites. (Ascites may also occur with disorders such as cancer, kidney disease, and heart failure.) With the movement of albumin from the serum to the peritoneal cavity, the osmotic pressure of the serum decreases. This, combined with increased portal pressure, results in movement of fluid into the peritoneal cavity (Fig. 39-4).

Clinical Manifestations

Increased abdominal girth and rapid weight gain are common presenting symptoms of ascites. The patient may be short of breath and uncomfortable from the enlarged abdomen, and striae and distended veins may be visible over the abdominal wall. Umbilical hernias also occur frequently in those patients with cirrhosis. Fluid and electrolyte imbalances are common.

Assessment and Diagnostic Findings

The presence and extent of ascites are assessed by percussion of the abdomen. When fluid has accumulated in the peritoneal cavity, the flanks bulge when the patient assumes a supine position. The presence of fluid can be confirmed either by percussing for shifting dullness or by detecting a fluid wave (Fig. 39-5). A fluid wave is likely to be found only if a large amount of fluid is present. Daily measurement and recording of abdominal girth and body weight are essential to assess the progression of ascites and its response to treatment.

Medical Management

Dietary Modification

The goal of treatment for the patient with ascites is a negative sodium balance to reduce fluid retention. Table salt,

Physiology ■■■ Pathophysiology

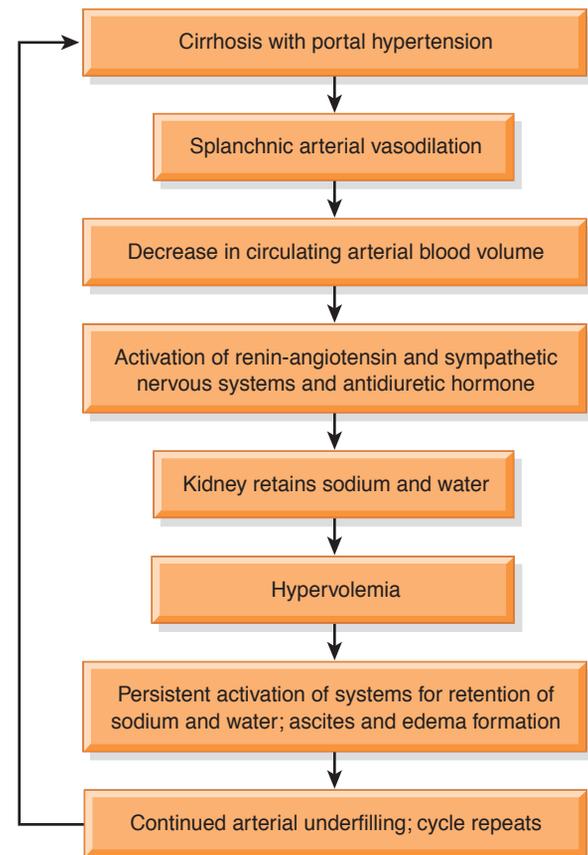

Figure 39-4 Pathogenesis of ascites (arterial vasodilation theory).

salty foods, salted butter and margarine, and all ordinary canned and frozen foods that are not specifically prepared for low-sodium (2-g sodium) diets should be avoided. It may take 2 to 3 months for the patient's taste buds to adjust to unsalted foods. In the meantime, the taste of unsalted foods can be improved by using salt substitutes such as lemon juice, oregano, and thyme. Commercial salt substitutes need to be approved by the physician, because those that contain ammonia could precipitate hepatic coma. Most salt substitutes contain potassium and should be avoided if the patient has impaired renal function. The patient should make liberal use of powdered, low-sodium milk and milk products. If fluid accumulation is not controlled with this regimen, the daily sodium allowance may be reduced further to 500 mg, and diuretics may be administered.

Dietary control of ascites via strict sodium restriction is difficult to achieve at home. The likelihood that the patient will follow even a 2-g sodium diet increases if the patient and the person preparing meals understand the rationale for the diet and receive periodic guidance about selecting and preparing appropriate foods. Approximately 10% of patients with ascites respond to these measures alone. Nonresponders and those who find sodium restriction difficult require diuretic therapy.

Figure 39-5 Assessing for abdominal fluid wave. The examiner places the hands along the sides of the patient's flanks, then strikes one flank sharply, detecting any fluid wave with the other hand. An assistant's hand is placed (ulnar side down) along the patient's midline to prevent the fluid wave from being transmitted through the tissues of the abdominal wall.

Diuretics

Use of diuretics along with sodium restriction is successful in 90% of patients with ascites. Spironolactone (Aldactone), an aldosterone-blocking agent, is most often the first-line therapy in patients with ascites from cirrhosis. When used with other diuretics, spironolactone helps prevent potassium loss. Oral diuretics such as furosemide (Lasix) may be added but should be used cautiously, because long-term use may induce severe sodium depletion (hyponatremia).

Ammonium chloride and acetazolamide (Diamox) are contraindicated because of the possibility of precipitating hepatic coma. Daily weight loss should not exceed 1 to 2 kg (2.2 to 4.4 lb) in patients with ascites and peripheral edema or 0.5 to 0.75 kg (1.1 to 1.65 lb) in patients without edema. Fluid restriction is not attempted unless the serum sodium concentration is very low.

Possible complications of diuretic therapy include fluid and electrolyte disturbances (including hypovolemia, hypokalemia, hyponatremia, and hypochloremic alkalosis) and encephalopathy. Encephalopathy may be precipitated by dehydration and hypovolemia. In addition, when potassium stores are depleted, the amount of ammonia in the systemic circulation increases, which may cause impaired cerebral functioning and encephalopathy.

Bed Rest

In patients with ascites, an upright posture is associated with activation of the renin-angiotensin-aldosterone system and sympathetic nervous system (Porth & Matfin, 2009). This causes reduced renal glomerular filtration and sodium excretion and a decreased response to loop diuret-

ics. Therefore, bed rest may be a useful therapy, especially for patients whose condition is refractory to diuretics.

Paracentesis

Paracentesis is the removal of fluid (ascites) from the peritoneal cavity through a puncture or a small surgical incision through the abdominal wall under sterile conditions. Ultrasound guidance may be indicated in some patients who are at high risk for bleeding because of an abnormal coagulation profile and in those who have had previous abdominal surgery and may have adhesions. Paracentesis was once considered a routine form of treatment for ascites. However, it is now performed primarily for diagnostic examination of ascitic fluid; for treatment of massive ascites that is resistant to nutritional and diuretic therapy and that is causing severe problems to the patient; and as a prelude to diagnostic imaging studies, peritoneal dialysis, or surgery. A sample of the ascitic fluid may be sent to the laboratory for cell count, albumin and total protein levels, culture, and other tests.

Large-volume (5 to 6 L) paracentesis has been shown to be a safe method for treating patients with severe ascites. This technique, in combination with the IV infusion of salt-poor albumin or other colloid, has become a standard management strategy yielding an immediate effect. Refractive, massive ascites is unresponsive to multiple diuretics and sodium restriction for 2 weeks or more and can result in severe sequelae such as respiratory distress, which requires rapid intervention. Albumin infusions help to correct decreases in effective arterial blood volume that lead to sodium retention. Use of this colloid reduces the incidence of postparacentesis circulatory dysfunction with renal dysfunction, hyponatremia, and rapid reaccumulation of ascites associated with decreased effective arterial volume (Hauser, et al., 2006). The beneficial effects of albumin administration on hemodynamic stability and renal functional status may be related to an improvement in cardiac function as well as a decrease in the degree of arterial vasodilation. Although the patient with cirrhosis has a greatly increased extracellular blood volume, the kidney incorrectly senses that the effective volume has decreased. The renin-angiotensin-aldosterone axis is stimulated, and sodium is reabsorbed (Rodes, et al., 2007). In addition, antidiuretic hormone (ADH) secretion increases, which leads to increased retention of free water and sometimes to the development of dilutional hyponatremia. Therapeutic paracentesis provides only temporary removal of fluid; ascites rapidly recurs, necessitating repeated fluid removal. Nursing care of the patient undergoing paracentesis is presented in Chart 39-3.

Transjugular Intrahepatic Portosystemic Shunt

Transjugular intrahepatic portosystemic shunt (TIPS) is a method of treating ascites in which a cannula is threaded into the portal vein by the transjugular route (Fig. 39-6). To reduce portal hypertension, an expandable stent is inserted to serve as an intrahepatic shunt between the portal circulation and the hepatic vein. TIPS is the treatment of choice for refractive ascites. It is extremely effective in decreasing sodium retention, improving the renal response to diuretic therapy, and preventing recurrence of fluid accumulation (Senzolo, Cholongitas, Tibballs, et al., 2006).

CHART
39-3

Guidelines for Assisting With a Paracentesis

Equipment

- Paracentesis tray (contains trocar, syringe, needles, drainage tube)
- Sterile gloves
- Antiseptic solution
- Local anesthetic
- Sterile dressing
- Drainage collection bottles, receptacles
- Sphygmomanometer to monitor BP

Implementation**Nursing Interventions****Preprocedure**

1. Check for signed consent form.
2. Prepare the patient by providing the necessary information and instructions and by offering reassurance.
3. Instruct the patient to void.
4. Gather appropriate sterile equipment and collection receptacles.
5. Place the patient in upright position on the edge of the bed or in a chair with feet supported on a stool. Fowler's position should be used by the patient confined to bed.
6. Place the sphygmomanometer cuff around patient's arm.

Procedure

1. The physician, using aseptic technique, inserts the trocar through a puncture below the umbilicus. The trocar or needle is connected to a drainage tube, the end of which is inserted into a collecting receptacle.
2. Help the patient maintain position throughout the procedure.
3. Measure and record blood pressure at frequent intervals throughout the procedure.
4. Monitor the patient closely for signs of vascular collapse: pallor, increased pulse rate, or decreased blood pressure.

Rationale

1. Ensures that patient has agreed to procedure.
2. Having information increases the patient's understanding of the procedure and the reason for it.
3. An empty bladder minimizes the risk of inadvertent puncture of the bladder and minimizes discomfort from a full bladder.
4. Sterility of equipment is essential to minimize risk of infection; having equipment available enables the procedure to be performed smoothly.
5. An upright position results in movement of the peritoneal fluid close to the abdominal wall and promotes easier puncture and removal of fluid.
6. This allows the nurse to monitor the patient's blood pressure during procedure.
1. Sterile technique minimizes the risk of infection. Bleeding at the puncture site is minimal at this location. The fluid drains by gravity or mild siphon into the container.
2. The patient who is fatigued or weak may have difficulty maintaining an optimal position for drainage of fluid.
3. Decreased blood pressure may occur with vascular collapse, which can result from removal of the fluid from the peritoneal cavity and fluid shifts.
4. Vascular collapse (hypovolemia) may occur as fluid moves from the vascular system to replace fluid drained from peritoneal cavity.

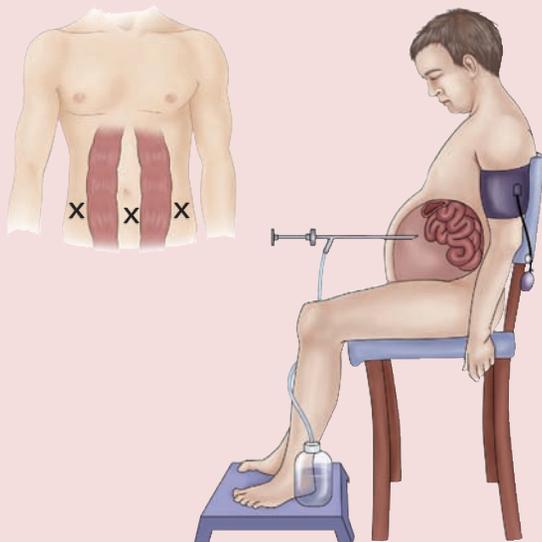

Figure on left shows possible sites for insertion of trocar.

Continued

CHART
39.3

Guidelines for Assisting With a Paracentesis (Continued)

Nursing Action

Postprocedure

1. Return the patient to bed or to a comfortable sitting position.
2. Measure, describe, and record the fluid collected.
3. Label samples of fluid and send to laboratory.
4. Monitor vital signs every 15 min for 1 h, every 30 min for 2 h, every hour for 2 h, and then every 4 h.
5. Measure the patient's temperature.
6. Assess for hypovolemia, electrolyte shifts, changes in mental status, and encephalopathy.
7. When taking vital signs, check puncture site for leakage or bleeding.
8. Provide patient teaching regarding need to monitor for bleeding or excessive drainage from puncture site, importance of avoiding heavy lifting or straining, the need to change position slowly, and frequency of monitoring for fever.

Rationale

1. The weak or fatigued patient may have difficulty resuming a comfortable position without assistance.
2. The volume of fluid removed may range from small to very large, and its removal may affect fluid and vascular status; volume should be included in input and output records. The characteristics of the fluid (clear vs. cloudy, red vs. colorless) may be helpful in diagnostic evaluation.
3. Peritoneal fluid is analyzed as part of the diagnostic workup.
4. Vital signs (blood pressure, pulse rate) may change as fluid shifts occur after removal of fluid, especially if a large volume of fluid has been removed.
5. An elevated temperature is a sign of infection and should be reported to the patient's physician.
6. Changes in fluid and electrolyte states and mental and cognitive status may occur with removal of fluid and fluid shifts, and should be reported.
7. Leakage of fluid may occur because of changes in abdominal pressure and may contribute to further loss of fluid if undetected. Leakage suggests a possible site for infection, and bleeding may occur in patients with altered clotting secondary to liver disease.
8. The patient (or family members) needs to monitor the puncture site for bleeding and excessive drainage if the patient is discharged home after the procedure. Heavy lifting or straining is avoided to enable the puncture site to close. Slow changes in position are recommended because of the risk of hypovolemia related to fluid removal. Monitoring for fever is needed to detect infection.

Because the development of ascites in patients with cirrhosis is associated with a 50% mortality rate, any patient who is considered a candidate for liver transplantation should be referred for TIPS.

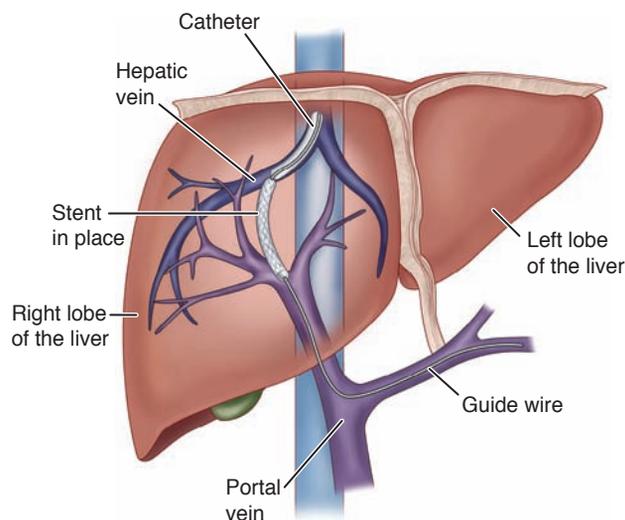

Figure 39-6 Transjugular intrahepatic portosystemic shunt (TIPS). A stent is inserted via catheter to the portal vein to divert blood flow and reduce portal hypertension.

Other Methods of Treatment

Ascites can also be treated by the insertion of a portovenous shunt to redirect ascitic fluid from the peritoneal cavity into the systemic circulation. However, this procedure is used only for patients who are not candidates for liver transplantation because of the high complication rate and high incidence of shunt failure.

Nursing Management

If a patient with ascites from liver dysfunction is hospitalized, nursing measures include assessment and documentation of intake and output, abdominal girth, and daily weight to assess fluid status. The nurse monitors serum ammonia and electrolyte levels to assess electrolyte balance, response to therapy, and indicators of encephalopathy.

Promoting Home and Community-Based Care

Teaching Patients Self-Care

The patient treated for ascites is likely to be discharged with some ascites still present. Before hospital discharge, the nurse teaches the patient and family about the treatment plan, including the need to avoid all alcohol intake, adhere to a low-sodium diet, take medications as prescribed, and check with the physician before taking any new medications (Chart 39-4). Additional patient and family teaching

CHART

HOME CARE CHECKLIST

Management of Ascites

At the completion of the home care instruction, the patient or caregiver will be able to:	PATIENT	CAREGIVER
• Make appropriate dietary choices consistent with dietary prescription and recommendations.	✓	✓
• State the importance of weighing self daily and keeping a daily record of weight.	✓	✓
• Maintain record of daily weight and identify daily weight-loss goals.	✓	✓
• List weight changes (loss or gain) that should be reported to the primary health care provider.	✓	✓
• Explain the rationale for monitoring and recording daily intake and output.	✓	✓
• Identify changes in output that should be reported to primary health care provider (eg, decreasing urine output).	✓	✓
• Identify rationale for fluid restrictions (if needed), and comply with fluid restriction.	✓	✓
• Discuss importance of avoiding nonsteroidal anti-inflammatory agents, medications (eg, cough mixtures) containing alcohol, antibiotics, or antacids containing salt.	✓	✓
• Describe effects, side effects, and monitoring parameters for diuretic therapy.	✓	✓
• Identify need to stop all alcohol intake as critical to well-being.	✓	✓
• Explain how to contact Alcoholics Anonymous or alcohol counselors in related organizations.	✓	✓
• Demonstrate how to care for skin, alleviate pressure over bony prominences by turning when in bed or chair, and decrease edema by position changes.	✓	✓
• Identify early signs and symptoms of complications (encephalopathy, spontaneous bacterial peritonitis, dehydration, electrolyte abnormalities, azotemia).	✓	✓

addresses skin care and the need to weigh the patient daily and to watch for and report signs and symptoms of complications.

Continuing Care

A referral for home care may be warranted, especially if the patient lives alone or cannot provide self-care. The home visit enables the nurse to assess changes in the patient's condition and weight, abdominal girth, skin, and cognitive and emotional status. The home care nurse assesses the home environment and the availability of resources needed to adhere to the treatment plan (eg, a scale to obtain daily weights, facilities to prepare and store appropriate foods, resources to purchase needed medications). It is important to assess the patient's adherence to the treatment plan and the ability to buy, prepare, and eat appropriate foods. The nurse reinforces previous teaching and emphasizes the need for regular follow-up and the importance of keeping scheduled health care appointments.

Esophageal Varices

Esophageal varices develop in the majority of patients with cirrhosis. Varices are varicosities that develop from elevated pressure in the veins that drain into the portal system. They are prone to rupture and often are the source of massive hemorrhages from the upper GI tract and the rectum. In addition, blood clotting abnormalities, often seen in patients with severe liver disease, increase the likelihood of bleeding and significant blood loss.

Once esophageal varices form, they increase in size and eventually bleed (Albillos, 2007); in cirrhosis, they are the

most significant source of bleeding. The first bleeding episode has a mortality rate of 30% to 50% and is one of the major causes of death in patients with cirrhosis. The mortality rate increases with each subsequent bleeding episode (Kravetz, 2007).

Pathophysiology

Esophageal varices are dilated, tortuous veins that are usually found in the submucosa of the lower esophagus but may develop higher in the esophagus or extend into the stomach. This condition is almost always caused by portal hypertension, which results from obstruction of the portal venous circulation within the damaged liver.

Because of increased obstruction of the portal vein, venous blood from the intestinal tract and spleen seeks an outlet through collateral circulation (new pathways for return of blood to the right atrium). The effect is increased pressure, particularly in the vessels in the submucosal layer of the lower esophagus and upper part of the stomach. These collateral vessels are not very elastic; rather, they are tortuous and fragile, and they bleed easily (Fig. 39-7). Less common causes of varices are abnormalities of the circulation in the splenic vein or superior vena cava and hepatic venothrombosis.

Bleeding esophageal varices are life-threatening and can result in hemorrhagic shock that produces decreased cerebral, hepatic, and renal perfusion. In turn, there is an increased nitrogen load from bleeding into the GI tract and an increased serum ammonia level, increasing the risk of encephalopathy. Usually the dilated veins cause no symptoms. However, if the portal pressure increases sharply and the mucosa or supporting structures become thin, massive hemorrhaging occurs.

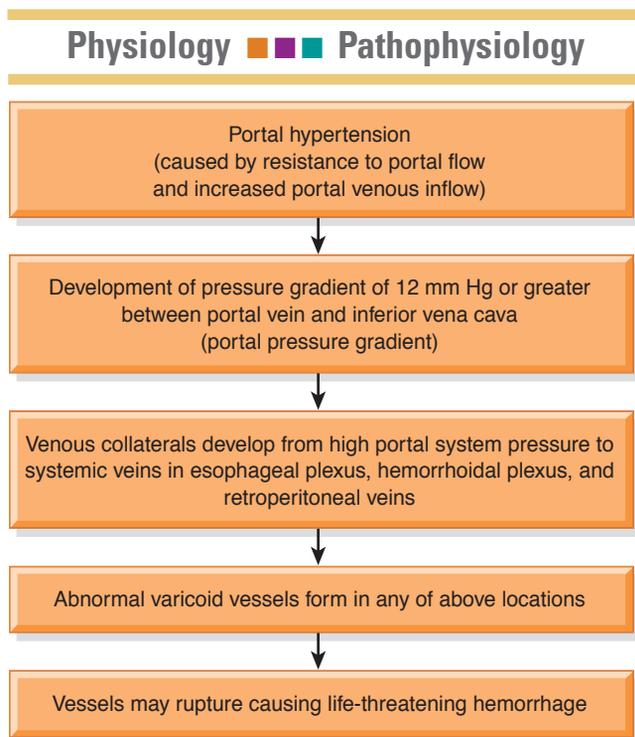

Figure 39-7 Pathogenesis of bleeding esophageal varices.

Factors that contribute to hemorrhage are muscular exertion from lifting heavy objects; straining at stool; sneezing, coughing, or vomiting; esophagitis; irritation of vessels by poorly chewed foods or irritating fluids; and reflux of stomach contents (especially alcohol). Salicylates and any medication that erodes the esophageal mucosa or interferes with cell replication also may contribute to bleeding.

Clinical Manifestations

The patient with bleeding esophageal varices may present with hematemesis, melena, or general deterioration in mental or physical status and often has a history of alcohol abuse. Signs and symptoms of shock (cool clammy skin, hypotension, tachycardia) may be present.

Assessment and Diagnostic Findings

Endoscopy is used to identify the bleeding site, along with barium swallow, ultrasonography, CT, and angiography. Because the incidence of varices is 50% in patients with cirrhosis, it is recommended that these patients undergo screening endoscopy every 2 years in an effort to identify and treat large varices, which are the ones most likely to bleed (Wolfe, 2006).

Endoscopy

Immediate endoscopy (see Chapter 34) is indicated to identify the cause and the site of bleeding; at least 30% of patients with suspected bleeding from esophageal varices are actually bleeding from another source (gastritis, ulcer). Nursing support is essential during this often stressful experience. Careful monitoring can detect early signs of cardiac dysrhythmias, perforation, and hemorrhage.

After the examination, fluids are not given until the patient's gag reflex returns. Lozenges and gargles may be used to relieve throat discomfort if the patient's physical condition and mental status permit. If the patient is actively bleeding, oral intake will not be permitted, and the patient will be prepared for further diagnostic and therapeutic procedures.

Portal Hypertension Measurements

Portal hypertension may be suspected if dilated abdominal veins and hemorrhoids are detected. A palpable enlarged spleen (splenomegaly) and ascites may also be present. Portal venous pressure can be measured directly or indirectly. Indirect measurement of the hepatic vein pressure gradient is the most common procedure. The measurement requires insertion of a catheter with a balloon into the antecubital or femoral vein. The catheter is advanced under fluoroscopy to a hepatic vein. Fluid is infused once the catheter is in position to inflate the balloon. A "wedged" pressure (similar to pulmonary artery wedge pressure) is obtained by occluding the blood flow in the blood vessel; pressure in the unoccluded vessel is also measured. Although the values obtained may underestimate portal pressure, this measurement may be taken several times to evaluate the results of therapy.

Direct measurement of portal vein pressure can be obtained by several methods. During laparotomy, a needle may be introduced into the spleen; a manometer reading of more than 20 mL saline is abnormal. Another direct measurement requires insertion of a catheter into the portal vein or one of its branches. Endoscopic measurement of pressure within varices is used only in conjunction with endoscopic sclerotherapy.

Laboratory Tests

Laboratory tests may include various liver function tests, such as serum aminotransferases, bilirubin, alkaline phosphatase, and serum proteins. Splenoportography, which involves serial or segmental x-rays, is used to detect extensive collateral circulation in esophageal vessels, which would indicate varices. Other tests are hepatoportography and celiac angiography. These are usually performed in the operating room or x-ray department.

Medical Management

Bleeding from esophageal varices is an emergency that can quickly lead to hemorrhagic shock. The patient is critically ill, requiring aggressive medical care and expert nursing care, and is usually transferred to the intensive care unit (ICU) for close monitoring and management. See Chapter 15 for a discussion of care of the patient in shock.

The extent of bleeding is evaluated, and vital signs are monitored continuously if hematemesis and melena are present. Signs of potential hypovolemia are noted, such as cold clammy skin, tachycardia, a drop in blood pressure, decreased urine output, restlessness, and weak peripheral pulses. The volume of circulating blood is estimated and monitored with a central venous catheter or pulmonary artery catheter. Blood pressure is monitored via an arterial catheter. Oxygen is administered to prevent hypoxia and to maintain adequate blood oxygenation.

Because patients with bleeding esophageal varices have intravascular volume depletion and are subject to electrolyte imbalance, IV fluids with electrolytes and volume expanders are provided to restore fluid volume and replace electrolytes. Transfusion of blood components also may be required.

Caution must be taken with volume resuscitation so that overhydration does not occur, because this would raise portal pressure and increase bleeding. An indwelling urinary catheter is usually inserted to permit frequent monitoring of urine output.

Although a variety of pharmacologic, endoscopic, and surgical approaches are used to treat bleeding esophageal varices, none is ideal, and most are associated with considerable risk to the patient. Nonsurgical treatment of bleeding esophageal varices is preferable because of the high mortality rate of emergency surgery to control bleeding esophageal varices and because of the poor physical condition that is typical of the patient with severe liver dysfunction.

Pharmacologic Therapy

In an actively bleeding patient, medications are administered initially because they can be obtained and administered quicker than other therapies. Vasopressin (Pitressin) may be the initial mode of therapy in urgent situations because it produces constriction of the splanchnic arterial bed and decreases portal pressure. As previously described, splanchnic circulation comprises the arterial blood supply and venous drainage of the entire GI tract from the distal esophagus to the midrectum, including the liver. Vasopressin constricts distal esophageal and proximal gastric veins, thus reducing the inflow into the portal system and therefore the portal pressure. Vital signs and the presence or absence of blood in the gastric aspirate indicate the effectiveness of vasopressin. Monitoring of fluid intake and output and electrolyte levels is necessary because hyponatremia may develop and vasopressin may have an antidiuretic effect.

Coronary artery disease is a contraindication to the use of vasopressin because coronary vasoconstriction is a side effect that may precipitate myocardial infarction. The combination of vasopressin with nitroglycerin (administered by the IV, sublingual, or transdermal route) has been effective in reducing or preventing the side effects (constriction of coronary vessels and angina) caused by vasopressin alone. Side effects include myocardial and extremity ischemia as well as cardiac dysrhythmias; therefore, vasopressin is used only in urgent situations (Floch, 2005; Wolfe, 2006).

Somatostatin and octreotide (Sandostatin) have been reported to be effective in decreasing bleeding from esophageal varices, and they lack the vasoconstrictive effects of vasopressin. These medications cause selective splanchnic vasoconstriction and are used mainly in the management of active hemorrhage. Propranolol (Inderal) and nadolol (Corgard), beta-blocking agents that decrease portal pressure, are the most common medications used both to prevent a first bleeding episode in patients with known varices and to prevent rebleeding (Wolfe, 2006). Beta-blockers should not be used in acute variceal hemorrhage, but they are effective prophylaxis against such an episode. Nitrates such as isosorbide (Isordil) lower portal pressure by venodilation and decreased cardiac output and

may be used in combination with beta-blockers (Wolfe, 2006). Further studies of these and other medications are necessary to evaluate their use in the treatment and prevention of bleeding episodes.

Balloon Tamponade

To control hemorrhage in certain patients, **balloon tamponade** may be used. In this procedure, pressure is exerted on the cardia (upper orifice of the stomach) and against the bleeding varices by a double-balloon tamponade (Sengstaken-Blakemore tube) (Fig. 39-8). The tube has four openings, each with a specific purpose: gastric aspiration, esophageal aspiration, gastric balloon inflation, and esophageal balloon inflation.

The balloon in the stomach is inflated with 100 to 200 mL of air. An x-ray confirms proper positioning of the gastric balloon. The tube is pulled gently to exert a force against the gastric cardia. The preferred method for applying traction may be with weights suspended from an overbed trapeze. Irrigation of the tubing is performed to detect bleeding; if returns are clear, the esophageal balloon is not used. If bleeding continues, the esophageal balloon is inflated. The desired pressure in the esophageal and gastric balloons is 25 to 40 mm Hg, as measured by the manometer. On inflation of the esophageal balloon, there is a possibility of injury or rupture of the esophagus, so constant nursing surveillance is necessary.

Gastric suction is provided by connecting the gastric catheter outlet to low suction (80 to 100 mm Hg). The tubing is irrigated hourly, and the color of the drainage indicates whether bleeding has been controlled. Room-temperature lavage or irrigation may be used in the gastric balloon. The pressure within the esophageal balloon is measured and recorded every 2 to 4 hours via the manometer to detect underinflation (which can allow bleeding to continue) or prevent overinflation (which can cause esophageal injury). When it appears that bleeding has stopped, the balloons are deflated carefully and sequentially. The esophageal balloon is deflated first, and the patient is monitored for recurrent bleeding. After several hours without bleeding, the gastric balloon can be deflated safely. If there is still no bleeding, the tamponade tube is removed. The therapy is used for as short a time as possible to control bleeding while emergency treatment is completed and definitive therapies are instituted (no longer than 24 hours).

Although balloon tamponade has been fairly successful, there are some inherent dangers. Displacement of the tube and the inflated balloon into the oropharynx can cause life-threatening obstruction of the airway and asphyxiation. This may occur if the patient pulls on the tube because of confusion or discomfort. It may also result from rupture of the gastric balloon, which causes the esophageal balloon to move into the oropharynx. Sudden rupture of the balloon causes airway obstruction and aspiration of gastric contents into the lungs. Therefore, the tube must be tested before insertion to minimize this risk by ensuring that the balloons can attain and maintain inflation. Aspiration of blood and secretions into the lungs is frequently associated with balloon tamponade, especially in the stuporous or comatose patient. Endotracheal intubation before insertion of the

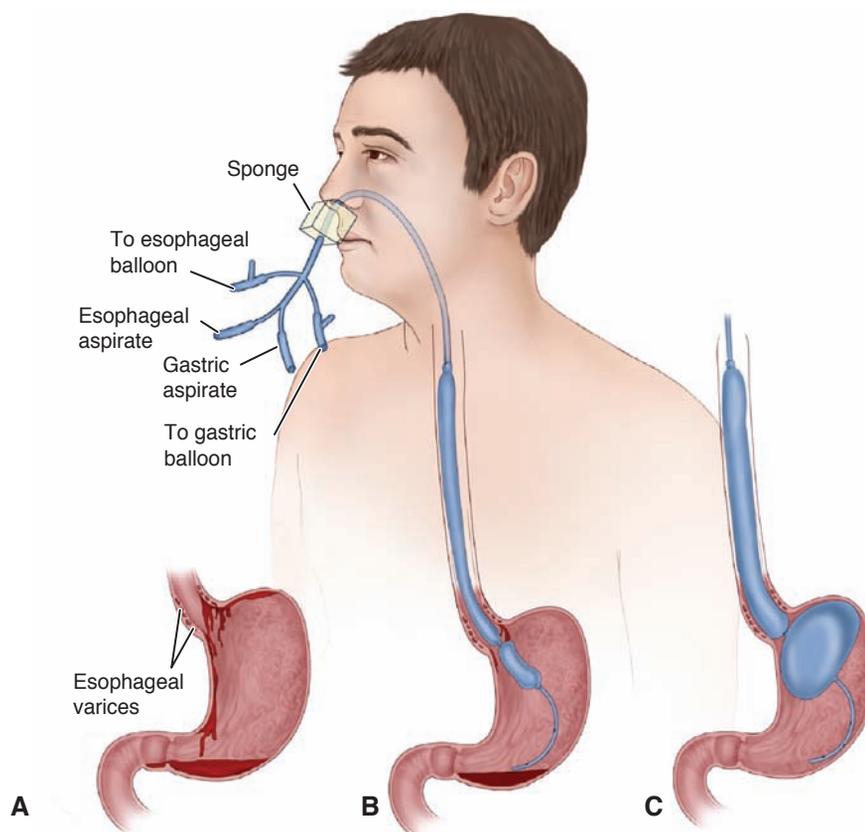

Figure 39-8 Balloon tamponade to treat esophageal varices. **A**, Dilated, bleeding esophageal veins (varices) of the lower esophagus. **B**, A four-lumen esophageal tamponade tube with balloons (uninflated) in place. **C**, Compression of bleeding esophageal varices by inflated esophageal and gastric balloons. The gastric and esophageal outlets permit the nurse to aspirate secretions.

tube protects the airway and minimizes the risk of aspiration. Ulceration and necrosis of the nose, the mucosa of the stomach, or the esophagus may occur if the tube is left in place too long, inflated too long, or inflated at too high a pressure.

NURSING ALERT

The patient being treated with balloon tamponade must remain under close observation in the ICU because of the risk of serious complications. The patient must be monitored closely and continuously. Precautions must be taken to ensure that the patient does not pull on or inadvertently displace the tube.

Nursing measures include frequent mouth and nasal care. For secretions that accumulate in the mouth, tissues should be within easy reach of the patient. Oral suction may be necessary to remove oral secretions.

The patient with esophageal hemorrhage is usually extremely anxious and frightened. Knowing that the nurse is nearby and ready to respond immediately can help alleviate some of this anxiety. Tube insertion is uncomfortable and never pleasant. Careful explanation during the procedure and while the tube is in place may be reassuring to the patient. Sedation may be prescribed.

Although balloon tamponade stops the bleeding in 90% of patients, bleeding recurs in 60% to 70%, necessitating other treatment modalities, such as sclerotherapy or banding (Wolfe, 2006). Once the balloons are deflated or the

tube is removed, the patient must be assessed frequently because of the high risk of recurrent bleeding.

Endoscopic Therapies

In endoscopic sclerotherapy (Fig. 39-9), also referred to as injection sclerotherapy, a sclerosing agent is injected through a fiberoptic endoscope into the bleeding esophageal varices to promote thrombosis and eventual sclerosis. The procedure has been used successfully to treat acute GI hemorrhage but is not recommended for prevention of first and subsequent variceal bleeding episodes (Albillos, 2007; Wolfe, 2006).

After treatment for acute hemorrhage, the patient must be observed for bleeding, perforation of the esophagus, aspiration pneumonia, and esophageal stricture. Antacids, histamine-2 antagonists such as cimetidine (Tagamet), or

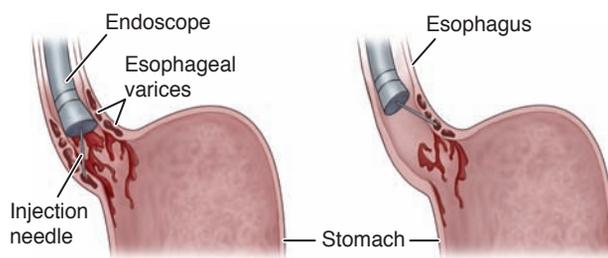

Figure 39-9 Endoscopic or injection sclerotherapy. Injection of sclerosing agent into esophageal varices through an endoscope promotes thrombosis and eventual sclerosis, thereby obliterating the varices.

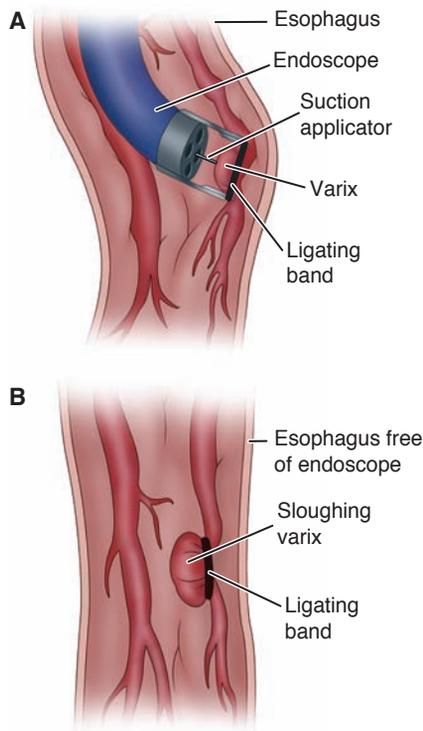

Figure 39-10 Esophageal banding. **A**, A rubber band–like ligature is slipped over an esophageal varix via an endoscope. **B**, Necrosis results, and the varix eventually sloughs off.

proton pump inhibitors such as pantoprazole (Protonix) may be administered after the procedure to counteract the chemical effects of the sclerosing agent on the esophagus and the acid reflux associated with the therapy.

Esophageal Banding Therapy (Variceal Band Ligation)

In **variceal banding** (Fig. 39-10), also referred to as esophageal variceal ligation (EVL), a modified endoscope loaded with an elastic rubber band is passed through an overtube directly onto the varix (or varices) to be banded. After the bleeding varix is suctioned into the tip of the endoscope, the rubber band is slipped over the tissue, causing necrosis, ulceration, and eventual sloughing of the varix.

Variceal banding is comparable to endoscopic sclerotherapy in its effectiveness in controlling acute bleeding. Compared with sclerotherapy, variceal banding also significantly reduces the rebleeding rate, mortality, procedure-related complications, and the number of sessions needed to eradicate varices. Esophageal band ligation has replaced sclerotherapy as the treatment of choice in the management of esophageal varices. Complications include superficial ulceration and dysphagia, transient chest discomfort, and, rarely, esophageal strictures. Band ligation in combination with pharmacologic therapy may be more effective than monotherapy (ie, a single mode of therapy) in the treatment of acute hemorrhage. EVL is recommended for patients who have experienced variceal bleeding while receiving beta-blocker therapy and for those who cannot tolerate beta-blocking agents (Albillos, 2007).

Transjugular Intrahepatic Portosystemic Shunting

A TIPS procedure (see Fig. 39-6) is indicated for the treatment of an acute episode of variceal bleeding refractory to pharmacologic or endoscopic therapy. In 10% to 20% of patients for whom urgent band ligation or sclerotherapy and medications are not successful in eradicating bleeding, a TIPS procedure can effectively control acute variceal hemorrhage by rapidly lowering portal pressure. TIPS is also indicated for those patients who rebleed after pharmacologic or endoscopic prophylaxis has failed. In addition, this technique is used as a bridge to liver transplantation. Potential complications include bleeding, sepsis, heart failure, organ perforation, shunt thrombosis, and progressive liver failure (Wolfe, 2006).

Surgical Management

Several surgical procedures have been developed to treat esophageal varices and to minimize rebleeding, but these procedures are often accompanied by significant risk. Procedures that may be used for esophageal varices are direct surgical ligation of varices; splenorenal, mesocaval, and portacaval venous shunts to relieve portal pressure; and esophageal transection with devascularization. Use of these procedures is controversial, and studies regarding their effectiveness and outcomes continue. What is known thus far is that these procedures are very effective in controlling variceal bleeding. They may be considered as second-line management (rescue therapy) for those patients for whom all other treatments have failed, those who are not candidates for liver transplantation, and those who require a bridge to transplantation. There is a high incidence of encephalopathy after the surgical shunting procedures, and morbidity and mortality statistics remain high (Rodes, et al., 2007). The TIPS procedure has largely replaced the use of surgical decompressive shunts and ligation procedures.

Surgical Bypass Procedures

Surgical decompression of the portal circulation can prevent variceal bleeding if the shunt remains patent (Rodes, et al., 2007). One of the various surgical shunting procedures (Fig. 39-11) is the distal splenorenal shunt, which is made between the splenic vein and the left renal vein after splenectomy. A mesocaval shunt is created by anastomosing the superior mesenteric vein to the proximal end of the vena cava or to the side of the vena cava using grafting material. The goal of distal splenorenal and mesocaval shunts is to decrease portal pressure by draining only a portion of venous blood from the portal bed; therefore, they are considered selective shunts. The liver continues to receive some portal flow, and the incidence of encephalopathy may be reduced. Portacaval shunts are considered nonselective shunts because they divert all portal flow to the vena cava via end-to-side or side-to-side approaches.

These procedures are extensive and are not always successful because of secondary thrombosis in the veins used for the shunt and because of complications (eg, encephalopathy, accelerated liver failure). The effectiveness of these procedures has been studied extensively. All shunt procedures are equally effective in preventing recurrent variceal bleeding but may cause further impairment of liver function and encephalopathy. Partial portacaval shunts with interposition grafts are as effective as other shunts but

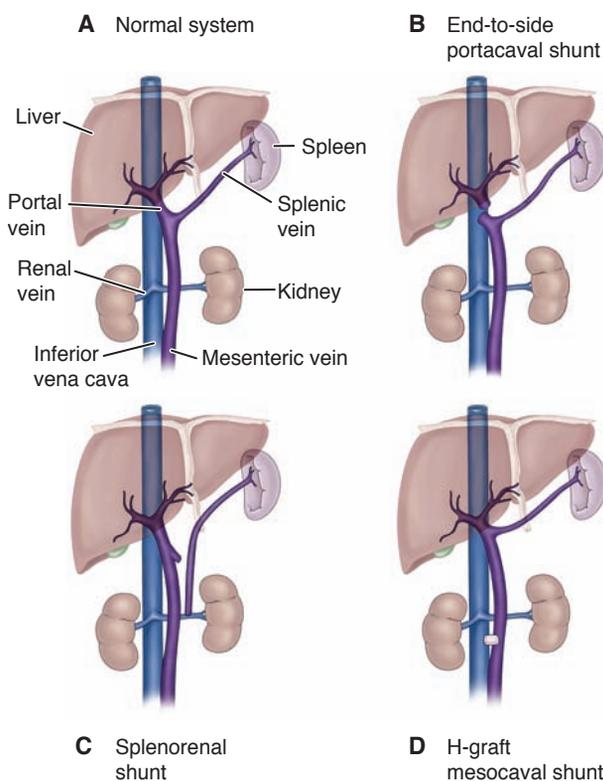

Figure 39-11 Portal systemic shunts. **A**, Normal portal system. **B–D**, Examples of portal shunts to reduce portal pressure.

are associated with a lower rate of encephalopathy (Rodes, et al., 2007). The severity of the disease (by a classification such as the Child-Pugh system, discussed later) and the potential for future liver transplantation guide the treatment decision. If the cause of portal hypertension is the rare **Budd-Chiari syndrome** or other venous obstructive disease, a portacaval or a mesoatrial shunt may be performed (see Fig. 39-11). The mesoatrial shunt is required when the infrahepatic vena cava is thrombosed and must be bypassed.

Devascularization and Transection

Devascularization and staple-gun transection procedures to separate the bleeding site from the high-pressure portal system have been used in the emergency management of variceal bleeding. The lower end of the esophagus is reached through a small gastrotomy incision; a staple gun permits anastomosis of the transected ends of the esophagus. Rebleeding is a risk, and the outcomes of these procedures vary among patient populations.

NURSING ALERT

Postoperative care is similar to that for any abdominal surgery, but the risk of complications (hypovolemic or hemorrhagic shock, hepatic encephalopathy, electrolyte imbalance, metabolic and respiratory alkalosis, alcohol withdrawal syndrome, and seizures) is high. The surgical procedures do not alter the course of the progressive liver disease, and bleeding may recur as new collateral vessels develop.

Nursing Management

Overall nursing assessment includes monitoring the patient's physical condition and evaluating emotional responses and cognitive status. The nurse monitors and records vital signs and assesses the patient's nutritional and neurologic status. This assessment assists in identifying hepatic encephalopathy, which may result from the breakdown of blood in the GI tract with a rising serum ammonia level. Manifestations range from drowsiness and confusion to profound coma.

If complete rest of the esophagus is indicated because of bleeding, parenteral nutrition is initiated. Gastric suction usually is initiated to keep the stomach as empty as possible and to prevent straining and vomiting. The patient often complains of severe thirst, which may be relieved by frequent oral hygiene and moist sponges to the lips. The nurse closely monitors the blood pressure. Vitamin K therapy and multiple blood transfusions often are indicated because of blood loss. A quiet environment and calm reassurance may help to relieve the patient's anxiety and reduce agitation.

Bleeding anywhere in the body is anxiety provoking, resulting in a crisis for the patient and family. If the patient has been a heavy user of alcohol, delirium secondary to alcohol withdrawal can complicate the situation. The nurse provides support and explanations about medical and nursing interventions. Close monitoring of the patient helps in detecting and managing complications. Management modalities and nursing care of the patient with bleeding esophageal varices are summarized in Table 39-2.

Hepatic Encephalopathy and Coma

Hepatic encephalopathy, or portosystemic encephalopathy (PSE), is a life-threatening complication of liver disease that occurs with profound liver failure. Patients with this condition have no overt signs of the illness but do have abnormalities on neuropsychologic testing (Hauser, et al., 2006). Hepatic encephalopathy is the neuropsychiatric manifestation of hepatic failure associated with portal hypertension and the shunting of blood from the portal venous system into the systemic circulation (Hauser, et al., 2006). This reversible metabolic form of encephalopathy can improve with recovery of liver function. The onset is often insidious and subtle, and initially the disease is termed subclinical or minimal hepatic encephalopathy.

Table 39-3 presents the stages of hepatic encephalopathy, common signs and symptoms, and potential nursing diagnoses for each stage.

Pathophysiology

Despite the frequency with which hepatic encephalopathy occurs, the precise pathophysiology is not fully defined (Feldman, Friedman & Brandt, 2006). Two major alterations underlie its development in acute and chronic liver disease. First, hepatic insufficiency may result in encephalopathy because of the inability of the liver to detoxify toxic byproducts of metabolism. Second, portal-systemic shunting, in which collateral vessels develop as a result of portal hypertension, allows elements of the portal blood

Table 39-2 MANAGEMENT MODALITIES AND NURSING CARE FOR THE PATIENT WITH BLEEDING ESOPHAGEAL VARICES

Treatment Modality*	Action	Nursing Priorities
Nonsurgical Modalities		
Pharmacologic agents		Observe response to therapy.
Propranolol (Inderal)/nadolol (Corgard)	Reduces portal pressure by β -adrenergic blocking action.	Monitor for side effects: <i>propranolol</i> and <i>nadolol</i> —decreased pulse pressure, impaired cardiovascular response to hemorrhage.
Vasopressin (Pitressin)	Reduces portal pressure by constricting splanchnic arteries.	<i>vasopressin</i> —angina; nitroglycerin may be prescribed to prevent or treat angina.
Somatostatin/octreotide (Sandostatin)	Reduces portal pressure by selective vasodilation of portal system.	Support patient during treatment.
Balloon tamponade	Exerts pressure directly to bleeding sites in esophagus and stomach.	Explain procedure to patient briefly to obtain cooperation with insertion and maintenance of esophageal/gastric tamponade tube and reduce patient's fear of the procedure. Monitor closely to prevent inadvertent removal or displacement of tube, subsequent airway obstruction, and aspiration. Provide frequent oral hygiene.
Room-temperature saline lavage	Clears blood and secretions before endoscopy and other procedures.	Ensure patency of the nasogastric tube to prevent aspiration. Observe gastric aspirate for blood and cessation of bleeding.
Injection sclerotherapy	Promotes thrombosis and sclerosing of bleeding sites by injection of sclerosing agent into the esophageal varices.	Observe for aspiration, perforation of the esophagus, and recurrence of bleeding after treatment.
Variceal banding	Provides thrombosis and mucosal necrosis of bleeding sites by band ligation.	Observe for recurrence of bleeding, esophageal perforation.
Transjugular intrahepatic portosystemic shunt (TIPS)	Reduces portal pressure by creating a shunt within the liver between the portal and systemic venous systems.	Observe for rebleeding and signs of infection.
Surgical Modalities		
Portal-systemic shunt	Reduces portal hypertension by diverting blood flow away from obstructed portal system.	Observe for development of portal-systemic encephalopathy (altered mental status, neurologic dysfunction), hepatic failure, and rebleeding. Requires intensive, expert nursing care for prolonged period.
Surgical ligation of varices	Ties off blood vessels at the site of bleeding.	Observe for rebleeding.
Esophageal transection and devascularization	Separates bleeding site from portal system.	Observe for rebleeding. Provide postthoracotomy care.

*Several modalities may be used concurrently or in sequence.

(laden with potentially toxic substances usually extracted by the liver) to enter the systemic circulation (Rodes, et al., 2007). Ammonia is considered the major etiologic factor in the development of encephalopathy. It enters the brain and excites peripheral benzodiazepine-type receptors on astro-

cyte cells, thus increasing neurosteroid synthesis; this then stimulates gamma-aminobutyric acid (GABA) neurotransmission. GABA causes depression of the central nervous system (Hauser, et al., 2007). Ammonia inhibits neurotransmission and synaptic regulation (Onion, 2006), producing

Table 39-3 STAGES OF HEPATIC ENCEPHALOPATHY AND POSSIBLE NURSING DIAGNOSES*

Stage	Clinical Symptoms	Clinical Signs and EEG Changes	Selected Potential Nursing Diagnoses
1	Normal level of consciousness with periods of lethargy and euphoria; reversal of day–night sleep patterns	Asterixis; impaired writing and ability to draw line figures. Normal EEG.	Activity intolerance Self-care deficit Disturbed sleep pattern
2	Increased drowsiness; disorientation; inappropriate behavior; mood swings; agitation	Asterixis; fetor hepaticus. Abnormal EEG with generalized slowing.	Impaired social interaction Ineffective role performance Risk for injury
3	Stuporous; difficult to rouse; sleeps most of time; marked confusion; incoherent speech	Asterixis; increased deep tendon reflexes; rigidity of extremities. EEG markedly abnormal.	Imbalanced nutrition Impaired mobility Impaired verbal communication
4	Comatose; may not respond to painful stimuli	Absence of asterixis; absence of deep tendon reflexes; flaccidity of extremities. EEG markedly abnormal.	Risk for aspiration Impaired gas exchange Impaired tissue integrity Disturbed sensory perception

*Nursing diagnoses are likely to progress, so that most nursing diagnoses present at earlier stages will occur during later stages as well.

sleep and behavior patterns associated with hepatic encephalopathy.

Circumstances that increase serum ammonia levels tend to aggravate or precipitate hepatic encephalopathy. The largest source of ammonia is the enzymatic and bacterial digestion of dietary and blood proteins in the GI tract. Ammonia from these sources increases as a result of GI bleeding (ie, bleeding esophageal varices, chronic GI bleeding), a high-protein diet, bacterial infection, or uremia. The ingestion of ammonium salts also increases the blood ammonia level. In the presence of alkalosis or hypokalemia, increased amounts of ammonia are absorbed from the GI tract and from the renal tubular fluid. Conversely, serum ammonia is decreased by elimination of protein from the diet and by the administration of antibiotic agents, such as neomycin sulfate (Mycifradin, Neo-fradin), which reduce the number of intestinal bacteria capable of converting urea to ammonia (Dudek, 2006).

Other factors unrelated to increased serum ammonia levels that can cause hepatic encephalopathy in susceptible patients include excessive diuresis, dehydration, infections, surgery, fever, and some medications (sedatives, tranquilizers, analgesics, and diuretics that cause potassium loss). Additional causes include elevated levels of serum manganese (Hauser, et al., 2006), as well as changes in the types of circulating amino acids, mercaptans, and levels of dopamine and other neurotransmitters in the central nervous system (Feldman, et al., 2006). Mercaptans are toxic metabolites of sulfur-containing compounds that are excreted by the liver under normal conditions. Mercaptans and these other so-called “false” neurotransmitters may be generated from an intestinal source or from metabolism of protein by the liver and, with defective hepatic clearance, may precipitate encephalopathy.

Clinical Manifestations

The earliest symptoms of hepatic encephalopathy include minor mental changes and motor disturbances. The patient appears slightly confused and unkempt and has alterations in mood and sleep patterns. The patient tends to sleep during the day and has restlessness and insomnia at night. As hepatic encephalopathy progresses, the patient may become difficult to awaken and completely disoriented with respect to time and place. With further progression, the patient lapses into frank coma and may have seizures.

Asterixis (flapping tremor of the hands) may be seen in stage II encephalopathy (Fig. 39-12). Simple tasks, such as handwriting, become difficult. A handwriting or drawing sample (eg, star figure), taken daily, may provide graphic evidence of progression or reversal of hepatic encephalopathy. Inability to reproduce a simple figure (Fig. 39-13) is referred to as **constructional apraxia**. In the early stages of hepatic encephalopathy, the deep tendon reflexes are hyperactive; with worsening of the encephalopathy, these reflexes disappear and the extremities may become flaccid.

Occasionally, **fetor hepaticus**, a sweet, slightly fecal odor to the breath that is presumed to be of intestinal origin, may be noticed. The odor has also been described as similar to that of freshly mowed grass, acetone, or old wine. Fetor hepaticus is prevalent with extensive collateral portal circulation in chronic liver disease.

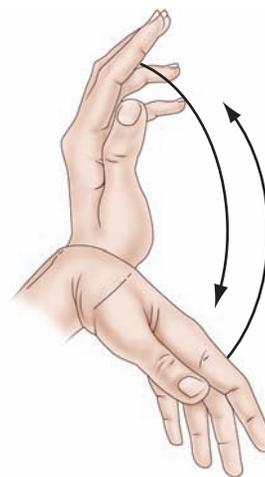

Figure 39-12 Asterixis or “liver flap” may occur in hepatic encephalopathy. The patient is asked to hold the arm out with the hand held upward (dorsiflexed). Within a few seconds, the hand falls forward involuntarily and then quickly returns to the dorsiflexed position.

Assessment and Diagnostic Findings

The electroencephalogram (EEG) shows generalized slowing, an increase in the amplitude of brain waves, and characteristic triphasic waves. The survival rate after a first episode of overt hepatic encephalopathy in patients with cirrhosis is approximately 40% at 1 year. Patients should be referred for liver transplantation after this initial episode (Hauser, et al., 2006).

Medical Management

Medical management of hepatic encephalopathy focuses on identifying and eliminating the precipitating cause if possible, initiating ammonia-lowering therapy, minimizing potential medical complications of cirrhosis and depressed consciousness, and reversing the underlying liver disease, if possible. Correction of the possible reasons for the deterioration such as bleeding, electrolyte abnormalities, sedation, or azotemia is essential (Feldman, et al., 2006). Lactulose (Cephulac) is administered to reduce serum ammonia levels.

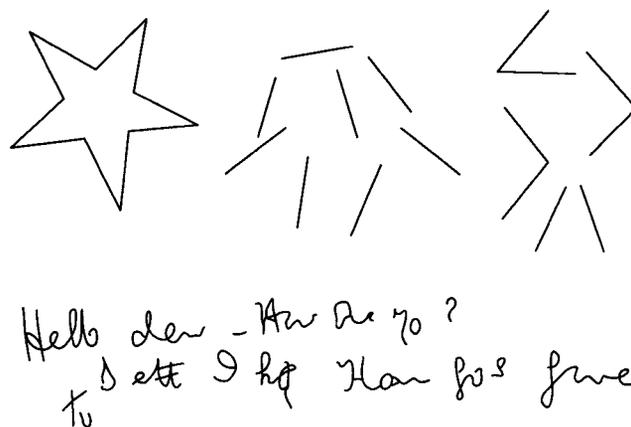

Figure 39-13 Effects of constructional apraxia. Deterioration of handwriting and inability to draw a simple star figure occurs with progressive hepatic encephalopathy. (With permission from Sherlock, S. & Dooley, J. (2002). *Diseases of the liver and biliary system* (11th ed.). Oxford, UK: Blackwell Scientific Ltd.)

It acts by several mechanisms that promote the excretion of ammonia in the stool: (1) ammonia is kept in the ionized state, resulting in a decrease in colon pH, reversing the normal passage of ammonia from the colon to the blood; (2) evacuation of the bowel takes place, which decreases the ammonia absorbed from the colon; and (3) the fecal flora are changed to organisms that do not produce ammonia from urea. Two or three soft stools per day are desirable; this indicates that lactulose is performing as intended.

NURSING ALERT

The patient receiving lactulose is monitored closely for the development of watery diarrheal stools, because they indicate a medication overdose.

Possible side effects of lactulose include intestinal bloating and cramps, which usually disappear within a week. To mask the sweet taste, which some patients dislike, it can be diluted with fruit juice. The patient is closely monitored for hypokalemia and dehydration. Other laxatives are not prescribed during lactulose administration because their effects disturb dosage regulation. Lactulose may be administered by nasogastric tube or enema for patients who are comatose or for those in whom oral administration is contraindicated or impossible.

Other aspects of management include IV administration of glucose to minimize protein breakdown, administration of vitamins to correct deficiencies, and correction of electrolyte imbalances (especially potassium). Antibiotics may also be added to the treatment regimen. Neomycin, metronidazole (Flagyl), and rifaximin (Xifaxan) have been used to reduce levels of ammonia-forming bacteria in the colon. However, no benefit has been shown for long-term treatment with these antibiotics (Hauser, et al., 2006). Additional principles of management of hepatic encephalopathy include the following:

- Neurologic status is assessed frequently.
- Mental status is monitored by keeping a daily record of handwriting and arithmetic performance.
- Fluid intake and output and body weight are recorded each day.
- Vital signs are measured and recorded every 4 hours.
- Potential sites of infection (peritoneum, lungs) are assessed frequently, and abnormal findings are reported promptly.
- Serum ammonia level is monitored daily.
- Protein intake is moderately restricted in patients who are comatose or who have encephalopathy that is refractory to lactulose and antibiotic therapy (Chart 39-5). Long-term restriction of dietary protein to less than 1 g/kg daily should be avoided. If animal protein precipitates encephalopathy, vegetable or dairy proteins may be used as most patients can tolerate a diet of vegetable protein up to 120 g/day (Hauser, et al., 2006).
- Patients and families are advised about foods that are high in protein (eg, meat, eggs), which may need to be eliminated from the diet for the short term to reduce production of ammonia.

Chart 39-5 • Nutritional Management of Hepatic Encephalopathy

- Prevent the formation and absorption of toxins, principally ammonia, from the intestine.
- Keep daily protein intake between 1.0 and 1.5 g/kg, depending on the degree of decompensation.
- Avoid protein restriction if possible, even in those with encephalopathy. If necessary, implement temporary restriction of 0.5 to 0.8 g/kg.
- For patients who are truly protein-intolerant, provide additional nitrogen in the form of an amino acid supplement. Use of branched-chain amino acids is still controversial.
- Provide small, frequent meals and an evening snack of complex carbohydrates to avoid protein loading.
- Substitute vegetable protein for animal protein in as high a percentage as possible.

- Enteral feeding is provided for patients whose encephalopathic state persists.
- Reduction in the absorption of ammonia from the GI tract is accomplished by the use of gastric suction, enemas, or oral antibiotics.
- Electrolyte status is monitored and corrected if abnormal.
- Sedatives, tranquilizers, and analgesic medications are discontinued.
- Benzodiazepine antagonists such as flumazenil (Romazicon) may be administered to improve encephalopathy, whether or not the patient has previously taken benzodiazepines. This action may have short-term efficacy because patients with hepatic encephalopathy have an increased concentration of benzodiazepine receptors.

Nursing Management

The nurse is responsible for maintaining a safe environment to prevent injury, bleeding, and infection. The nurse administers the prescribed treatments and monitors the patient for the numerous potential complications. The potential for respiratory compromise is great given the patient's depressed neurological status. The nurse encourages deep breathing and position changes to prevent the development of atelectasis, pneumonia, and other respiratory complications. Despite aggressive pulmonary care, patients may develop respiratory compromise. They may require intubation and mechanical ventilation to protect the airway, and they are frequently admitted to the ICU.

The nurse communicates with the patient's family to inform them about the patient's status and supports them by explaining the procedures and treatments that are part of the patient's care. If the patient recovers from hepatic encephalopathy and coma, rehabilitation is likely to be prolonged. Therefore, the patient and family will require assistance to understand the causes of this severe complication and to recognize that it may recur.

Promoting Home and Community-Based Care

Teaching Patients Self-Care

If the patient has recovered from hepatic encephalopathy and is to be discharged home, the nurse instructs the family

to watch for subtle signs of recurrent encephalopathy. In the acute phase of hepatic encephalopathy, dietary protein may be reduced for a brief period to 0.8 to 1.0 g/kg per day. During recovery and in the home situation, it is important to instruct the patient in maintenance of a moderate-protein, high-calorie diet. Protein may then be added in 10-g increments every 3 to 5 days if mental status is improving. Any relapse (worsening neurologic assessment) is treated by returning protein intake to the previous level. The limits of tolerance are usually 1.0 to 1.5 g/kg per day. Continued use of lactulose in the home environment is not uncommon, and the patient and family should closely monitor its efficacy and side effects. They should also be cautioned that constipation can precipitate encephalopathy and should be prevented through the prescribed use of lactulose, which is crucial in preventing constipation. Use of vegetable rather than animal protein may be indicated in patients whose total daily protein tolerance is less than 1 g/kg. Vegetable protein intake may result in improved nitrogen balance without precipitating or advancing hepatic encephalopathy (Feldman, et al., 2006).

Continuing Care

Referral for home care is warranted for the patient who returns home after recovery from hepatic encephalopathy. The home care nurse assesses the patient's physical and mental status and collaborates closely with the physician. The home visit also provides an opportunity for the nurse to assess the home environment and the ability of the patient and family to monitor signs and symptoms and to follow the treatment regimen. It is important to evaluate the patient's fluid volume status and be alert for changes indicative of hypovolemia due to decreased intake and for decreased urine output associated with hepatorenal syndrome. Monitoring of laboratory values continues to be important, and the home care nurse must obtain physician orders to correct abnormalities, especially electrolyte imbalances, which also can worsen encephalopathy.

The safety of the home environment is also assessed closely to identify areas of risk for falls and other injuries. Home care visits are especially important if the patient lives alone because encephalopathy may affect the patient's ability to remember or follow the treatment regimen. The nurse reinforces previous teaching and reminds the patient and family about the importance of dietary restrictions, close monitoring, and follow-up. In addition, the nurse must observe the patient for subtle behavior changes of worsening hepatic encephalopathy. Patients with all types and stages of hepatic encephalopathy should have periodic neurologic evaluations to determine their cognitive function so that they do not engage in potentially harmful activities. Even subtle neuropsychiatric abnormalities may preclude patients from driving, operating machinery, or participating in other activities that require psychomotor coordination.

Patients and families may need additional support during those times that the patient exhibits mood disturbances and sleep disorders. Patients should be as active as possible during the day and develop a normal sleep-wake pattern. Sedating medications should be avoided because they may precipitate encephalopathy. Patients and families may require assistance in developing plans to cope with changes in

mood and mental status changes. This plan should identify support persons to attend to the patient in the home situation if needed. Social workers and case managers may make appropriate referrals for assistance with physical and psychosocial support and care. Referrals to other experts such as psychologists, psychiatric liaison nurses, case managers, social workers, or therapists may assist family members with coping. Spiritual advisors may also provide another outlet for communication and guidance. If alcohol played a role in the development of the liver disease and encephalopathy, referral to Alcoholics Anonymous or Al-Anon may provide needed support and education.

Other Manifestations of Hepatic Dysfunction

Edema and Bleeding

Many patients with liver dysfunction develop generalized edema caused by hypoalbuminemia due to decreased hepatic production of albumin. The production of blood clotting factors by the liver is also reduced, leading to an increased incidence of bruising, epistaxis, bleeding from wounds, and, as described previously, GI bleeding.

Vitamin Deficiency

Decreased production of several clotting factors may be partially due to deficient absorption of vitamin K from the GI tract. This probably is caused by the inability of liver cells to use vitamin K to make prothrombin. Absorption of the other fat-soluble vitamins (vitamins A, D, and E) as well as dietary fats may also be impaired because of decreased secretion of bile salts into the intestine.

Another group of problems common to patients with severe chronic liver dysfunction results from inadequate intake of sufficient vitamins. These include the following:

- Vitamin A deficiency, resulting in night blindness and eye and skin changes
- Thiamine deficiency, leading to beriberi, polyneuritis, and Wernicke-Korsakoff psychosis
- Riboflavin deficiency, resulting in characteristic skin and mucous membrane lesions
- Pyridoxine deficiency, resulting in skin and mucous membrane lesions and neurologic changes
- Vitamin C deficiency, resulting in the hemorrhagic lesions of scurvy
- Vitamin K deficiency, resulting in hypoprothrombinemia, characterized by spontaneous bleeding and ecchymoses
- Folic acid deficiency, resulting in macrocytic anemia

Because of these avitaminoses, the diet of every patient with chronic liver disease (especially if alcohol related) is supplemented with vitamins A, B complex, C, K, and folic acid.

Metabolic Abnormalities

Abnormalities of glucose metabolism also occur; the blood glucose level may be abnormally high shortly after a meal (a diabetic-type glucose tolerance test result), but hypoglycemia may occur during fasting because of decreased

hepatic glycogen reserves and decreased gluconeogenesis. Medications must be used cautiously and in reduced dosages because the ability to metabolize medications is decreased in the patient with liver failure.

Many endocrine abnormalities also occur with liver dysfunction because the liver cannot properly metabolize hormones, including androgens and sex hormones. Failure of the damaged liver to inactivate estrogens normally can cause gynecomastia, amenorrhea, testicular atrophy, loss of pubic hair in the male, menstrual irregularities in the female, and other disturbances of sexual function and sex characteristics.

Pruritus and Other Skin Changes

Patients with liver dysfunction resulting from biliary obstruction commonly develop severe pruritus due to retention of bile salts. Patients may develop vascular (or arterial) spider angiomas (Fig. 39-14) on the skin, usually above the waistline. These are numerous small vessels resembling a spider's legs. They are most often associated with cirrhosis, especially in alcoholic liver disease. Patients may also develop reddened palms ("liver palms" or palmar erythema).

Figure 39-14 Spider angioma. This vascular (arterial) spider appears on the skin. Beneath the elevated center and radiating branches, the blood vessels are looped and tortuous.

VIRAL HEPATITIS

Viral hepatitis is a systemic, viral infection in which necrosis and inflammation of liver cells produce a characteristic cluster of clinical, biochemical, and cellular changes. To

date, five definitive types of viral hepatitis have been identified: hepatitis A, B, C, D, and E. Hepatitis A and E are similar in mode of transmission (fecal–oral route), whereas hepatitis B, C, and D share many other characteristics. Terms associated with viral hepatitis are listed in Chart 39-6.

Hepatitis is easily transmitted and causes high morbidity and prolonged loss of time from school or employment. Acute viral hepatitis affects 0.5% to 1% of people in the

Chart 39-6 • Hepatitis Terms and Abbreviations

Hepatitis A	
HAV	Hepatitis A virus; etiologic agent of hepatitis A (formerly infectious hepatitis)
Anti-HAV	Antibody to hepatitis A virus; appears in serum soon after onset of symptoms; disappears after 3–12 mo
IgM anti-HAV	IgM antibody to HAV; indicates recent infection with HAV; positive up to 6 mo after infection
Hepatitis B	
HBV	Hepatitis B virus; etiologic agent of hepatitis B (formerly serum hepatitis)
HBsAG	Hepatitis B surface antigen (Australian antigen); indicates acute or chronic hepatitis B or carrier state; indicates infectious state
Anti-HBs	Antibody to hepatitis B surface antigen; indicates prior exposure and immunity to hepatitis; may indicate passive antibody from HBIG or immune response from hepatitis B vaccine
HBeAg	Hepatitis B e-antigen; present in serum early in course; indicates highly infectious stage of hepatitis B; persistence in serum indicates progression to chronic hepatitis
Anti-HBe	Antibody to hepatitis B e-antigen; suggests low titer of HBV
HBcAg	Hepatitis B core antigen; found in liver cells; not easily detected in serum
Anti-HBc	Antibody to hepatitis B core antigen; most sensitive indicator of hepatitis B; appears late in the acute phase of the disease; indicates infection of HBV at some time in the past
IgM anti-HBc	IgM antibody to HBcAg; present for up to 6 mo after HBV infection
Hepatitis C	
HCV	Hepatitis C virus (formerly non-A, non-B virus); may be more than one virus
Hepatitis D	
HDV	Hepatitis D virus (delta agent); etiologic agent to hepatitis D; HBV required for replication
HDAg	Hepatitis delta antigen; detectable in early acute HDV infection
Anti-HDV	Antibody to HDV; indicates past or present infection with HDV
Hepatitis E	
HEV	Hepatitis E virus; etiologic agent of hepatitis E
Hepatitis G	
HGV	Hepatitis G virus; also known as GB virus C or GB-C

Table 39-4 COMPARISON OF MAJOR FORMS OF VIRAL HEPATITIS

	Hepatitis A	Hepatitis B	Hepatitis C	Hepatitis D	Hepatitis E
<i>Previous names</i>	Infectious hepatitis	Serum hepatitis	Non-A, non-B hepatitis		
Epidemiology					
<i>Cause</i>	Hepatitis A virus (HAV)	Hepatitis B virus (HBV)	Hepatitis C virus (HCV)	Hepatitis D virus (HDV)	Hepatitis E virus (HEV)
<i>Mode of transmission</i>	Fecal–oral route; poor sanitation. Person-to-person contact. Waterborne; foodborne. Transmission possible with oral–anal contact during sex.	Parenterally; by intimate contact with carriers or those with acute disease; sexual and oral–oral contact. Perinatal transmission from mothers to infants. An important occupational hazard for health care personnel.	Transfusion of blood and blood products; exposure to contaminated blood through equipment or drug paraphernalia. Transmission possible with sex with infected partner; risk increased with STD.	Same as HBV. HBV surface antigen necessary for replication; pattern similar to that of hepatitis B.	Fecal–oral route; person to person contact may be possible, although risk appears low
<i>Incubation (days)</i>	15–50 days	28–160 days	15–160 days	21–140 days	15–65 days
<i>Immunity</i>	Average: 30 days Homologous	Average: 70–80 days Homologous	Average: 50 days Second attack may indicate weak immunity or infection with another agent.	Average: 35 days Homologous	Average: 42 days Unknown
Nature of Illness					
<i>Signs and symptoms</i>	May occur with or without symptoms; flulike illness <i>Preicteric phase:</i> Headache, malaise, fatigue, anorexia, fever <i>Icteric phase:</i> Dark urine, jaundice of sclera and skin, tender liver	May occur without symptoms May develop arthralgias, rash	Similar to HBV; less severe and anicteric	Similar to HBV	Similar to HAV. Very severe in pregnant women.
<i>Outcome</i>	Usually mild with recovery. Fatality rate: <1%. No carrier state or increased risk of chronic hepatitis, cirrhosis, or hepatic cancer.	May be severe. Fatality rate: 1–10%. Carrier state possible. Increased risk of chronic hepatitis, cirrhosis, and hepatic cancer.	Frequent occurrence of chronic carrier state and chronic liver disease. Increased risk of hepatic cancer.	Similar to HBV but greater likelihood of carrier state, chronic active hepatitis, and cirrhosis	Similar to HAV except very severe in pregnant women

United States each year. Hepatitis A is responsible for 37% of all cases, and hepatitis B is the offending agent in 18% of cases. The occurrence rate has been decreasing steadily since 1990, largely because of the use of hepatitis A and B vaccines as well as public health education regarding high-risk behaviors (Goldman & Ausiello, 2008). It is estimated that 60% to 90% of viral hepatitis cases go unreported. The occurrence of subclinical cases, failure to recognize mild cases, and misdiagnosis are thought to contribute to the underreporting. Table 39-4 compares the major forms of viral hepatitis.

Hepatitis A Virus

Hepatitis A virus (HAV) accounts for 20% to 25% of cases of clinical hepatitis in the United States and other developed countries (Rodes, et al., 2007). Hepatitis A, formerly

called infectious hepatitis, is caused by an RNA virus of the Enterovirus family. In the United States, the disease is seen mainly in the adult population. Fewer than 25% of children have antibodies to HAV. This form of hepatitis is transmitted primarily through the fecal–oral route, by the ingestion of food or liquids infected by the virus. It is more prevalent in countries with overcrowding and poor sanitation. The virus has been found in the stool of infected patients before the onset of symptoms and during the first few days of illness.

Typically, a child or a young adult acquires the infection at school through poor hygiene, hand-to-mouth contact, or close contact during play. The virus is carried home, where haphazard sanitary habits spread it through the family. An infected food handler can spread the disease, and people can contract it by consuming water or shellfish from sewage-contaminated waters. Outbreaks have occurred in

day care centers and institutions as a result of poor hygiene among people with developmental disabilities. Hepatitis A can be transmitted during sexual activity; this is more likely with oral–anal contact or anal intercourse and with multiple sex partners (Rodes, et al., 2007). It is rarely, if ever, transmitted by blood transfusions.

The incubation period is estimated to be between 2 to 6 weeks, with a mean of approximately 4 weeks (Rodes, et al., 2007). The illness may be prolonged, lasting 4 to 8 weeks. It usually lasts longer and is more severe in those older than 40 years of age. Most patients recover from hepatitis A; it rarely progresses to acute liver necrosis or fulminant hepatitis resulting in cirrhosis of the liver or death. The mortality rate of hepatitis A is approximately 0.5% for those younger than 40 years of age and 1% to 2% for older people. In patients with underlying chronic liver disease, morbidity and mortality are increased in the presence of an acute hepatitis A infection. No carrier state exists, and no chronic hepatitis is associated with hepatitis A. The virus is present only briefly in the serum; by the time jaundice occurs, the patient is likely to be noninfectious. Although hepatitis A confers immunity against itself, the person may contract other forms of hepatitis.

Clinical Manifestations

Many patients are anicteric (without jaundice) and symptomless. When symptoms appear, they resemble those of a mild, flulike upper respiratory tract infection, with low-grade fever. Anorexia, an early symptom, is often severe. It is thought to result from release of a toxin by the damaged liver or from failure of the damaged liver cells to detoxify an abnormal product. Later, jaundice and dark urine may become apparent. Indigestion is present in varying degrees, marked by vague epigastric distress, nausea, heartburn, and flatulence. The patient may also develop a strong aversion to the taste of cigarettes or the presence of cigarette smoke and other strong odors. These symptoms tend to clear as soon as the jaundice reaches its peak, perhaps 10 days after its initial appearance. Symptoms may be mild in children; in adults, they may be more severe and the course of the disease prolonged.

Assessment and Diagnostic Findings

The liver and spleen are often moderately enlarged for a few days after onset; other than jaundice, there are few other physical signs. Hepatitis A antigen may be found in the stool 7 to 10 days before illness and for 2 to 3 weeks after symptoms appear. HAV antibodies are detectable in the serum, but usually not until symptoms appear. Analysis of subclasses of immunoglobulins can help determine whether the antibody represents acute or past infection.

Prevention

A number of strategies exist to prevent transmission of HAV. Patients and their families are encouraged to follow general precautions that can prevent transmission of the virus. Scrupulous handwashing, safe water supplies, and proper control of sewage disposal are just a few of these prevention strategies.

Effective (95% to 100% after two to three doses) and safe HAV vaccines include Havrix and Vaqta (Goldman &
